Proposed at CSC Tripartite

### Executive Summary

The purpose of this project was to obtain data on the bacterial quality of the Delaware River and Bay to determine if Commission water quality standards should be changed to permit seasonal disinfection by dischargers to the tidal Delaware River from the head of tide at Trenton, N.J., to the Pennsylvania-Delaware state line at Marcus Hook, Pa. Current standards require year-round disinfection.

The major source of funding for the project was a \$200,000 grant from the National Oceanic and Atmospheric Administration (NOAA). The remainder of the funding was from municipal contributions.

The data were collected over a two-year period. During the first year dischargers upstream of the Pennsylvania-Delaware state line were excused from providing disinfection from October through April. Continuous disinfection was required at all other times.

The data indicate that bacterial levels in the winter when the disinfection requirement was excused were significantly higher than in the winter with disinfection. The impact extended over the entire length of the river sampled, including the shellfishing area. The greatest impact was in the Philadelphia - Camden area. Bacterial levels during the entire Study period were affected by untreated sewage from combined sewers during both dry and wet weather. Bacterial levels during the first winter were obviously affected by the suspension of disinfection. Only order of magnitude estimates can be made of the impact of the combined sewers.

It is concluded that the current year-round wastewater disinfection requirement should remain in effect. This conclusion should be re-examined after combined sewer overflows have been corrected to essentially eliminate dry weather discharges and reduce wet weather discharges.

## Introduction

The Delaware River Basin Commission held a public hearing in September 1983 on a proposal to change its disinfection requirements from year-round to seasonal. The rationale and justification were presented in a June 1983 Commission staff report\*. The report discussed the basis of the need for disinfection, the disadvantages of disinfection with particular reference to chlorine, and the data on river bacterial quality available at that time. After consideration of the hearing testimony and further discussion, it was concluded by the Commission that additional data on river bacterial quality were needed.

This project was designed to assess the impact on river bacterial quality of changes in municipal wastewater disinfection practices. The Study design was based on the recommendations of the Commission's Water Quality Advisory Committee, which includes one member from the water pollution control agencies of the Basin states (Delaware, New Jersey, New York, and Pennsylvania) and the U.S. Environmental Protection Agency (EPA). Representatives of the U.S. Food and Drug Administration and the Delaware and New Jersey units responsible for shellfish management and protection participated in the discussions.

A two-year Study was recommended, which began in July 1987 and ended in June 1989. Figure One is a map of the Study area. During the first winter (October 1987 to April 1988) municipal wastewater facilities discharging to the tidal Delaware River between Trenton and the Pennsylvania-Delaware state border (Delaware River Zones 2,3, and 4) were excused from the disinfection requirement. Bacterial criteria for that reach of the Delaware River in water quality standards of the New Jersey Department of Environmental Protection (NJDEP), the Pennsylvania Department of Environmental Resources (PaDER), and the Commission were formally suspended from October 1, 1987 to April 30, 1988. NPDES permits for a total of 26 wastewater treatment facilities were amended by NJDEP and PaDER to suspend the disinfection requirement for the same period. All other treatment requirements remained in effect for these facilities and continuous disinfection was required at all other times.

Samples of the Delaware River and Bay were collected and analyzed by the Delaware Department of Natural Resources and Environmental Control (DNREC) and the New Jersey Department of Environmental Protection (NJDEP) under a series of contracts with the Commission. All field and laboratory work in this Study was carried out in accordance with a quality assurance project plan\*\* approved by EPA. All data obtained have been entered into STORET, the EPA national computer system for water quality data.

\* Seasonal Disinfection Policy for the Delaware River, Delaware River Basin Commission, June 1983.

\*\*Quality Assurance Project Plan, Seasonal Disinfection Study, DRBC - QA 004.

Funds to defray the costs of the basic Study program which encompassed analyses for total and fecal coliform (MPN), were provided by a \$200,000 grant from the National Oceanic and Atmospheric Administration and \$23,000 matching non-Federal funds contributed by municipal wastewater discharge operating agencies. Additional municipal contributions were used to support analyses for two new recreational bacterial parameters (enterococcus and E. coli) and a related fecal coliform analysis (mTEC).

