ABSTRACT

The spatial and temporal occurrence of Atlantic bottlenose dolphins (*Tursiops truncatus*) in the coastal and estuarine waters near Charleston, SC were evaluated. Sighting and photographic data from photo-identification (ID), remote biopsy, capture-release and radio-tracking studies, conducted from 1994 through 2003, were analyzed in order to further delineate residence patterns of Charleston area bottlenose dolphins. Data from 250 photo-ID, 106 remote biopsy, 15 capture-release and 83 radio-tracking surveys were collected in the Stono River Estuary ($n = 247$), Charleston Harbor ($n = 86$), North Edisto River ($n = 54$), Intracoastal Waterway ($n = 26$) and the coastal waters north and south of Charleston Harbor ($n = 41$). Coverage for all survey types was spatially and temporally variable, and in the case of biopsy, capture-release and radio-tracking surveys, data analyzed in this report were collected incidental to other research. Eight-hundred and thirty-nine individuals were photographically identified during the study period. One-hundred and fifteen (13.7%) of the 839 photographically identified individuals were sighted between 11-40 times, evidence of consistent occurrence in the Charleston area (*i.e.*, site fidelity). Adjusted sighting proportions (ASP), which reflect an individual's sighting frequency in a subarea relative to other subareas after adjusting for survey effort, were analyzed in order to evaluate dolphin spatial occurrence. Forty-three percent ($n = 139$) of dolphins that qualified for ASP analyses exhibited a strong subarea affiliation while the remaining 57% ($n = 187$) showed no strong subarea preference. Group size data were derived from field estimates of 2,342 dolphin groups encountered in the five Charleston subareas. Group size appeared positively correlated with degree of “openness” of the body of water where dolphins were encountered; and for sightings

along the coast, group size was larger during summer months. This study provides valuable information on the complex nature of bottlenose dolphin spatial and temporal occurrence near Charleston, SC. In addition, it helps us to better understand the stock structure of dolphins along the Atlantic seaboard.

INTRODUCTION

Sighting and photographic data from photo-identification (ID), remote biopsy, capture-release and radio-tracking studies carried out between 1994-2003 on bottlenose dolphins (*Tursiops truncatus*) near Charleston, South Carolina (Figure 1) were analyzed to gain a better understanding of their temporal and spatial occurrence (Montie *et al.* 2000, Zolman 2002, Bossart 2003, Hansen *et al.* 2004, Recks 2004, Stenftenagel *et al.* 2004, Laska 2005) (Table 1). Analyses and interpretations in this report were intended to further refine our current understanding of Charleston area dolphins. For example, the long-term nature of these observations, and the spatial perspective they afford, will extend the understanding of residence patterns of Charleston area dolphins first reported by Zolman (2002). This report was also intended to be of heuristic value in exploring useful approaches for some of the analyses which will accompany more systematic photo-ID based studies which are part of the Charleston Dolphin Abundance and Distribution (CDAD) project begun in January 2004 (Defran 2003).

METHODS

Data Sources

Information about the research projects which contributed dolphin sighting and photo-ID data to the current report are described in this section and summarized in Table 1. In addition, this section describes the rationale, derivation and application of adjusted sighting proportions (ASP) which provide a measure of subarea preferences by Charleston dolphins.

Field Work

Photo-ID - In July 1994 systematic boat-based photo-ID surveys for bottlenose dolphins were begun in the Stono River estuary (SRE) (Figure 2). The objective of this National Marine Fisheries Service (NMFS) research was to examine the short-term residence patterns of local dolphins, with the ultimate goal of aiding in the resolution of coastal dolphin stock structure. A pilot study, consisting of four surveys, was carried out from July through September, 1994; following this preliminary work, 74 complete and seven incomplete surveys were conducted from October 1994 through January 1996 (Zolman 2002).

Surveys proceeded along a specific route through the estuary and selected tributaries at approximately 8-16 km/hr, using small (5-7 m) outboard motor powered boats. During surveys, two to three crew members visually searched the surrounding waters until dolphins were sighted. When sighted, animal location was recorded by estimating position on a nautical chart or by GPS positioning, in addition to time, heading and environmental conditions. A dolphin group (sighting) was defined as all dolphins within relatively close proximity (<100 m) to one another, generally moving in the same direction and engaged in similar behavior(s) (Urian and Wells 1996).

