Forage fish bycatch has been a minimal component of the commercial fisheries, remaining under 75 mt in the BSAI and under 130 mt in the GOA, although in 2001, bycatch exceeded 500 mt in the GOA. Osmerids (smelts) make up the largest portion of the bycatch and tend to be caught in the pollock fishery in both the BSAI and GOA. While it is not known what percentage these values are of their actual biomasses in the BSAI or GOA, this bycatch amount probably has little effect on the reproducibility of each species, nor does it represent significant competition with other apex predators (marine mammals, birds, and other fish).

It is inferred that past JV and domestic fisheries had forage fish bycatch rates that are proportionally similar to the current domestic fisheries. It is likely that effects on the populations have occurred; however, magnitude of the effects is unknown due to the lack of pertinent bycatch information.

Recent changes in predator abundance and significant declines in seabirds (and marine mammals) in the BSAI and GOA have raised concerns that a decrease in the forage fish biomass may contribute to the further decline of seabird, marine mammal, and commercially important fish populations. The previous regulatory regime allowed for the retention of forage fish under the other species category TAC or as a non-specified species, but there was no measure in place to prevent the development of a directed fishery.

In April 1997, NPFMC adopted Amendment 36 to the BSAI FMP and Amendment 39 to the GOA FMP to prevent the development of commercial fisheries for forage fish. NOAA Fisheries published the final rule implementing the regulations on March 17, 1998 (63 FR 13009). Amendments 36/39 defined a forage fish species category and prevented the development of a commercial directed fishery for forage fish. The amendment established a 2 percent MRB amount in other directed fisheries and prohibited the selling, bartering, trading, or receiving any other remuneration for forage fish species. However, within the 2 percent limit, forage fish could be reduced to fish meal and sold.

While NPFMC considered options that would have put forage fish in the other species category or the prohibited species category, the alternative chosen was more effective in that it explicitly prohibited a directed fishery and the sale and barter of forage fish. The amendment also reduced waste by allowing retention (up to the 2 percent MRB amount) and processing (into fishmeal) of those forage fish caught incidentally in groundfish fisheries.

This action is appropriately precautionary and proactive to protect these ecologically important species from the development of target fisheries. However, protection from overfishing and maintenance of healthy stocks for species in this category might be better achieved if limits were set on total catch of these species in addition to MRB rates. These limits are difficult to set at present because biomass estimates are lacking for most of these species.

Change in Reproductive Success

External Foreign Groundfish Fisheries (pre-MSA)

Forage fish are a large prey item of several target species, removal of these predators by the fisheries could potentially have had a beneficial population level effect on forage fish abundance, favoring forage fish recruitment. However, the magnitude of these potential benefits are unknown.

External Climate Changes and Regime Shifts

Some evidence exists that osmerid abundance (see below for life history and distribution information), particularly capelin and eulachon, have significantly declined since the mid-1970s. Evidence for this comes from marine mammal food habits data from the GOA (Calkins and Goodwin 1988), as well as from data collected in GOA biological surveys not designed to sample capelin (Anderson *et al.* 1997) and EBS commercial fisheries bycatch (Fritz *et al.* 1993). It is not known, however, whether smelt abundance has declined or whether the populations have redistributed vertically, presumably due to warming surface waters in the region beginning in the late 1970s. This conclusion could also be drawn from the data presented by Yang (1993), who documented considerable consumption of capelin by arrowtooth flounder, a demersal lower-water-column feeder, in the GOA.

Research by Brodeur *et al.* (1999) has shown some spatial separation of some forage fish species and some changes in distribution in a cold versus warm year. Capelin were associated with colder temperatures in the northen part of the Bering Sea, while age-0 pollock were associated with warmer temperatures than the overall measured temperature. Eulachon were found only in the warmer temperatures at the southernmost part of the sampling area. Although this study did not find any long-term trends in forage fish abundance in the Bering Sea, the study period began in 1982, which is generally considered to be a warmer period in the Bering Sea. Analysis of 36 years of Russian pelagic trawl data indicates different periods of fish abundance, depending on environmental conditions. In the western Bering Sea and Okhotsk Sea, herring and capelin appear to alternate in abundance with pollock. Such a pattern has not been definitively identified for the EBS.

Internal JV and Domestic Fisheries (post-MSA)

Forage fish are a large prey item of several target species; removal of these predators by the fisheries could potentially have a beneficial population level effect on forage fish abundance, favoring forage fish recruitment. However, the magnitude of these potential benefits are unknown.

