INTRODUCTION

A STANDARD SCHEME FOR COUNTING SUNSPOTS

In 1848 the Swiss astronomer Johann Rudolph Wolf introduced the sunspot number index--an estimate of the number of spots visible on one hemisphere of the sun. The observation consists of a daily count over the solar disk of the number of spots (regardless of size) and of the number of groups into which they cluster.

Rudolph Wolf arbitrarily defined his daily sunspot number as the total spot count added to 10 times the number of spot groups, because neither the number of groups

JOHANN RUDOLPH WOLF*
1816-1893

In 1848 Rudolph Wolf devised a daily method of estimating solar activity by counting the number of individual spots and groups of spots on the face of the sun. Wolf chose to compute his sunspot number by adding 10 times the number of groups to the total count of individual spots, because neither quantity alone completely captured the level of activity. Today, Wolf sunspot counts continue, since no other index of the sun's activity reaches into the past as far and as continuously.

An avid astronomical historian and an unrivaled expert on sunspot lore, Wolf confirmed the existence of a cycle in sunspot numbers. He also more accurately determined the cycle's length to be 11.1 years by using early historical records. Wolf, who became director of the Zurich Observatory, discovered independently the coincidence of the sunspot cycle with disturbances in the Earth's magnetic field.

nor the number of spots alone adequately measured the activity. Counting only groups would ignore their great variation in size, since some can contain more than 100 single spots, while others, only a few. Counting only individual spots, on the other hand, would ignore their unequal rank, because spots appearing within an existing group have less significance than ones emerging where none existed before.

CHANGES TO THE COUNTING METHOD

Since Rudolph Wolf began the sunspot measurement, he set the standard. And although he counted each spot regardless of its size, he failed to include those smallest spots visible only under a stable atmosphere. Around 1882 Wolf's successors permanently changed the counting method in two ways to compensate for the large variation in spot size:

- (1) by including the smallest spots visible under an atmosphere of constant transparency and
- (2) by weighting spots with penumbrae according to their size and umbral structure.

Because both modifications raised the daily count from what Wolf would have recorded, results from the old and the new methods had to be compared over many years. To isolate the relative difference between the two techniques, the ratio of the sum of the counts recorded simultaneously under both schemes was formed, and then that constant was used to adjust the new observations to Wolf's original scale.

Wolf, himself, preferred measuring sunspot areas, not estimating sunspot counts, but his limited equipment prevented him from drawing the projected solar image to scale. Photography could not be used either, since at the time, the technique was too primitive. Later measurements of area did show the yearly mean sunspot number to be almost proportional to sunspot area. It meant that Wolf, through a fortunate definition of the spot count, nearly achieved his original goal. Deviations, though, from this proportionality can be significant, as a large, single spot with its penumbra makes only a small contribution to the sunspot number but a large one to the area. In contrast, a group consisting of many tiny spots makes a large contribution to the sunspot number but only a small one to the area.

VARIATIONS IN THE MEASUREMENT

Sunspot counts are an estimate, not a quantitative measurement, because different equipment, different observer experience, and different observing conditions all affect the result.

Equipment. Under the same observing conditions, the number of spot groups and the number of individual spots recognized depend on the magnifying power of the telescope. Rudolph Wolf observed through a Fraunhofer refractor of 8 cm aperture, of 64x magnification, of 8 cm aperture, and of 110 cm focal length.

Personal Judgment. Even when different observers use identical instruments, different counts of the number of groups and of the number of spots emerge for several reasons. One person, for example, will count very small spots; another will consider them to be only pores; and still a third will fail to see them at all. Each observer sets a different threshold between what to count as spots and what to count as pores. [Pores are smaller, brighter, shorter-lived features than spots, and they should not be included in the count, yet many observers underestimate the number of spots, because they define any spot without a penumbra to be a pore.] Some persons also consider large spots to be composed of many individual ones, while others count isolated parts of a penumbra as spots. Finally, if large clusters of spots appear, observers often disagree on the way in which they should be grouped.

Seeing. The sunspot count depends strongly not only on the person and his instrument but also on the stability of the atmosphere above the observing site. In other words, the count depends on the seeing conditions--those constant, turbulent motions of the air around and above a telescope that blur an image. If the seeing worsens, very small spots disappear, reducing the total count. If these small spots happen to be isolated ones, then the number of groups counted decreases too.

Differences between an observer's judgment, equipment, and seeing conditions and those of Wolf in 1848 are taken into account by a scaling factor or observatory constant, K . K is determined for a new station by calculating the ratio of the sum of the counts from the new site to the sum of the counts from the old one. K measures the relative difference between the sunspot numbers recorded at the two stations. Multiplying "raw" observations by K adjusts them to values that approximate what Wolf himself would have recorded.