Upon completion of initial data collection, the vessel was maneuvered close to the dolphin group and an attempt was made to videotape (Hi8 video was used from July 1994 to April 1998; digital video was then used through October 2002) the dorsal fins of all group members. After completion of video recording, information on group size, composition, and behavior were recorded. The survey then resumed along the designated route and identical procedures were followed for subsequent dolphin groups.

Post-survey, video was reviewed and images of apparently distinctively marked fins were digitized and printed. Printed images of distinctively marked dorsal fins were sorted by recognizable notch patterns, with the best image for each dolphin selected as the “type specimen” to which all other images were compared. Subsequently, only unambiguous matches with the “type specimen” were accepted as re-identifications of a known individual. These methods were followed for subsequent field and laboratory photo-ID research until November 2002.

There was a break in photo-ID fieldwork from February 1996 to December 1996. In January 1997, the NMFS site-specific photo-ID surveys resumed in the SRE. In March 1997, survey effort was extended to three additional estuarine subareas in western Charleston County in order to expand our understanding of the residence patterns and short-range movements of Charleston-area dolphins. These new survey subareas included: Charleston Harbor (CHS) (Figure 3), the North Edisto River (NER) (Figure 4), and a section of the Intracoastal Waterway (ICW), approximately 13 km northeast of CHS (Figure 5). Between January 1997 and May 2003, 136 surveys were conducted near Charleston.

These photo-ID surveys were spatially and temporally variable in occurrence, sometimes including partial coverage of the designated survey route in a subarea. For example, the full survey route for the NER was rarely completed. Also, the interval between surveys (within subareas as well as overall) was variable, with very few surveys carried out in either 2000 or 2001.

Beginning in September 2002, photo-ID survey effort was initiated along the coast, northeast and south and west of CHS (Figure 6). Five preliminary coast (CST) surveys

were carried out between September and December 2002; from January through December 2003, 24 bimonthly surveys were conducted. Coastal photo-ID surveys followed a systematic survey route and inaugurated the use of digital photography (Laska 2005). Digital photography was used exclusively in all Charleston subareas after November 2002 (Defran 2003, Schwacke *et al.* 2003).

Photographic and sighting data from all surveys (including remote biopsy, radio-tracking and capture-release) were entered into *FinBase*. This customized National Ocean Service database (Microsoft Access) enables researchers to store and manage textual and numerical data from photo-ID surveys, as well as perform many tasks associated with image management and analysis, including matching and cataloging (Schwacke *et al.* 2003). The downloading, sorting, matching and cataloging procedures used are summarized as follows: photographs were downloaded from the Canon EOS 1D camera's compact flash card onto a Dell Dimension 4550 computer using a USB-connected SanDisk card reader. Individual folders were created on the memory card to coincide with each sighting from that particular survey where the last two digits in the folder number were linked with the sighting number (*e.g.*, folder 101 held all photos from sighting 1). All sighting folders were stored in a survey folder created for that day and then backed up on a Maxtor external hard drive. Photos were then batch renamed by adding the survey date and sighting number to the image frame number. Utilizing the file browser utility in Adobe Photoshop 7.0, images were sorted and cropped and the best dorsal fin image of each individual dolphin was saved and labeled with a temporary identifier. For CST photos only, best images were then rated based on overall photographic quality and distinctiveness as described by Urian *et al.* (In Review), with

overall photographic quality scored independent of the distinctiveness of the fin. Photographic quality was ranked using a weighted scale based on focus, contrast, angle, partial obstruction, and distance. Images were then divided into three categories: excellent, average, and poor. Images with a poor rating were deleted and not used in photographic analysis. Overall fin distinctiveness was determined based on the amount of information present on the leading and trailing edges of the fin, as well as pattern, marks, and scars. Fin distinctiveness was divided into three categories: high distinctiveness, average distinctiveness, and not distinctive. Upon completion of quality ratings, all individuals were compared to the NOS/CCEHBR bottlenose dolphin photo-ID catalog using *FinBase*. *FinBase* allows researchers to search the entire dorsal fin catalog for a particular individual utilizing prioritized fin characteristics (*e.g.*, chopped fin, apex notch, leading edge notch, upper, middle, and lower fin notches, bend, freeze-brand) (Schwacke *et al.* 2003). When a match was made, the image from the new sighting was entered into the dolphin's existing sighting history as a tentative match. Confirmation by a second researcher was then required before it was stored as a match in *FinBase*. If a fin was not matched following an independent search of the entire catalog by two researchers, that fin was entered as a new individual in the database and given a unique catalog identification number based on the dominant fin characteristic. If a fin was determined to be non-distinctive, it was entered into the database as a clean fin and given a place-holding code from the appropriate number series. For all fins entered into the database (matched, new, and clean), additional information pertaining to that individual was also entered (*e.g.* dolphin age class (neonate, calf, other, or unknown), level of distinctiveness, presence of stalked barnacles (*Xenobalanus globicipitis*), and mother/calf information). Group size

data collected prior to 2003 was extrapolated from notes recorded on data sheets at the time of the survey, and then entered into *FinBase*.