Change in Prey Availability

External Climate Changes and Regime Shifts

The effects of climate changes and regime shifts are identified as potentially beneficial or adverse on prey availability. For example, when the Aleutian Low is strong, water temperatures are higher, and biomass in the catches is dominated by cod, pollock and flatfishes. Community structure in nearshore areas around Kodiak Island changes in this same period with decreasing populations of shrimps and small forage fish, and increasing populations of large, fish-eating species, such as Pacific cod, and flatfishes (see Section 3.10.1.5). Since both ENSO and decadal-scale ecosystem shifts are environmentally controlled, the results of this analysis support environmental variance as an important controlling factor for the population (see Section 3.10.1.5).

Change in Important Habitat

External Foreign Groundfish Fisheries (pre-MSA)

See Sections 3.5.1.1 and 3.5.1.13 (past/present effects analysis: change in important habitat) for statistics on the number of bottom trawls occurring in these areas, and also see Section 3.6.4 for a discussion of the potential impacts of fishery gear on habitat. The specific effects of foreign fishery gear on forage fish habitat are unknown.

External Climate Changes and Regime Shifts

The effects of climate changes and regime shifts are identified as potentially beneficial or adverse on habitat suitability and prey availability. For example, when the Aleutian Low is strong, water temperatures are higher, and biomass in the catches is dominated by cod, pollock and flatfishes. Community structure in nearshore areas around Kodiak Island changes in this same period with decreasing populations of shrimps and small forage fish, and increasing populations of large, fish-eating species, such as Pacific cod, and flatfishes (see Section 3.10.1.5). Since both ENSO and decadal-scale ecosystem shifts are environmentally controlled, the results of this analysis support environmental variance as an important controlling factor for the population (see Section 3.10.1.5).

Internal JV and Domestic Groundfish Fisheries (post-MSA)

See Sections 3.5.1.1 and 3.5.1.13 (past/present effects analysis: change in important habitat) for statistics on the number of bottom trawls occurring in these areas, and also see Section 3.6.4 for a discussion of the potential impacts of fishery gear on habitat. The specific effects of JV and domestic fishing gear on forage fish habitat are unknown. However, trawling efforts in forage fish habitat have been reduced in recent years due to Steller sea lion habitat conservation measures.

BSAI and GOA Forage Fish Comparative Baseline

Most of the fisheries catch is composed of target species, which are rigorously managed under an elaborate system of data collection, inseason management, and stock assessment. The management emphasis on target species, though arguably justified given the observed catch composition, leaves little time and resources for the management of non-target species. Historically, non-target species have been given relatively low priority in both fishery-dependent and fishery-independent data collection programs because of limitations on management resources. Although this has changed in recent years in the North Pacific, data limitation remains the primary assessment and management problem for most non-target species in the forage species, other species, and non-specified species categories (see Appendix B for more information on methods used to assess non-target species).

BSAI and GOA Forage Fish Cumulative Effects Status

The following sections describe the life history, distribution and baseline information for each forage species group where information is available. However, forage fish are only assessed as a group, not as the separate species groups in the past/present effects as discussed above and in the cumulative effects analysis of Chapter 4.

3.5.4.1 Osmeridae

Life History and Distribution

Smelts (capelin, rainbow smelt, and eulachon, family Osmeridae) are slender schooling fishes that can be either marine, such as capelin (*Mallotus villasus*) or anadromous, such as rainbow smelt (*Osmerus mordax dentex*) and eulachon (*Thaleichthys pacificus*). Figure 3.5-32 shows a generalized distribution of these three smelt species in the south EBS based on data collected by NOAA Fisheries summer groundfish trawl surveys and by fisheries observers.

Capelin

Capelin are distributed along the entire coastline of Alaska and south along British Columbia to the Strait of Juan de Fuca. In the North Pacific Ocean, capelin can grow to a maximum of 25 cm at age-4. Most capelin spawn at age-2 or -3, when they are only 11 to 17 cm (Pahlke 1985). Spawning occurs in spring in intertidal zones of coarse sand and fine gravel, especially in Norton Sound, northern Bristol Bay, and around Kodiak Island. Very few capelin survive spawning. The age of maturity of capelin in the Barents Sea has been shown to be a function of growth rate, with fast-growing cohorts reaching maturity at an earlier age than slow-growing cohorts. Thus, it is possible to have slow- and fast-growing cohorts mature in the same year, resulting in large spawning biomasses one year preceded and potentially followed by small spawning biomasses.