This Study was directed to the impact of changes in wastewater disinfection practices on river bacterial quality. The Study assessed health risks only to the extent that the bacterial parameters tested are measures of health risk. Since it is not practical to test for disease-producing organisms, tests for "indicator" organisms are used: counts of "indicator" organisms above a "standard" established on a regulatory basis are considered to be presumptive evidence of the presence of disease-producing organisms at unacceptable levels. The limitations of this approach must be recognized: once established a bacterial standard becomes a constraint upon water quality management by regulatory agencies, yet concentrations of indicator organisms below the standard does not necessarily guarantee safety from disease.

#### Sampling Program

Two sets of data were collected from the Delaware River and Bay, river run and shellfish area. Each were collected at an average interval of twice per month over the entire 24-month Study period.

Collection and analysis of river run samples was performed by DNREC at a minimum of 40 locations. Of these 40 locations, 15 were in the center of the navigation channel and 25 were at locations between the navigation channel and the shores of the river. The 15 center navigation channel locations are shown on Figure One. Latitude, longitude, river mile, and STORET station number for the 40 locations are given in Table 1.

Sample collection began in upper Delaware Bay in the shellfishing area in the upper reaches of Zone 6, and extended up the Delaware River into Zone 2, a few miles below the head of tide at Trenton, N.J. All samples were analyzed for total and fecal coliform MPN and enterococcus. Samples from locations upstream of River Mile 75 and from all center navigation channel locations were also analyzed for E. coli and fecal coliform mTEC. Enterococcus, E.coli, and fecal coliform mTEC are "membrane filter" analyses.

Collection and analysis of shellfish area samples was performed by NJDEP at 60 locations. The general location of the area from which samples were taken is shown on Figure One. Latitude, longitude, river mile, and STORET station numbers are given in Table 2. There were five cross-sections or "transects" with six to nine sampling loctions each. The remainder of the locations were along the shores of the river or in embayments. All samples were analyzed for total and fecal coliform MPN and half the samples were analyzed for enterococcus.

### Sources of Bacteria

In this Study bacterial concentrations were measured at sampling locations in the tidal Delaware River and upper Delaware Bay. The observed concentrations show the combined effects from all sources, which includes wastewater discharges, combined sewers, tributary streams, and non-point sources. The purpose of this Study was to assess the impact on river bacterial concentrations of changes in wastewater discharge characteristics resulting from the suspension of wastewater disinfection.

From October 1, 1987 to April 30, 1988, 26 wastewater treatment plants discharging to Zones 2,3, and 4 of the Delaware River did not practice disinfection. See Table 3 for a list of these discharges, including flow data. During this period the total volume discharged by these facilities averaged 613 mgd. Virtually all of this volume received secondary treatment before discharge. During July and August 1987, the CCMUA Delaware No. 1 plant, with an average flow of 17 mgd, provided primary treatment without disinfection. During the month of September 1987 this plant was upgraded to secondary treatment with disinfection. The Baldwin Run plant (3 mgd), operated by CCMUA, provided secondary treatment without disinfection for the entire two-year Study period. The Falls Township Authority plant (3 mgd) ceased operation in March 1989 and transferred its wastewaters to the Philadelphia - Northeast plant. From October 1, 1988 to April 30, 1989, a combined volume of 595 mgd was discharged by the plants that did not practice disinfection the previous winter.

Bacteriological quality of the Delaware River is affected by over three hundred combined sewer overflows (CSOs) between Trenton and Wilmington\*, including 176 in Philadelphia and 66 in Camden. CSOs are designed to discharge a mixture of untreated wastewater and stormwater runoff during wet weather.

A recently completed study\*\* revealed that many of the CSOs in the Philadelphia and Camden area discharge during dry-weather conditions. Analyses reported in that study indicated that the impact of the dry-weather CSOs exceeds that of the wet-weather CSOs. The impact of dry-weather CSOs would be fairly constant over the two-year Seasonal Disinfection Study period, increasing overall river bacterial levels. The impact of wet-weather CSOs would vary depending on rainfall. The report\*\* cited above estimated that correction of dry-weather CSOs would result in a 75-80 percent reduction in the numbers of bacteria discharged under dry and wet weather conditions combined. The report did not estimate the resulting reduction in river bacterial levels.