Remote Biopsy - Group sighting and photo-ID data were collected during boat-based remote biopsy sampling surveys (Mesnick *et al.* 1999). Dolphin dorsal fins were photographed or videotaped using either a manually-operated camera or camcorder and/or from a camcorder (“guncam”) mounted on the biopsy projector, before, during and after biopsy samples were collected. Biopsy surveys differed from photo-ID surveys primarily in that the former did not typically follow predefined routes, but rather targeted locations where dolphins were more likely to be found. Contact time with dolphin groups during biopsy sightings was typically longer than photo-ID sightings due to the demands of the biopsy sampling process. Researchers routinely attempted to photograph or video all dolphins within a group, but an emphasis was placed on obtaining images of the target dolphin(s). Photographic techniques and analyses were the same as those associated with dedicated photo-ID surveys.

A one-week pilot demonstration of remote biopsy equipment and methodologies was completed in April 1996 by NMFS personnel (*e.g.*, see Weller *et al.* 1997). Biopsy samples were collected from free-ranging dolphins using darts fired from a modified 0.22-cal. rifle. During this work, four surveys were conducted in the SRE on concurrent days. While the emphasis was on collecting skin/blubber samples, encountered dolphin groups were also videotaped for subsequent identification and data sheets were filled out for each sighting. As part of NMFS efforts to investigate the stock structure of bottlenose dolphins in US Atlantic waters, tissue collected via remote biopsy sampling was utilized in mtDNA and nuclear DNA analyses (Rosel *et al.* 2003).

Beginning in September 1997, remote biopsy sampling of Charleston area dolphins commenced and continued through January 2002, totaling 41 surveys (Zolman *et al.* 2001, CCEHBR unpublished data). During the early stages of this research, dolphins were targeted based primarily on approachability. Over time, the criteria used in evaluating the suitability of dolphins for biopsy sampling was refined to include dorsal fin distinctiveness and prior sampling history. Similar to the photo-ID site-specific surveys, biopsy survey coverage was both temporally and spatially variable. Another caveat for remote biopsy surveys was that data were not collected for every dolphin group encountered. Single dolphins were rarely targeted for sampling and consequently, were often not photographed. Groups that contained calves estimated to be less than two years old, or those that reacted negatively to the initial boat approach, were also not sampled and similarly, were typically not photographed. However, data sheets were completed for sightings in which photographs were taken, regardless of whether a biopsy sample was collected.

A year long study to collect a core blubber sample, in addition to the overlying skin, was conducted from March 2002 through February of 2003 (Recks 2004). The blubber portion was used in an investigation of the prey composition of inshore bottlenose dolphins through analysis of fatty acids. Over the course of this project, 61 surveys were completed. As in previous biopsy efforts, sighting data on dolphins encountered and targeted for sampling was collected.

Capture-Release - In October 1999, the NMFS conducted a one week capture-release in the SRE in support of the coastal bottlenose dolphin stock assessment program (CCEHBR unpublished data). Over the five days of the project, 14 dolphins were

captured, briefly restrained and released using methods similar to those described by Wells (1991). During capture-release procedures, dolphins were given a physical examination, measured and weighed and biological samples were collected. Twelve (of the 14) dolphins were freeze-branded (on both sides of the dorsal fin and the left and right flanks immediately below the dorsal fin) with 3 digit numbers and 12 were tagged with small “cattle-ear” tags along the trailing edge of the dorsal fin. Some of the captured dolphins were instrumented with VHF radio ($n = 7$) or satellite/VHF radio ($n = 2$) transmitters. Prior to release, each captured dolphin was comprehensively photographed.