In the Bering Sea, adult capelin are only found nearshore during the months surrounding the spawning run. During other times of the year, capelin are found far offshore in the vicinity of the Pribilof Islands and the continental shelf break. The seasonal migration may be associated with the advancing and retreating polar ice front, as it is in the Barents Sea. In the EBS, winter ice completely withdraws during the summer months. If migration follows the ice edge, the bulk of the capelin biomass in the Bering Sea could be located in the northern Bering Sea, beyond the area worked by the groundfish fisheries and surveys. Very few capelin are found in surveys, yet they are a major component of the diets of marine mammals feeding along the winter ice edge (Wespestad 1987), and of marine birds, especially in the spring. In the GOA, which remains ice-free year-round, capelin overwinter in the bays of Kodiak Island and in Kachemak Bay.

Rainbow smelt

Rainbow smelt ascend rivers to spawn in spring shortly after the ice breakup. After spawning, they return to the sea to feed. Surveys have found concentrations of rainbow smelt off Kuskokwim Bay, Togiak Bay, and Port Heiden (Figure 3.5-32), but they also probably occur near many river mouths. Rainbow smelt mature at ages 2 or 3 (19 to 23 cm), but can live to be as old as 9 years and as large as 30 cm. Little is known about abundance trends of this species.

Eulachon

Eulachon also spawn in spring in rivers of the Alaska Peninsula, and possibly other rivers draining into the south EBS. Eulachon live to age-5 and grow to 25 cm, but most die following their first spawning at age-3. Eulachon are consistently found by groundfish fisheries and surveys between Unimak Island and the Pribilof Islands in the Bering Sea (Figure 3.5-32), and in Shelikof Strait in the GOA.

Trophic Interactions

Capelin

The diet of capelin in the North Pacific Ocean, as summarized by Hart (1973) and Trumble (1973), is primarily planktivorous. Small crustaceans such as euphausiids and copepods are common to the diet of capelin, although marine worms and small fish are also part of their diet. In the Bering Sea, adult capelin consume copepods, mysids, euphausiids, and chaetognaths. Juveniles primarily consume copepods (Naumenko 1984). The largest capelin (over 13 cm) consume euphausiids nearly exclusively. Capelin feed throughout the year in the Bering Sea. However, the diet exhibits seasonal variation that is due in part to spawning migration and behavior.

Eulachon

The diet of eulachon in the North Pacific Ocean generally consists of planktonic prey (Hart 1973, Macy *et al.* 1978). As larvae they primarily consume copepod larvae; post-larvae consume a wider variety of prey, including phytoplankton, copepod eggs, copepods, mysids, ostracods, barnacle larvae, cladocerans worm larvae, and larval eulachon. Juvenile and adult eulachon feed almost exclusively on euphausiids, with copepods and cumaceans occasionally in the diet.

The primarily planktivorous diets of eulachon, sand lance, and capelin reduce the potential for dietary competition with the piscivorus and benthic diets of most groundfish. However, the potential for dietary competition is greater between pollock and osmerids due to the importance of planktonic prey, such as euphausiid and copepod in their diets.

BSAI Osmeridae Comparative Analysis

Smelts make up the majority of the forage fish bycatch. Catches tend to be more erratic in the GOA; ranging from 23.1 to 534.8 mt per year from 1997 to 2001. In the BSAI, total bycatch ranges from 29.8 to 80.1 mt from 1997 to 2000. Smelt bycatch drastically increased in 2001in both the BSAI and GOA regions (Mark Nelson, personal communication, 22 January 2003). The cause of this increase is unknown at this time.

In the BSAI, the majority (64 percent - 94 percent) of the smelt bycatch occurs in the pollock fishery. Most of the remainder of the bycatch occurs in various flatfish fisheries. In the GOA, smelt bycatch is almost exclusively (92 percent to >99 percent) attributed to the pollock fishery.

GOA Osmeridae Comparative Baseline

Capelin

Capelin have shown abrupt declines in occurrence in small-mesh trawl survey samples in the GOA (Piatt and Anderson 1996, Anderson and Piatt 1999). In both NOAA Fisheries and ADF&G survey data, capelin first declined along the east side of Kodiak Island and bays along the Alaska Peninsula. Subsequent declines took place in the bays along the west side of Shelikof Strait. These declines happened quickly, and low abundance has persisted for over a decade. The decline was coincident with increases in water temperature of the order of 2°C, which began in the late 1970s. Capelin have fairly narrow temperature preferences and probably were very susceptible to the increase in water column temperatures (Piatt and Anderson 1996, Anderson *et al.* 1997). Mapping of relative densities of capelin showed defined areas of relative high abundance. The Shelikof Strait region showed relatively high catches in Kujulik, Alitak, and Olga bays. Most catches of capelin were closely associated with bays, except for high catches offshore of Cape Ikolik at the southwest end of Kodiak Island. Isolated offshore areas east of Kodiak Island showed some high catches, with most of the high catches associated with Ugak and Kazakof Bays. Only isolated catches of less than 50 kg were evident in the database from PWS, the Kenai Peninsula, and lower Cook Inlet.