Since the last century, Wolf sunspot counts have shown no seasonal periodicity, the reduction factors K of all contributors have remained unchanged, and the proportionality between sunspot area and sunspot number has shown little variation. All three conditions suggest that (since 1848) this long-term series of numbers has remained consistent and homogeneous and close to Wolf's original scale.

MAINTAINING SUBJECTIVE STANDARDS

Two policies have helped reduce the influence of personal judgment on the estimates of sunspot counts:

- (1) the appointment of a permanent arbiter to oversee computation of all final counts and
- (2) the reliance on a few principal reporting stations manned by trained and dedicated observers.

To cover gaps in observations owing to overcast skies at Zurich, Wolf sought collaborators at places as distant as possible from each other--collaborators who would carry out their daily counts of sunspots under his strict guidance. Wolf eventually established an international network of observatories, which since the middle of the 19th Century, has grown to about 30 cooperating stations and to about an equal number of cooperating amateurs.

HISTORICAL MEASUREMENTS

Wolf searched the literature and observatory archives for numerical measures of sunspot activity during times before 1848. He did locate many descriptions and drawings of the sun and from them reconstructed an almost complete series of daily numbers back to 1818, of monthly means back to 1749, and of annual means back to 1700. He even traced the activity to 1610, the year Galileo Galilei first observed sunspots through a small telescope. With these early data Wolf confirmed the existence of a cycle in sunspot numbers, and he more accurately determined that cycle's average length to be 11.1 years.

Not surprisingly, historical sunspot data proved less reliable than the controlled counts made in 1848 and thereafter. Many observations, for example, displayed a seasonal variation--a fluctuation in the count owing to the weather, not to the sun.

HISTORICAL MEASUREMENTS (Continued)

Moreover, during the 17th and 18th Centuries, the few observers who noted sunspots made their observations from Central Europe, where the atmospheric transparency differed greatly between the summer and the winter months.

The numbers tabulated here are not of uniform quality: they range from poor between 1700 and 1748 to questionable between 1749 and 1817 and from good between 1818 and 1847 to reliable from 1848 on. Despite these serious limitations, sunspot numbers increase in importance with each passing year, because they reach back further in time than any other index of solar activity. This continuous daily diary serves as an important link with the past for studies of the sun's long-term variability. Furthermore, the measurement of sunspot numbers does not require sophisticated and costly equipment, and they become available soon after they are recorded.

*When observations permit, a date selected as either a cycle minimum or maximum is based in part on an average of the times extremes are reached in the monthly mean sunspot number, in the smoothed monthly mean sunspot number, and in the monthly mean number of spot groups alone. Two more measures are used at time of sunspot minimum: the number of spotless days and the frequency of occurrence of "old" and "new" cycle spot groups.

**The smoothed monthly mean sunspot number is defined here as the arithmetic average of two sequential 12-month running means of monthly mean numbers.

YEARLY MEAN SUNSPOT NUMBERS 1700 - 1985. Sunspot counts rise and fall approximately every 11.1 years. The cycle, though, is not symmetrical, for the spot count takes on the average about 4.8 years to rise from a minimum to a maximum and another 6.2 years to fall to a minimum once again. The largest annual mean number (190.2) occurred in 1957.

MONTHLY MEAN SUNSPOT NUMBERS January 1749 - December 1985. Monthly mean numbers reveal the sunspot count's variability. Monthly averages also contain a 27-day fluctuation that reflects the rotation period of the sun and the uneven distribution of spot groups across solar longitudes. The largest monthly mean (253.8) occurred in October 1957.

SMOOTHED MONTHLY SUNSPOT NUMBERS July 1749 - June 1985. Each smoothed number represents the average of two adjacent 12-month running means of monthly means. Consider, for example, the June 1980 value. One builds this number by first computing two 12-month means: one that averages monthly means from December 1979 through November 1980 and a second that averages monthly means from January 1980 through December 1980. The arithmetic mean of these two running means gives the June 1980 smoothed number.

DAILY SUNSPOT NUMBERS January 8, 1818 - December 31, 1985. Although the smallest division marked along the horizontal axis is 1 year, all daily values for a year have been plotted within each small line segment. Here, as before, the vertical axis gives the value of the sunspot number. A striking day-by-day variability clearly shows. The gap in the numbers between 0 and 11 illustrates how insensitive sunspot counts are to periods of low solar activity, because the appearance of a single, isolated spot causes the number to jump from 0 to 11; only by averaging reports from several observatories do values less than 11 emerge. Today, more sophisticated observations of the sun's atmosphere have demonstrated that large gradations of activity can exist even in the absence of visible spots. Note, too, the density pulsations in points along the graph's vertical dimension; they reflect the strong contribution to the sunspot number that the factor 10 makes in the definition of the count. On December 24 and 25, 1957, the largest daily number on record occurred. For each of those days the sunspot number totaled 355.