A second capture-release project, intended to explore the health of local dolphins, was conducted over ten days in August 2003. The primary goal of this research was to collect a comprehensive suite of health-related samples for the bottlenose dolphin Health and Environmental Risk Assessment (HERA) project (Bossart 2003). Capture-release operations spanned ten days in both the SRE and CHS. Altogether, 50 dolphins were handled, 44 of which were freeze-branded (on both sides of the dorsal fin but not on the flanks) while 46 were tagged. Twelve of the 46 tagged dolphins were instrumented with VHF radio transmitters. As in 1999, a complete photographic record was collected for each sampled dolphin. Additionally, photographs were taken and sighting data recorded for a small number of dolphin groups that were encountered during operations but not captured. Such sighting data was collected in an *ad hoc* fashion though, because predefined survey routes were not followed (as in photo-ID surveys). Effort was primarily focused in areas that offered better opportunities to capture dolphins.

Radio-Tracking - From October 12, 1999 until January 28, 2000, dolphins radio-tagged during the 1999 NMFS capture-release project were tracked and visually

monitored from small boats. The objectives of this radio-tracking project were to: 1) elucidate fall and early winter movements of dolphins and 2) monitor the status and behavior of dolphins after capture-release and observe healing of the surgical biopsy site (Montie *et al.* 2000). Forty-three radio-tracking surveys were conducted. Tag life ranged from 0 to 93 days, with a mean of 48 days. In addition to the data collected via radio-tracking surveys, the two dolphins instrumented with satellite tags provided information about movements between adjacent estuarine areas.

A second radio-tracking study followed the 2003 NOS HERA capture-release project. The goals of the radio-tracking were to: 1) monitor short-term dolphin habitat use and movement patterns, 2) document association patterns between instrumented dolphins and conspecifics, and 3) assess post-capture behavior and overall health, including biopsy wound and freeze-brand healing. An effort was made to follow all 12 radio-tagged dolphins immediately post-release to assess any signs of distress, behavioral changes and potential group reformation. Between August 11 and October 10, 2003, 40 radio-tracking surveys were carried out, predominantly in CHS and SRE, and with occasional survey effort in areas beyond these two subareas. Transmitter life ranged from 8 to 45 days with a mean of 27 days. Additionally three land-based radio-tracking surveys were conducted around CHS and SRE when inclement weather precluded boat surveys (Stenftenagel *et al.* 2004).

The 1999/2000 and 2003 radio-tracking surveys, involved searching for and then photographing “specific” (tagged) dolphins, as well as additional group members (Montie *et al.* 2000, Stenftenagel *et al.* 2004). Specific dolphin’s radio-tag frequencies were monitored while the research platform moved between “listening posts”; at each

“listening post” each frequency was monitored for 3 min. After detecting a signal, tagged dolphins were localized using a combination of signal strength and directional bearings. Due to the size and complexity of the Charleston study area, the process of locating radio-tagged dolphins was often time consuming. As a result, other dolphins encountered while searching for tagged individuals were often not photographed; on occasion, though, groups that did not contain radio-tagged dolphins were photographed and sighting data collected. Once radio-tagged dolphins were located, an attempt was made to photograph as many group members as possible.

A small number ($n = 15$) of miscellaneous boat “trips” were made during the period 1994-2003 in which dolphin photographs and/or sighting data were collected. These “trips” were undertaken for a variety of reasons, including: exploratory surveys, stranding response, interventions related to entangled or out-of-habitat dolphins and surveys by other researchers. Data collected during “trips” were not used in any calculations, but images of distinctively marked dolphins were incorporated into the dorsal fin catalog and into *FinBase*.

Adjusted sighting proportions

Sightings where individual dolphins were photographically identified during boat-based photo-ID and remote biopsy surveys carried out near Charleston between 1994-2003 (Table 2) were used to examine the proportions of sightings for each individual within three different subareas: CHS, CST and SRE. These three subareas were selected because they are among the primary sampling areas for ongoing photo-ID studies, as well as health assessment efforts. Sightings from capture-release, radio-tracking, and ‘other’ surveys were excluded from this analysis because of the tendency for partial coverage of

the survey area and the typically brief sighting duration, hence limited photo coverage of groups seen during these types of surveys. It is likely that not every individual within a subarea was sighted (detected) on a given survey and the probability of detection likely varied between subareas. Hence, we cannot infer the actual proportion of time an individual spent in a given subarea from the calculated proportion of sightings. However, if we assume that “detectability” did not vary between individuals within the same subarea, then the proportion of sightings can provide a useful index of an individual’s time spent within a subarea relative to other catalog dolphins. In turn, these sighting proportions may be useful in defining different cohorts for comparison of health and/or exposure parameters.