Eulachon

Evidence from fishery observer and survey data suggests that eulachon abundance declined in the 1980s (Fritz *et al.* 1993). These data should be interpreted with caution because surveys were not designed to sample small pelagic fishes such as eulachon, and fishery data were collected primarily to estimate total catch of target groundfish. Causes of the decline, if real, are unknown, but may be related to variability in year-class strength, as noted for capelin. Small-mesh shrimp trawl surveys in the GOA coastal areas suggest that eulachon has remained at a low level of relative abundance since 1987. Eulachon are currently at the lowest recorded level in the survey series (1972 to 1997) at 0.01 kg/km (Anderson and Piatt 1999).

3.5.4.2 Myctophidae

Life History and Distribution

Lantern fishes (family Myctophidae) are distributed pelagically in the deep sea throughout the world's oceans. Most species in this family occur at depth during the day and migrate to near the surface to feed (and be fed upon) at night. A common myctophid in the Bering Sea and GOA is the northern lampfish (*Stenobrachius leucopsarus*), which has a maximum length of approximately 13 cm. Lanternfish are important forage fishes for marine birds and mammals.

Trophic Interactions

Because of their large mouth, relatively sparse and denticulate gill rakers, well-developed stomach, and short intestine, lantern fishes mostly consume actively swimming animals such as copepods and euphausiids (Balanov *et al.* 1995).

BSAI and GOA Myctophidae Comparative Baseline

Because they are rarely caught in survey or fishery trawls, nothing is known of recent trends in Myctophidae abundance. Lanternfish make a minor portion of the BSAI and GOA forage fish bycatch (Nelson 2002), less than half a metric ton between 1997-2001.

3.5.4.3 Bathylagidae

Life History and Distribution

Deep-sea smelts (family Bathylagidae) are distributed pelagically in the deep sea throughout the world's oceans. Most species in this family occur at depth during the day and migrate to near the surface to feed (and be fed upon) at night. Deep-sea smelt of the North Pacific Ocean include blacksmelt (*Bathylagus* spp.) and northern smoothtongue (*Leuroglossus stilbius schmidti*), each of which has maximum length of 12 to 25 cm. Deep-sea smelt are important forage fishes for marine birds and mammals.

Trophic Interactions

Because deep-sea smelts have a small mouth, dense flat gill rakers, a small stomach, and long intestine, they consume weak-swimming, soft-bodied animals such as pteropods, appendicularia, ctenophores, chaetognaths, polychaetes, and jellyfishes. Deep-sea smelts in the epipelagic zone can also feed on euphausiids and copepods at night when they are abundant (Balanov *et al.* 1995, Gorelova and Kobylyanskiy 1985).

BSAI and GOA Bathylagidae Comparative Baseline

Because they are rarely caught in survey or fishery trawls, nothing is known of recent trends in Bathylagidae abundance.

3.5.4.4 Ammodytidae

Life History and Distribution

Pacific sandlance (*Ammodytes hexapterus*, family Ammodytidae) are usually found on the sea bottom, at depths between 0 and 100 m except when feeding (pelagically) on crustaceans and zooplankton. Spawning is believed to occur in winter. Sand lance mature at 2 to 3 years and lengths of 10 to 15 cm. Little is known of their distribution and abundance; they are rarely caught by trawls. Given the sand lance's short life span, and the large number of species that prey on it, mortality, fecundity, and growth rates are probably high.

Sand lance in the Kodiak Island region undergo an extensive migration that is counter to the normal pattern found with many inshore species. Spawning takes place in the late fall and winter, and usually is completed in January. Hatching of larvae continues over an extended time, until March and perhaps April (Blackburn *et al.* 1983, Blackburn and Anderson 1997), and some larval fish may spend up to several months in beach sediments. Newly hatched larval sand lance and adults start migrating offshore in the early spring and spend some time in offshore bank areas, where they can often be abundant (Clemens and Wilby 1961). Offshore ichthyoplankton surveys in the GOA indicated high larval abundance, first appearing in early March and remaining high until early July, but then disappearing. In the late summer, massive schools of fish start migrating inshore to suitable beach habitat for spawning and overwintering. These inshore migrating schools provide important forage for species such as offshore migrating seabirds during late summer and early fall. Hence, sand lance are among one of the few fish that migrate inshore during the late summer months to overwinter near-shore while most other fish migrate offshore prior to winter months.