\*Quality Assurance Project Plan, Seasonal Disinfection Study, DRBC - QA 004, p. 25.

\*\*Combined Sewer Overflow Report, Del USA Project Element 8, Delaware Estuary Use Attainability Project, January 1988.

Non-point sources also contribute bacteria to the Delaware River. Runoff originating as rainfall flows overland and is contaminated by fecal and other matter containing bacteria that it comes in contact with. Waterfowl are also a significant source of fecal bacteria. There are extensive waterfowl feeding areas in wetlands bordering the Delaware River and Bay. Sources of bacteria from wetlands are virtually uncontrollable.

### Results

To evaluate the effect on river bacterial levels of the suspension of the disinfection requirement for 26 wastewater discharges in Zones 2,3, and 4, from October 1987 through April 1988, geometric means and medians of bacterial concentrations observed at the various sampling locations for that period were compared with the same measures of central tendency for the October 1988 through April 1989 period. The data are presented in a series of graphs in two appendixes, Appendix I, River Run Data, and Appendix II, Shellfish Area Data. Selected graphs are discussed below.

#### River Runs - Center Channel

Graphs 1.1 to 1.10 present geometric means and medians for each of the five bacterial parameters at the 15 center navigation channel "river run" sampling locations for three periods - October 1987 through April 1988, the "non-disinfection" winter, October 1988 through April 1989, the "disinfection" winter, and May through September 1988, the intervening summer. During the "non-disinfection" winter bacterial levels were higher than during the "disinfection" winter for the entire length of the river represented by the 15 sampling locations. The greatest differences in bacterial levels between the two winters occurred in the reach which received the discharges excused from disinfection in the non-disinfection winter. These differences decrease more or less gradually moving downstream until about River Mile 66. Downstream of River Mile 66, the differences in bacterial levels between the two winters do not appear to decrease moving downstream. This suggests that the higher bacterial levels in the lower river and upper Bay in the non-disinfection winter may not be entirely due to the suspension of disinfection. It is not possible to pinpoint the cause or causes. One likely candidate is streamflow. During the non-disinfection winter, October 1987 to April 1988, the flow of the Delaware River at Trenton, N.J., averaged 11,138 cfs. During the disinfection winter, October 1988 to April 1989, the flow averaged 7,633 cfs. The higher flows in the non-disinfection winter might have transported the bacteria further downstream than in the disinfection winter.

Graph 1.1 (Figure Two) compares geometric mean fecal coliform levels for the two winters and the intervening summer. Also shown are the current Commission fecal coliform criteria and a criterion (2000/100ml) used by some agencies for surface waters as a source of raw water supply.

The current Commission criterion of 770/100 ml in Zones 2, 3, and 4 was exceeded in the non-disinfection winter. This criterion was based on year-round disinfection. The 770/100ml criterion was also exceeded in the non-disinfection winter in the upper reach of Zone 5 for a distance of about four miles.

In parts of Zones 3 and 4 geometric mean fecal coliform levels were as high as 5000/100ml in the non-disinfection winter. Zone 3 is designated in Commission water quality standards as suitable for sources of public drinking water supplies after reasonable treatment. A geometric mean of 2000/100ml is a commonly accepted criterion for a raw water supply. There are no public water supply withdrawals from Zone 3.

In part of Zone 3, the current 770/100ml Commission criterion was exceeded in the disinfection winter and in the summer of 1988. Virtually all wastewater discharges received disinfection during these two periods. Only an insignificant 3 mgd was not disinfected.

Zone 3 is significantly affected by the discharge of untreated sewage from combined sewer overflows (CSOs) under both dry and wet weather conditions. It is believed that the CSOs are the cause of the exceedance of the 770/100ml fecal coliform criterion in the disinfection winter and the summer. The CSOs also contributed significantly to the high bacterial levels observed in Zones 3 and 4 in the non-disinfection winter. The exceedance of the 770/100ml fecal coliform criterion in the upper four miles of Zone 5 in the non-disinfection winter may also be due in large measure, if not entirely, to the CSOs. It is not possible to estimate the impact of the CSOs with any degree of precision. Available water quality models would yield order of magnitude results only. While this would indicate the general impact, it would not be considered definitive. Because of this uncertainty in the area of greatest impact of the CSOs and the distance and time of passage downstream, it is not possible to estimate the effect of the CSOs on the bacterial levels observed in the shellfish area.