Survey frequency varied across the three different subareas: SRE ($n = 179$), CHS ($n = 56$), CST ($n = 41$) (Table 2). As a result, a direct calculation of proportion of sightings in a given subarea is not meaningful. Therefore, an adjusted sighting proportion (ASP) was calculated for each individual within each subarea, which accounted for unequal survey effort expended in the three subareas. The ASP statistic was calculated by first estimating the probability of sighting the individual on a survey for subarea i :

$$p_i = \frac{n_i}{N_i}$$

where,

n_i = number of times an individual was sighted in subarea i , and

N_i = total number of surveys recorded in subarea i .

If all subareas had been surveyed an equal number of times, S , then an expected proportion of an individual’s sightings in a given subarea i , ASP_i , could be calculated:

$$ASP_i = \frac{\frac{n_i}{N_i} \times S}{\sum_{j=1}^N \frac{n_j}{N_j} \times S}$$

or equivalently,

$$ASP_i = \frac{\frac{n_i}{N_i}}{\sum_{j=1}^N \frac{n_j}{N_j}}$$

An individual's ASP for a given subarea represents the expected proportion of the individual's sightings that would have been in the given subarea if all subareas had been surveyed with equal frequency. For example, $ASP_{CHS} = 0.80$ would indicate that if all the subareas had been surveyed with the same frequency and the individual was sighted 100 times, we would have expected 80 of those sightings to be within the CHS subarea.

The surveys included for an individual dolphin were limited to those between the individual's first and last sighting date. This restriction avoided the inclusion of surveys in the time period prior to the animal being born (or at least distinctively marked) and periods when the animal may no longer be in the area due to emigration or death. After imposing the above limitations, 326 individuals were included in the ASP analysis.

Lower 90% confidence limits were also calculated for the ASP statistics using a bootstrap resampling approach. Briefly, for each individual in a given subarea, the number of sightings was assumed to follow a binomial distribution, with parameter p , the probability of sighting. While p can be easily estimated as the number of sightings of an individual in a subarea divided by the number of surveys in the same subarea, this does not provide information as to the confidence of p . For example, an individual sighted three times over four surveys and an individual sighted 75 times over 100 surveys would

both have a probability of sighting = 0.75, but there would obviously be more confidence in the estimate for the latter individual. Therefore, the uncertainty in p was modeled using a beta variate with shape parameters $x, n-x+1$ where x is the number of sightings and n is the total number of surveys for a given individual in a given subarea. One thousand simulations were executed for each individual within each subarea, drawing a random p from the estimated beta distribution, then drawing a random number of sightings from a binomial distribution with parameter p . One thousand ASP statistics for each individual and each subarea were then calculated based on the simulation results. ASP values (calculated as mean) and lower 90% CI were calculated from the 1000 replicate simulations.

Dolphins which had an estimated $ASP_i > 0.75$ (*i.e.* after adjusting for survey effort, more than 75% of the sightings would be expected to be from a single subarea) were considered to have an affiliation for subarea i . The affiliation was judged to be statistically significant if the lower bound of ASP_i was greater than 0.75, and in these cases the individual was classified as a dolphin with a strong subarea affiliation.

RESULTS and DISCUSSION

As noted, some of the sighting and photo-ID data analyzed for this report were collected incidentally to other research operations (*i.e.*, remote biopsy, capture-release and radio-tracking). In addition, survey coverage for all survey types, including photo-ID, was spatially and temporally variable. These characteristics of our methodology limit, to a degree, the type of data and analyses that can be derived. For example, because of the variable survey coverage, the absence of sightings for one or more individuals cannot be

interpreted as the absence of the unsighted individuals from the study area. The absence of sightings might as easily be attributable to limited survey coverage (effort) rather than an actual absence. Photo-documented sightings of individuals, however, constitute unambiguous evidence that a certain individual was present on a particular date, in a particular location (subarea). In addition, the size of dolphin groups observed in all subareas over time was probably unaffected by variable survey coverage, except perhaps when the spatial scale was very small and the temporal scale very short.