Trophic Interactions

Hart (1973) and Trumble (1973) summarized the diet of sand lance in the North Pacific Ocean as primarily planktivorous, their primary prey changing with ontogeny. Larval sand lance consume diatoms (microscopic one-celled or colonial algae) and dinoflagellates (photosynthetic marine organisms); post-larvae prey upon copepods and copepod nauplii. More recent information on the food habits of age-0 and age-1 sand lance shows a dominance of calanoid copepods in the diet, with barnacle nauplii, larvaceans, and shrimp larvae as other important prey (Blackburn and Anderson 1997). Adult sand lance prey upon chaetognaths, fish larvae, amphipods, annelids, and common copepods. Sand lance exhibit seasonal and diurnal variation in feeding activity and are opportunistic feeders upon abundant plankton blooms.

In the Bering Sea, sand lance are common prey of salmon, northern fur seals, and many marine bird species. Thus, they may be abundant in Bristol Bay and along the Aleutian Islands and Alaska Peninsula. In the GOA, sand lance are prey of harbor seals, northern fur seals, and marine birds, especially in the Kodiak Island area and along the southern Alaska Peninsula.

BSAI and GOA Ammodytidae Comparative Baseline

Little is known about the historical abundance of Pacific sandlance in the BSAI or GOA. Sandlance are not effectively sampled in current NOAA Fisheries surveys and make a very minor portion of the forage fish bycatch (Nelson 2002).

3.5.4.5 Trichodontidae

Life History and Distribution

The Pacific sandfish (*Trichodon trichodon*, family Trichodontidae) lives in shallow inshore waters to about 50 m depth and grows to a maximum length of 30 cm. Some evidence shows sandfish exhibit burrowing behavior in which they bury themselves in the sand and come to rest with only their dorsal surface showing. Nothing is known of trends in their abundance.

Trophic Interactions

In the EBS, the diet of Pacific sandfish is primarily (95 percent by weight) fish, especially gadids (Brodeur and Livingston 1988). They are fed upon by salmon and other fish, as well as pinnipeds.

In the GOA, the diet of sandfish consists of small crustaceans such as mysids, amphipods, and cumaceans (Kenyon 1956, Mineva 1955). More recent information from the GOA shows that sandfish consume sand lance, several types of shrimp, crab larvae, cumaceans, and polychaetes (Paul *et al.* 1997). They are fed upon by salmon and other fish, as well as pinnipeds.

BSAI and GOA Trichodontidae Comparative Baseline

Pacific sandfish make up the second largest portion of the forage fish bycatch, after smelts; however, they are still lightly exploited in both the BSAI and GOA, generally ranging between 0.4 and 3.7 mt in recent years (Mark Nelson, personal communication, 22 January 2003). In 2000 the catch in the BSAI reached a peak of 20.3 mt. This unusually high bycatch came primarily from the flathead sole fishery (14.3 mt). At this time, the cause of this anomalous catch is unknown.

3.5.4.6 Pholidae

Life History and Distribution

Gunnels (family Pholidae) are long, compressed, eel-like fishes with long dorsal fins often joined with the caudal fin. Gunnels have flexible dorsal fin rays; they differ from pricklebacks in that the anal fin is smaller (the distance from the tip of the snout to the front of the anal fin is shorter than the length of the anal fin). Most species in this family live in shallow nearshore waters among seaweed and under rocks and are mostly less than 45 cm in length. Approximately 5 species of pholids occur in Alaska. Nothing is known about their abundance, and little is known about growth rates, maturity, and trophic relationships, although they are believed to grow quickly.

Trophic Interactions

The diets of gunnels (family Pholidae) consist primarily of benthic and epibenthic prey. Amphipods, isopods, polychaete worms, harpacticoid copepods, cumaceans, munid crabs, insects, mysids, algae, ostracods, bivalves, crustacean larvae, and tunicates have been described as their main prey (Simenstad *et al.* 1979, Williams 1994). Juvenile fish prey (English sole, *Parophry vetulus*, and sand lance, *Ammodytes hexapterus*) have also been described as infrequent components of its diet in Puget Sound, Washington (Simenstad *et al.* 1977).

Pholids (saddleback gunnel) were found in Pacific cod stomachs in the Aleutian Islands, but their contribution was less than one percent by weight of the total stomach content. Pholids were not found as a significant portion of the diets of EBS shelf or slope groundfish. Pholids are probably not important prey of the GOA groundfish area because they were not found in a study of groundfish diets in that area (Yang 1993).