Graph 1.1 (Figure Two) shows that fecal coliform levels were higher in the non-disinfection winter than in the disinfection winter for the entire length of the river, including the shellfishing area. The primary cause of the differences in bacterial levels between the two winters was the suspension of disinfection in the Trenton to Marcus Hook reach. Other factors, such as differences in streamflows, may have contributed to the severity and extent of the river affected. Discharges from CSOs, particularly under dry-weather conditions, increased bacterial levels throughout the entire Study period.

Graph 1.2 (Figure Three) compares median fecal coliform levels for the two winters and the intervening summer, along with the fecal coliform criterion for shellfishing waters (14/100ml). Generally, median levels are quite similar to the levels observed for the geometric mean. Graph 1.2 (Figure Three) shows that in the non-disinfection winter the fecal coliform shellfishing criterion was just met at the upper end of the area currently approved for shellfishing. However, at the furthest downstream sampling location the non-disinfection winter median was 11/100 ml, compared to 8/100 ml during the disinfection winter.

Graph 1.4 (Figure Four) compares median total coliform levels for the two winters and the intervening summer, along with the total coliform criterion for shellfishing waters (70/100ml). Medians for the non-disinfection winter are significantly higher than for the disinfection winter over the entire length of the river sampled, including the shellfishing area. In the reach below River Mile 40, where shellfishing is currently permitted, the 70/100ml total coliform shellfishing criterion was met in the disinfection winter but was exceeded in the non-disinfection winter. At the furthest downstream sampling location, the median was 112/100 ml in the non-disinfection winter and 22.5/100 ml in the disinfection winter. This is a significant difference. It is noted that there was no danger to public health during the non-disinfection winter. Although taking of shellfish for direct marketing is permitted, shellfish taken from this area are considered too small and are therefore replanted to allow them to grow to a size more suitable for marketing.

#### River Runs - Additional Sampling Locations

Under the river-run sampling program, samples were also collected at 25 locations between the center of the navigation channel and the shores of the river. Geometric means and medians for the various bacterial parameters for the two winters at these 25 locations along with the geometric means and medians at the 15 center navigation channel sampling locations are presented in Appendix I in three-dimensional graphs numbered 1.11A through 1.20C. It should be noted that the relationships of the positions of the sampling locations shown on these graphs are "schematic" only, particularly the relationships between the "additional" locations and the center channel locations. Values for the non-disinfection winter are presented in the "A" series, values for the disinfection winter are presented in the "B" series, and the ratios of the non-disinfection winter value to the disinfection winter value are presented in the "C" series. In each of these graphs, the value (or ratio of values) is presented as a vertical bar. Solid black bars apply to the 15 sampling locations in the center of the navigation channel. The values represented by the solid black bars in the "A" series are the values indicated by "diamonds" in Graphs 1.1 - 1.10. In the "B" series, values represented by solid black bars are the values indicated by "x" in Graphs 1.1 - 1.10. Values obtained at sampling locations between the navigation channel and the Pennsylvania or Delaware shore are represented by open

bars denoted in the legend "Left of Chan.(Pa-De)". Values obtained at locations between the channel and the New Jersey shore are represented by bars filled by diagonals rising to the left and denoted in the legend "Right of Chan.(NJ)". There were also two sampling locations between the channel location and the right of channel location. These are represented by bars filled with horizontal lines and denoted by "Mid-River" in the legend.

The relationships between the values obtained at the center channel locations and the values obtained at the additional locations varied; many center channel location values were lower than the values at the nearby additional locations, some were higher. Generally, the relationship between the center and a nearby additional location was the same for both winters, e.g., if the additional location value was higher than the center value in the non-disinfection winter, it was also higher than the center value in the disinfection winter. This suggests that, generally, differences between center location values and the additional location values were influenced more by local factors than by changes in disinfection practices.