Temporal Occurrence Patterns

Photo-ID data collected within the SRE over 19 months (July 1994 - January 1996) provided evidence for short-term site fidelity to this small estuary (Zolman 2002). The current data were examined for evidence of more wide-scale, longer-term site fidelity among Charleston area dolphins. Eight-hundred thirty-nine individuals were photographically identified between 1994-2003 across the five subareas of the Charleston study area (Figures 7 and 8). While 724 of these individuals were sighted 10 times or less, the remaining 115 individuals were sighted between 11-40 times, and these dolphins were labeled as having a 'very high sighting frequency' (VHSF). Very high sighting frequencies, occurring within the context of the high total number of surveys ($n = 454$), provide evidence of consistent occurrence by certain dolphins in the Charleston area (*i.e.*, site fidelity).

Evidence for sightings over time (*e.g.*, months, years, *cf.* Campbell *et al.* 2002), however, is also needed to establish site fidelity. Ninety-three of the 115 (81%) VHSF dolphins were sighted over a period of >60 mo., and 51 of these dolphins were sighted over a period of 90-117 mo. (7.7-9.8 yr.) (Figure 9). In the aggregate, these 'sighting-

frequency' and 'months-sighted' data suggest that some dolphins in the Charleston area are long-term residents.

The high number of individuals sighted 10 or fewer times, along with the steep slope of the rate of discovery curve, especially during Years 2002 and 2003 (Figure 8) suggests that some, and perhaps many, dolphins are short-term or infrequent visitors (*i.e.*, transients) to the Charleston area. Thus, at least two resident classes appear to exist among Charleston area dolphins. At one extreme are long-term resident dolphins, some with sighting histories approaching 10 years in the area; while other dolphins, perhaps many, appear to be infrequent and/or short-term visitors. Due to the variable survey effort in this dataset, caution must be exercised when applying a site fidelity interpretation to low sighting frequencies. Nonetheless, the co-occurrence of dolphins who show long-term residence, along with dolphins who show short-term residence, has been reported in other study areas where long-term and high-effort surveys have been conducted such as Belize (Campbell *et al.* 2002, Kerr *et al.* 2005) and Florida (Mazzoil *et al.* 2005). Further, these hypothesized residence classes are consistent with Zolman's (2002) observations on a smaller and earlier subset of the Charleston photo-ID dataset.

Spatial Occurrence Patterns

One of the objectives of the dolphin health studies in the Charleston area was to investigate area-specific health related impacts associated with this urban-industrial marine environment (Bossart and Fair 2002). A starting point for addressing such area-specific questions was to examine photo-ID data for possible evidence of fidelity to, or higher occurrence within, specific subareas by individual dolphins. The dataset for

subarea fidelity analyses included 2,059 individual sightings, including multiple sightings of some individuals.

The ASP analysis results indicated that 139 of the 326 (42%) dolphins had a strong subarea affiliation (lower bound of $ASP > 0.75$ for a single subarea) (Figure 10). The greatest number of these individuals were affiliated with the CST subarea ($79/139 = 57\%$).

In some cases, a high ASP was estimated even though an individual was sighted on a limited number of surveys. This occurred when all of the individual's sightings, albeit very few in total, were within a single subarea, making the estimated probabilities of the individual being sighted in the two alternate subareas very close to zero. To examine the effect of this phenomenon, individuals that were sighted in less than 5 percent of the surveys that occurred during their valid sighting period (between first and last sighting dates) were re-classified as "NA" and proportions were re-calculated (Figure 11). Although this reduced the total number of individuals considered as having a strong subarea affiliation (77 versus previous 139) the highest proportion of individuals with a high ASP were still affiliated with the CST subarea ($59/77 = 77\%$).

Apart from whether Charleston area dolphins show a strong affiliation to a particular subarea, is the more general question of whether the sighting record for Charleston area dolphins contains evidence of individuals using multiple subareas. This analysis included all dolphins sighted within one or more of the five Charleston subareas (Figure 12).

Nearly twice as many dolphins had sightings in the CST subarea ($n = 568$) than in the CHS subarea ($n = 315$), even though more surveys were conducted in the CHS subarea. In turn, the number of dolphins with sightings in the CHS subarea was over 50% higher

than in the SRE ($n = 160$), over 40% higher than in the NER ($n = 128$), and almost nine times greater than in the ICW ($n = 37$). Dolphins sighted in the CST subarea were of particular interest because of hypotheses that have been raised about the existence of multiple bottlenose dolphin stocks along the Atlantic seaboard, as well as migration by, and potential mixing between, these stocks (Hohn 1997). The degree to which ‘coastal’ dolphins (those with one or more CST sightings) also used other Charleston subareas was examined for dolphins with five or more total sightings (high sighting frequency – HSF) (Figure 13). Among these HSF dolphins, 196 individuals had CST sightings (range = 1-14). Of these 196 HSF ‘coastal’ dolphins: 1) 3% had all their sightings in the CST subarea, 2) 62% had sightings in only one other subarea, 3) 27% had additional sightings in two other subareas, and 4) 8% had sightings in three additional subareas (Figure 14).