BSAI and GOA Pholidae Comparative Baseline

Gunnels make up a very minor portion of the forage fish bycatch in the BSAI and GOA (Nelson 2002).

3.5.4.7 Stichaeidae

Life History and Distribution

Pricklebacks (family Stichaeidae, including warbonnets, eelblennys, cockscombs and shannys) are long, compressed, eel-like fishes with long dorsal fins often joined with the caudal fin. Pricklebacks are so named because of the spiny rays in the dorsal fin in most species (some have soft rays at the rear of the dorsal fins). Most species of this family live in shallow nearshore waters among seaweed and under rocks and are mostly less than 45 cm in length. Approximately 14 species of stichaeids occur in Alaska. Nothing is known about their abundance, and little is known about growth rates, maturity, and trophic relationships, although they are believed to grow quickly. Some cockscombs in British Columbia attain sexual maturity at age-2 years.

Trophic Interactions

The longsnout prickleback (*Lumpenella longirostris*) eats copepods almost exclusively (Barraclough 1967). Young ribbon pricklebacks (*Phytichthys chirus*) eat copepods and oikopleura (Robinson *et al.* 1968). The food of the adults of this species includes crustaceans and red and green algae. Black pricklebacks (*Xiphister atropurpureus*) consume copepods, copepod nauplii, and clam larvae (Barraclough *et al.* 1968). It has also been reported that an important food of high cockscomb (*Anoplarchus purpurescens*) is green algae. Other food of this species include polychaete worms, amphipods, mollusks, and crustaceans.

Stichaeids represent a minimal portion of the diets of several groundfish species in the EBS shelf region. Pacific cod (Livingston 1991b), arrowtooth flounder (Yang 1996), and flathead sole (Pacunski 1991) consume unidentified stichaeids as less than one percent of their diets by weight. Greenland turbot consume a combination of unidentified stichaeids and daubed shanny (*Lumpenus maculatus*) as a small portion (less than one percent) of their diet. Stichaeids represent a small portion (less than one percent by weight) of the diet of Pacific cod, arrowtooth flounder, and Greenland turbot in the EBS slope region (Lang and Livingston 1996). Yang (1996) studied the diets of groundfish in the Aleutian Islands and found that stichaeids comprised 2 percent of the stomach contents weight of arrowtooth flounder. Stichaeids comprised less than one percent of the diets of Pacific cod, walleye pollock, and Atka mackerel.

Yang (1993) also studied the diets of the groundfish in the GOA during summer and found that stichaeids comprised about one percent of the stomach content weight of arrowtooth flounder, Pacific cod, and walleye pollock, respectively. Pacific halibut, sablefish, and Pacific ocean perch also consumed stichaeids, but their contribution to the diets was small less than one percent).

BSAI and GOA Stichaeidae Comparative Baseline

Pricklebacks make up a minor portion of the BSAI and GOA forage fish bycatch (Nelson 2002), ranging between 0 and 0.4 mt in the BSAI from 1997-2001, and 0 and 4.7 mt in the GOA for the same period (Mark Nelson, personal communication, 22 January 2003).

3.5.4.8 Gonostomatidae

Life History and Distribution

This is a large and diverse family (Gonostomatidae) of small (to about 8 cm), mesopelagic and bathypelagic fish that are rarely observed except by researchers. They can be abundant at depths of up to 5,000 m. As many as six species may occur in the North Pacific Ocean and Bering Sea. Bristleworms, lightfishes, and anglemouths have large gill openings and well-developed gill rakers, characteristics of zooplankton feeders.

Trophic Interactions

The primary zooplankton prey of gonostomatids are calanoid copepods. Other food includes ostracods and euphausiids. Some larger gonostomatids also consume some fish (Gorelova 1980).

Gonostomatids were not found to be a significant portion of the diets of EBS shelf or slope groundfish (Livingston and deReynier 1996). However, they were found in pollock stomachs in the Aleutian Islands, but contributed less than one percent by weight of the total stomach content (Yang 1996). Gonostomatids are probably not important prey of GOA groundfish because they were not found in a study of groundfish diets in that area (Yang 1993).

BSAI and GOA Gonostomatidae Comparative Baseline

Members of the Gonostomatidae family are found in mesopelagic waters around the world. Due to their distribution and scope of their habitat members of the genus *Cyclothone* are thought to be the most abundant fish in the world (Moyle and Cech 1988). Nothing is known about the abundance of these fish in the BSAI or GOA region.