The "C" series (Graphs 1.11C - 1.20C) present the ratio of the geometric mean or median value observed in the non-disinfection winter to the value observed in the disinfection winter. Virtually all ratios are greater than one, that is, the value observed in the non-disinfection winter is higher than the value observed in the disinfection winter. This confirms for the 25 sampling locations between the channel and the shores what Graphs 1.1 - 1.10 show for the 15 center navigation channel sampling locations: in the non-disinfection winter bacterial levels were higher than in the disinfection winter for the entire length of the river sampled, including the shellfishing area.

#### Shellfish Area Sampling

The results of sampling in the shellfish area are presented in Appendix II in three-dimensional graphs numbered 2.1A to 2.6C. Geometric means and medians for fecal and total coliform and enterococcus are presented for the non-disinfection winter in the "A" series, and for the disinfection winter in the "B" series. The ratios of the non-disinfection winter value to the disinfection winter value are presented in the "C" series. The great majority of ratios are more than one, that is, the value observed in the non-disinfection winter is greater than the value observed in the disinfection winter. This is consistent with what was found in the "river-run" data.

In the "C" series graphs for the shellfish area, the highest ratios appear to occur at sampling locations near the shores rather than at sampling locations near the middle of the river. The shellfish area is more than 30 miles downstream from the reach which received undisinfected wastewater discharges. By the time these wastewaters reached the shellfish area, they would be mixed quite well with the

river water and would have moved downstream with the bulk of the river water, which occurs in mid-river rather than near shore. The higher ratios of non-disinfection winter value to disinfection winter value near the shores suggests that shore effects contributed significantly to the high bacterial levels observed in the shellfish area in the non-disinfection winter. The cause or causes are unknown.

One possibility is a difference in rainfall patterns between the two years, resulting in different impacts from land runoff. Rainfall occurring a day or two prior to the day that the shellfish area was sampled would have had a greater impact on river bacterial levels than rainfall occurring much earlier. Table 4 compares precipitation data at Wilmington for the two winter periods. Precipitation occurring on the day of a survey and on each of the seven days preceding the survey are tabulated. The precipitation recorded for the second through the seventh day was "weighted" by dividing by the number of the day. The sum of the "weighted" precipitation values for the non-disinfection winter is significantly more than the sum for the disinfection winter. This suggests that the rainfall pattern in the non-disinfection winter resulted in runoff contributing more bacteria to the samples collected in that winter than runoff contributed to the samples collected in the disinfection winter.

Fecal and total coliform data for most of the shellfish area sampling locations are also presented in Graphs 2.11A to 2.14H. Fecal and total coliform geometric means and medians for the two winter periods are compared along the five cross-sections or "transects" (series A,B,C,D and E), along the centerline channel profile (series F), and along shore profiles (series G and H). Once again, at nearly all locations, the non-disinfection winter value was significantly greater than the disinfection winter value. The transects also show that in this reach of the river, in both winters the highest values did not occur in the navigation channel, but along the Delaware or west shore or between the channel and the Delaware shore.

#### Statistical Analysis

To assess the statistical significance of the data, analysis of covariance tests were performed on fecal and total coliform concentrations. The purpose was to determine whether the differences in bacterial levels observed between years were primarily due to chance rather than to changes in disinfection practices.

The data were divided into two groups: (1) upper river - all river run sampling locations above River Mile 55 - encompassing 29 locations, and (2) lower river - the remaining river run sampling locations and all the shellfish area sampling locations - a total of 71 locations. For each data group for each parameter, analysis of covariance tests were performed using the following sources: a. disinfection practices, sampling locations, and the covariate streamflow, utilizing seven-day average flow of the Delaware River at Trenton, N.J. (see Table 7); and b. disinfection practices, sampling locations, and "weighted" precipitation. For the lower river, precipitation at Wilmington, Del., was used (Tables 4 and 5), and for the upper river, precipitation at Philadelphia, Pa., was used (Table 6).