A relatively small proportion (35%) of dolphins with a CST sighting ($n = 568$) qualified as a HSF dolphin. Since CST surveys were not begun until 2002, this small proportion may be the result of a more limited opportunity to be observed and photographed. Alternatively, these resighting patterns may reflect a degree of transience of some or many of these ‘coastal’ dolphins. Finding that 97% of the HSF dolphins with CST sightings had sightings in at least one other subarea suggests that ‘coastal’ dolphins make use of other Charleston subareas. Closer inspection of the ‘coastal’ dolphin sighting data moderates this impression. Among the HSF ‘coastal’ dolphins, 79% of the 121 dolphins with a sighting in just one other subarea, were sighted in the CHS subarea. The broad expanse of Charleston’s harbor entrance, coupled with the fact that many of the dolphin groups sighted in the harbor are sighted near the mouth of the harbor, or following shrimp boats (CCEHBR unpublished data), suggests that for many dolphins

with coastal sightings, their incursions into Charleston's estuaries are restricted to waters immediately adjacent to the CST subarea.

Group Size

In the earliest years, there was variability in the application of group size criteria. It appeared, however, that this variability was not selective in its occurrence (*e.g.*, across seasons, survey types or survey areas). Although calculation of mean group size may prove useful for relative comparisons across subareas and between seasons, it should be viewed with caution and will be re-evaluated as more reliable data become available.

Mean group size was calculated from best field estimates of 2,342 dolphin groups encountered in the five Charleston subareas. Sightings from photo-ID, remote biopsy, capture-release, and radio-tracking surveys were included in calculating group size. In addition, subarea assignment was based on a sighting location (from GPS) within predetermined GIS-based polygons defined for each subarea (*i.e.*, residence polygons; Figs. 1, 2, and 5) rather than the survey's intended subarea. Thus, 169 sightings located outside of a residence polygon were not included in the analysis. Almost as many groups were encountered and used to calculate the mean group size in the SRE ($n = 1,076$) as in all other subareas combined ($n = 1,266$). Group size appeared to vary directly with the openness of the body of water where dolphins were encountered, a relationship also noted when contrasting coastal California dolphins with those from Florida and South Carolina in more protected environments (Defran and Weller 1999, Defran *et al.* 1999, Caldwell 2001). Among Charleston subareas, the mean group size was smallest in the SRE and ICW, and largest in CHS and along the CST, with groups in the NER being intermediate in mean size (Figure 15).

The relationship between mean group size and season (summer versus winter) was examined. Summer was defined as the months June – August when mean water temperature was 28.8°C and ranged from 24.5° – 34.3°C; and winter was defined as the months December - February when mean water temperature was 10.8°C and ranged from 6.0°C – 19.0°C. Water temperatures were based on real-time surface water temperatures collected during 1,284 sightings located throughout the study area from photo-ID, remote biopsy, capture-release, and radio-tracking surveys conducted from 1994 to 2003. Water temperatures were collected using a bucket and thermometer from 1994 to 2002 and then using a YSI 30 salinity, conductivity, temperature probe starting in 2003. Mean group size was found to differ between summer and winter in the more open CST waters, but not for more protected waters (*i.e.*, CHS, SRE, NER and ICW). For the CST ($t = 3.85$, $df = 190$, $P < 0.001$) subarea, the mean group size was higher in the summer (Figure 16).

Variations in the group size of small cetaceans are usually thought to be a product of predation, foraging and prey abundance related variables (Connor 2000). When dolphins must contend with predatory threats, namely sharks, as they are presumed to do in Charleston area waters, then allowances are likely made between optimizing foraging efficiency while reducing predation pressure (Bertram 1978; Lima and Dill, 1990; Cowlshaw 1997, Farmer 2004). In Sarasota Bay, for example, where both low-density food resources and high predation pressure exist, dolphin group size variation relative to micro-habitat usage patterns appears to be a mechanism for balancing predation risk with food availability (Wells *et al.* 1980; Wells *et al.* 1987).