3.5.4.9 Euphausiacea

Life History and Distribution

Along with many copepod species, the euphausiids (*Euphausiacea*) form a critical zooplanktonic link between the primary producers (phytoplankton) and all upper pelagic trophic levels. These crustaceans, also known as krill, occur in large swarms in both neritic (nearshore) and oceanic (offshore) waters. Members of at least 11 genera of euphausiids are known from the North Pacific Ocean, the most important (in terms of numbers of species) being *Thysanopoda, Euphausia, Thysanoëssa,* and *Stylocheiron* (Boden *et al.* 1955, Ponomareva 1963).

Euphausiids are generally thought to make diurnal vertical migrations, remaining at depth (usually below 500 m) during the day and ascending at night to 100 m or less to feed. However, this is complicated by the fact that as euphausiids grow they are found at deeper depths, except during spawning, which occurs in surface waters.

Spawning occurs in spring to take advantage of the spring phytoplankton bloom, and the hatched nauplii larvae live near the surface (down to about 25 m). By fall and winter, the young crustaceans are found mainly at depths of 100 m or less, and make diurnal vertical migrations. Sexual maturity is reached the following spring at age-1. After spawning, adult euphausiids gradually descend to deeper depths until fall and winter, when they no longer migrate daily to near-surface waters. In their second spring, they again rise to the surface to spawn; euphausiids older than 2 years are very rarely found. This classical view of euphausiid life history and longevity was recently questioned by Nichol (1990), who reported that Antarctic euphausiids may live as long as 6 to 10 years; annual euphausiid production, then, would be much lower than if they lived only 2 years.

While euphausiids are found throughout oceanic and neritic waters, their swarms are most commonly encountered in areas where nutrients are available for phytoplankton growth. This occurs primarily in areas where upwelling of waters from depths into the surface region is a consistent oceanographic feature. Areas with such features are at the edges of the various domains on the shelf or at the shelf-break, at the heads of submarine canyons, on the edges of gullies on the continental shelf (e.g., Shumagin, Barnabus, Shelikof gullies in the GOA), in island passes (on certain tides) in the Aleutian Islands (e.g., Seguam Pass, Tanaga Pass), and around submerged seamounts (e.g., west of Kiska Island). It is no coincidence that these are also prime fishing locations used by commercial fishing vessels seeking zooplanktivorous groundfish, such as pollock, Atka mackerel, sablefish, and many rockfish and flatfish species (Fritz *et al.* 1993, Livingston and Goiney 1983, Yang 1993).

Trophic Interactions

The species comprising the euphausiid group occupy a position of considerable importance within the North Pacific Ocean food web. Euphausiids are eaten by almost all other major taxa inhabiting the pelagic realm. The diet of many fish species other than the groundfish listed previously, including salmon, smelt (capelin, eulachon, and other osmerids), gadids such as Arctic cod and Pacific tomcod, and Pacific herring, is composed, to varying degrees, of euphausiids (Livingston and Goiney 1983). They are also the principal item in the diet of most baleen whales (e.g., minke, fin, sei, humpback, northern right, and bowhead whales) (Perez 1990). While copepods generally constitute the major portion of the diet of planktivorous birds (e.g., auklets), euphausiids are prominent in the diets of some predominantly piscivorus birds in certain areas (e.g., kittiwakes on Buldir Island in the Aleutian Islands, Middleton Island in the GOA, and Saint Matthew Island in the Bering Sea) (Hatch *et al.* 1990). Euphausiids are not currently sought for human use or consumption from the North Pacific Ocean on a scale other than local, but large (about 500,000 mt per year) krill fisheries from Japan and Russia have been operating in Antarctic waters since the early 1980s (Swartzman and Hofman 1991).

The diets of euphausiids in the North Pacific Ocean consist of planktonic prey. Species of the genus *Euphausia* consume diatoms, dinoflagellates, tintinnids, chaetognaths, echinoderm larvae, amphipods, crustacean larvae, ommatidians, and detritus (Mauchline 1980). Species of the genus *Thysanoessa* consume diatoms, dinoflagellates, tintinnids, radiolarians, foraminiferans, chaetognaths, echinoderm larvae, mollusks, crustacean larvae, ommatidians and detritus (Mauchline 1980). In the GOA, several species of *Thysanoessa* also consume walleye pollock eggs (Brodeur and Merati 1993).