The results are presented in Tables 8, 9, 10, and 11, for the upper and lower river for fecal and total coliform, respectively. All four tables show that bacterial levels were significantly affected by the disinfection practices and sampling location. For example, the probability that the differences between years were due to chance is always less than five percent and nearly always less than one percent (column 6 for the source "disinfection" in column 1).

The tables also show that bacterial levels were affected by both streamflow and precipitation, but the effect was different for each, and different for the upper river than for the lower river. Column 6 in part A of Tables 8 and 9 indicates that the interaction of the covariate streamflow and disinfection was not significant. This means that the response of bacterial levels in the upper river to streamflow was the same in both the non-disinfection winter and the disinfection winter, that is, a given rate of streamflow would produce the same change in bacterial levels in either winter. Since streamflows were significantly greater in the non-disinfection winter, the higher bacterial levels in that winter can be partially attributed to the higher streamflows.

Part B of Tables 8 and 9 indicate that the interaction of the covariate precipitation was very significant. This means that the response to precipitation in the non-disinfection winter was different from the response to precipitation in the disinfection winter. This could be the result of a difference in rainfall patterns between the two winters in relation to the times of sampling surveys. Such a difference would, for example, result in different contributions to bacterial levels due to discharges from combined sewers.

Tables 10 and 11 show that the response to both precipitation and streamflow was different in the two winters in the lower river, including the shellfish area. This is consistent with higher streamflows in the non-disinfection winter transporting bacteria further downstream than in the disinfection winter. It is also consistent with different precipitation patterns in the two winters resulting in different contributions of bacteria from land runoff.

The results of the analysis of covariance tests are consistent with higher bacterial levels in the non-disinfection winter being due to the combined effect of the suspension of disinfection, different streamflows, and different precipitation patterns in the two winters. When the influences of streamflow, precipitation, and sampling location are removed, bacterial levels remain higher in the non-disinfection winter over the entire study area.

#### Discussion

During the period when the wastewater disinfection requirement was suspended, bacterial levels were significantly higher than during the other portions of the two-year Study period. Higher values occurred over the entire length of the river sampled, and were evident at the

sampling locations in the center of the navigation channel, at the river-run sampling locations between the channel and the shores, and at the sampling locations in the shellfish area. Factors other than the suspension of disinfection, such as dry and wet weather CSOs, land runoff, or streamflows, may have contributed to the higher values. However, it must be recognized that these other factors in combination with the suspension of disinfection resulted in the high bacterial levels. Of the various factors, disinfection is the only one currently subject to control. There is a program underway to correct some of the dry-weather CSOs.

In this Study, there were two sets of samples collected, "river-run" and "shellfish area". There were 40 river-run sampling locations, 15 in the center of the navigation channel, and 25 between the channel and the shores. There were 60 sampling locations in the shellfish area. The key results were evident from the data obtained at the 15 center channel locations. Data from the other 85 locations were essentially consistent with the data from the 15 and did not materially affect the findings.

Samples were analyzed for up to five bacterial parameters - fecal coliform (MPN), total coliform (MPN), fecal coliform (mTEC), E. coli, and enterococcus. The key results were based on total and fecal coliform MPN. Results obtained for the other three parameters were essentially consistent with the results obtained for total and fecal coliform MPN. When this Study was concluded, analyses for total and fecal coliform MPN ceased, but analyses for enterococcus, E. coli, and fecal coliform mTEC on samples taken from the center of the navigation channel are continuing. The data obtained in this Study provide an excellent data base for relating total and fecal coliform MPN to enterococcus, E. coli, and fecal coliform mTEC, and for setting recreational water quality criteria based on E. coli and enterococcus, which are beyond the scope of this report.

Considerable effort during this Study was devoted to obtaining data during the winter months, December, January, and February. The data were examined to determine if the key results were obtainable without the samples collected in December, January, and February. Figure Five compares geometric mean fecal coliform MPN for the period October 1, 1987 - November 30, 1987 and March 1, 1988 - April 30, 1988 with geometric means for the period October 1, 1988 - November 30, 1988 and March 1, 1989 - April 30, 1989. It is evident from a comparison of Figure Five with Figure Two that data for the December - February periods made a significant difference.