Group sizes reported for coastal bottlenose dolphins, including those found in estuarine habitats, vary widely (Connor 2000). The smaller mean group size associated

with the IWC and SRE may reflect, as they are hypothesized to in Turneffe Atoll, Belize (Campbell *et al.* 2002), that dolphins using these areas divide into small social and foraging units which are thought to effectively reduce competition among conspecifics, especially when prey density is low (Bertram 1978, Connor 2000).

In more open waters, preferred prey items may be more patchily distributed, thus placing selective pressure on the formation of larger groups. Increased group size allows dolphins to take advantage of integrated sensory information and feed cooperatively, thus increasing the energy intake of each group member (Hanson and Defran 1993, Defran and Weller 1999, Wells and Scott 1999).

As noted, predation risk is also a primary factor that can influence group size (Bertram, 1978; Van Schaik and Van Noordwijk, 1985; Lima and Dill, 1990). Larger groups provide greater protection to group members through improved predator detection and defense. The larger group sizes formed during summer months with higher water temperatures by Charleston dolphins in the CHS and CST correspond with the seasonal influx of predators, such as bull sharks (*Carcharhinus leucas*) and tiger sharks (*Galeocerdo cuvieri*) into estuarine waters (Farmer 2004). However, other foraging and prey related variables, such as more patchily distributed and more abundant prey, may also contribute to the formation of larger groups.

Another potential factor contributing to the larger group sizes in the CST could have been the presence of shrimp boats. Dolphins were often seen traveling and feeding behind working shrimp boats, benefiting from prey that is either tossed overboard as by-catch or feeding on prey stirred up by the nets. Sightings ($n = 231$) in which shrimp boat association data were recorded were examined to see if there was a difference in mean

group size when shrimp boats were present. Of the 231 total sightings, dolphins were observed actively associating behind shrimp boats during 47 (20%) sightings between the months of June and November, in which the mean group size was 15 (Figure 17). In contrast, the mean group size (mean = 7.81) from 184 sightings in which shrimp boats were not present was considerably smaller. Thus, in addition to predation, foraging and prey abundance, the presence of shrimp boats appears to be a contributing factor to group size differences among CST dolphins.

Concluding Comments

In the aggregate, the data and analyses presented suggest that temporal and spatial aspects of bottlenose occurrence near Charleston are complex, with no one generalization predominating. Spatial data and analyses indicate some Charleston dolphins restrict their movements and activities to a limited area, such as one of the five Charleston subareas. Other Charleston dolphins appear to partition their time between two or more subareas. In addition, many Charleston dolphins appear to be transients or short term visitors.

The spatial distribution of dolphins with coastal sightings is of particular interest in attempts to understand the stock structure of bottlenose dolphins along the Atlantic seaboard. In the Charleston area, these dolphins predominantly restrict their movements to the coast or to the adjacent, more open waters of lower Charleston Harbor.

These data also extend the evidence for long-term site fidelity among some Charleston dolphins first reported by Zolman (2002). However, Zolman's conclusions were based on data collected solely from the SRE over a period of 19 months. The greater temporal and spatial extent of observations in this report show that a considerable number of Charleston area dolphins exhibited site fidelity over periods approaching 10

years. Finally, group size data show that there is a direct relationship between the 'openness' of an area and the size of the group, and that coastal groups are larger during summer months. Several hypotheses for these groups size differences are proposed (*e.g.*, predator defense, presence of shrimp boats) but no definitive determination, favoring a particular hypothesis, has been reached.

While these observations improve our understanding of Charleston area bottlenose dolphins, they are limited in their scope and depth by the variable survey effort which occurred across time and space (Table 2). The Charleston Dolphin Abundance and Distribution (CDAD) Project, initiated in January 2004, is designed to determine: (1) abundance and density estimates for the Charleston population partitioned by seasonal, environmental and annual variables; (2) habitat type preferences and usage through spatial distribution; (3) the possible resident/transient status of dolphins that use this study area; (4) the home range and core area usage patterns of identified dolphins; (5) social structure of identified residents including group size and composition (Defran 2003). In order to accomplish these goals, CDAD surveys implement standardized photo-ID survey routes completed once or twice per month within the SRE, CST, and CHS as well as within sections of the Ashley, Cooper and Wando Rivers. Further, advanced technology data collection (*e.g.*, digital photography) and analysis protocols, which are centered around the digital image and spatial functionality of *FinBase*, promise to significantly enhance the resolution and power of our understanding of Charleston area bottlenose dolphins.