#### Conclusions

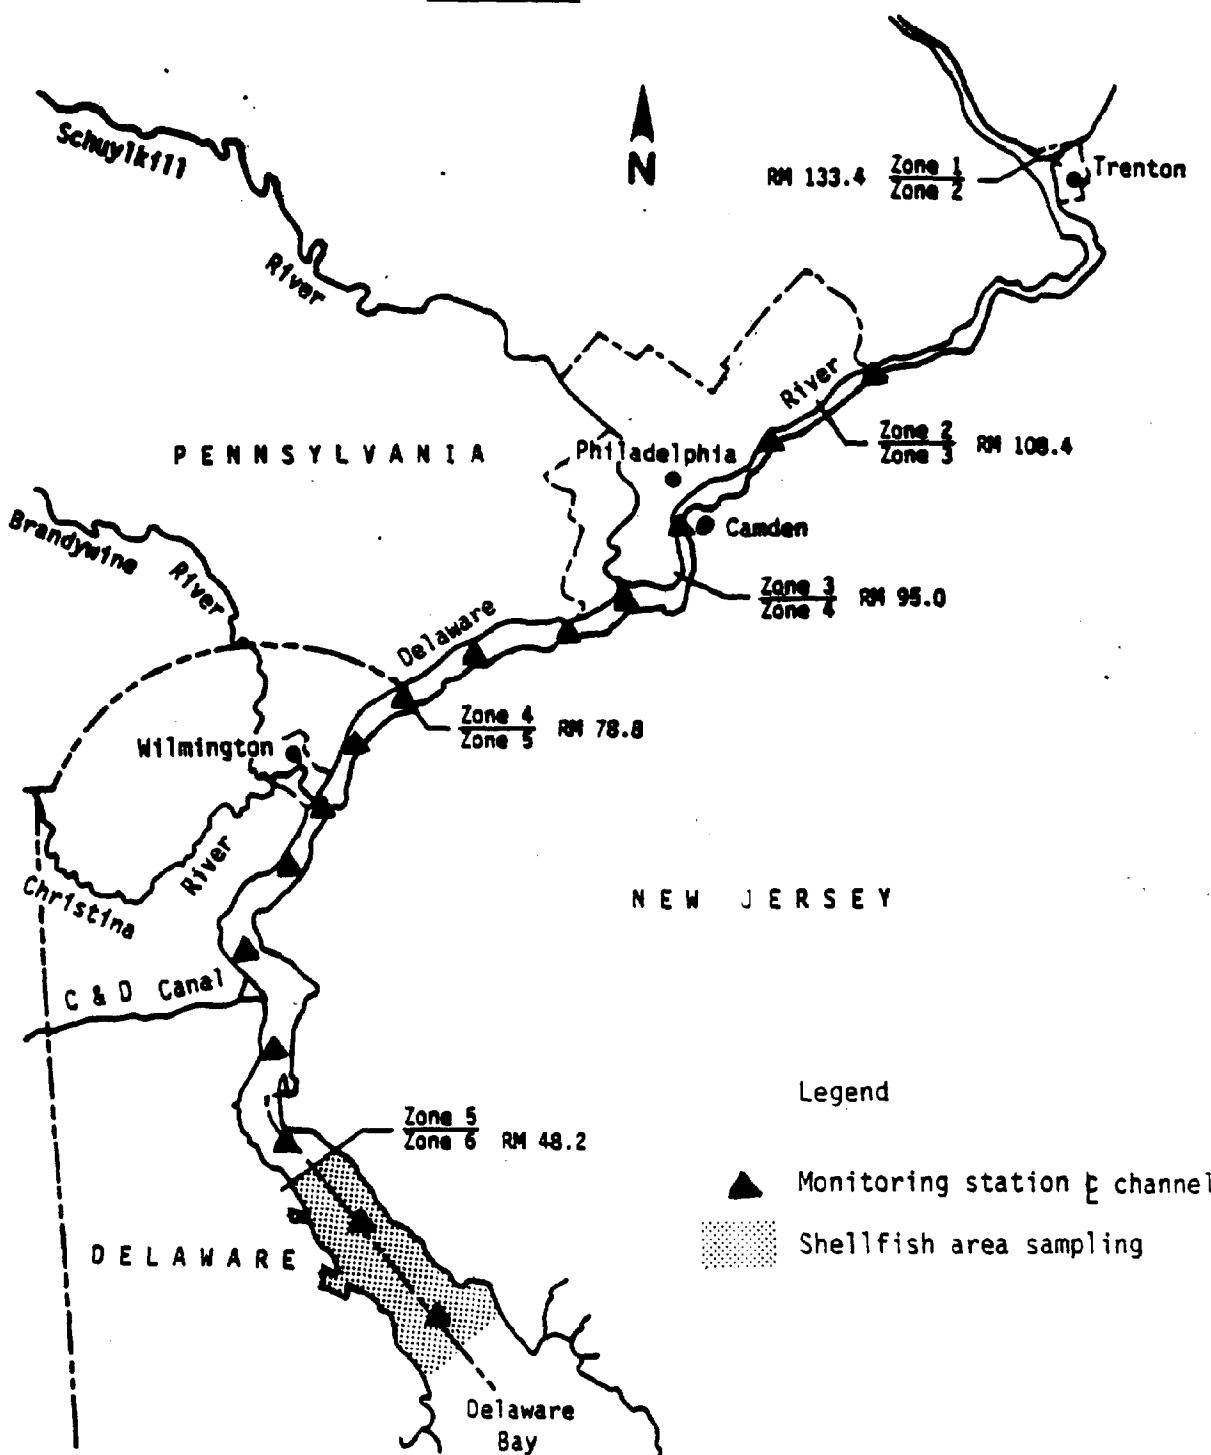

1. Bacterial levels in the non-disinfection winter were significantly higher than in the disinfection winter. The impact can be seen for the entire length of the river sampled, including the shellfishing area.

2. In the non-disinfection winter, geometric mean fecal coliform MPN values exceeded 5000/100ml in a zone designated as suitable for water supply in Commission water quality standards. A commonly accepted criterion for a raw water supply is a geometric mean of 2000/100ml. However, there are no public water supply withdrawals in the affected zone.
3. In the non-disinfection winter, geometric mean fecal coliform MPN exceeded the current Commission 770/100ml criterion for a distance of about four miles below the Pennsylvania-Delaware state line.
4. In the non-disinfection winter, median total coliform exceeded the 70/100ml shellfishing waters criterion in the approved shellfishing area. However, there was no danger to public health since, when shellfish are taken from that area, they are replanted to allow them to grow to a size suitable for marketing.
5. In addition to the suspension of disinfection, factors that contributed to the observed bacterial levels include combined sewer overflows under both dry and wet weather conditions, and non-point sources such as runoff from land surfaces resulting from rainfall.
6. Correction of dry weather combined sewer overflows and reduction of wet weather combined sewer overflows would substantially reduce river bacterial levels in the Philadelphia-Camden reach of the Delaware River. It is not possible to predict the length of river where bacterial levels would improve.
7. Bacterial data obtained at the 15 sampling locations in the center of the navigation channel between Torresdale and Ship John Light were essential to arrive at the above conclusions. Data obtained at the other 85 sampling locations confirmed the results but the conclusions would stand without the data from these additional locations.
8. Total and fecal coliform MPN measurements were used to reach the above conclusions. The measurements of the other three bacterial parameters provide a valuable data base for setting water quality criteria to protect recreation and for management of Delaware River water quality.
9. Collection of samples during the months of December, January, and February was essential to carry out this Study.

Recommendations

1. The current year-round wastewater disinfection requirement for discharges to the tidal Delaware River should remain in effect.
2. The above recommendation should be re-examined after combined sewer overflows have been corrected to eliminate dry weather flows, and reduce wet weather flows, or if environmental data collected to assess the health protection benefits of current disinfection practices indicate that disinfection is not effective for ensuring such protection.
3. Data for future studies should include analyses for appropriate parameters to support current and proposed standards and assess health risks. To the extent practical, factors such as rainfall, streamflows, and time of sampling should be considered in the study design.
4. Data on the new recreational bacterial parameters collected in this Study should be reviewed and assessed for the purpose of revising current water quality standards.