Euphausiids represent a significant portion of the diet of walleye pollock in the EBS shelf region (Livingston 1991a). Euphausiids represent as much as 70 percent of the diet in the winter and spring and are generally more important to larger pollock than smaller ones. Euphausiids are also the primary prey of small (less than 35 cm) Greenland turbot in the EBS shelf, but are of little importance to larger fish (Livingston and deReynier 1996). Small (less than 35 cm) arrowtooth flounder also consume euphausiids as a large (50 percent by weight) portion of their diet; euphausiids are of little importance to the larger ones (Livingston and deReynier 1996). Euphausiids were not found to be a significant diet component of any other EBS shelf groundfish. In the EBS slope region, euphausiids were found in the diets of several groundfish species. They represent 26 percent of the overall diet by weight of walleye pollock, but are more important by season (80 percent by weight in winter) and to smaller fish (less than 50 cm) fish (Lang and Livingston 1996). Euphausiids also play a small role (less than one percent by weight) in the diets of Pacific cod, flathead sole, and arrowtooth flounder (Lang and Livingston 1996). In the Aleutian Islands, euphausiids also comprised 43, 55, 51, and 50 percent of the stomach contents of walleye pollock, Atka mackerel, Pacific ocean perch, and northern rockfish, respectively. Euphausiids were also in the diets of arrowtooth flounder (5 percent), rougheye rockfish (2 percent), shortspine thornyhead (1 percent), and shortraker rockfish (1 percent) in the Aleutian Islands (Yang 1996).

Euphausiids are an important food item of many groundfish species in the GOA and Aleutian Islands. Yang (1993) showed that the diets of plankton-feeding groundfish in the GOA, such as dusky rockfish, Pacific ocean perch, and northern rockfish had large percentages (more than 65 percent) of euphausiids. Euphausiids also comprised 39 percent of the diet of walleye pollock in the GOA.

BSAI and GOA Euphausiacea Comparative Baseline

There are no current data available on the abundance of Euphausiacea in the BSAI or GOA.

3.5.5 Non-Specified Species

The non-specified species category contains a huge diversity of species, including invertebrates, that are not defined in the FMP as target, other, forage, or prohibited species, except for animals protected under the MMPA or the ESA. There is currently no management or monitoring of any species in this category, and the retention of any non-specified species is permitted. No reporting is required for non-specified species, and there are no catch limitations or stock assessments. Most of these animals are not currently considered commercially important and are not targeted or retained in groundfish fisheries.

The complete lack of reporting requirements may be problematic because it allows a species to slip through the system unnoticed. For example, bycatch of grenadiers, a non-specified species group, is higher in the GOA than the catch of all species in the other species category combined (Gaichas *et al.* 1999), and yet bycatch of grenadiers is not regulated. The current non-management of grenadiers could mask declines in individual grenadier species and therefore, lead to overfishing of a given grenadier species. Grenadiers are long-lived species (e.g., Andrews *et al.* 1999) that may be extremely vulnerable to and slower to recover from heavy fishing pressure, similar to rockfish and elasmobranch populations. Information and scientific data regarding the grenadier are very minimal in comparison to other species such as halibut. Due to the lack of information on other species within the non-specified category, grenadier is the only species that will be discussed in this document.

3.5.5.1 Grenadier

Life History and Distribution

Grenadiers (family Macrouridae) are deep-sea fishes that are related to hakes and cods. They have large heads and elongated bodies that taper to a thin pointed tail. Grenadiers are found throughout the North Pacific as far east as the Okhotsk Sea near Japan, north to the Bering Sea and down the west coast of the U.S. to Mexico. There are at least three common species in the BSAI and GOA: the giant grenadier (*Albatrossia pectoralis*) (Figure 3.5-33), the Pacific grenadier (*Coryphaenoides acrolepis*), and the popeye grenadier (*Coryphaenoides cinereus*). An additional eight species from the Pacific Ocean are known, and may be present in the North Pacific. Grenadiers dominate the fish fauna of continental slopes worldwide and may be pelagic or demersal, but are found only in deep waters (Eschmeyer *et al.* 1984).

The grenadiers found in the GOA are very long-lived animals, despite the fact that some do not grow large. The maximum reported age for the giant grenadier is 56 years, and for the Pacific grenadier is 73 years. Giant grenadiers are appropriately named, as they are the largest of all macrourid species. They are usually found between 140 and 1,740 m deep. According to research in Russian waters, giant grenadiers form sex-specific aggregations, with females found in shallower water than males, and they migrate seasonally between shallower and deeper waters according to the timing of ovarian maturation and spawning (Novikov 1970, as referenced in Burton 1999). Giant grenadiers are oviparous, with a planktonic larval stage (Ambrose 1996). The giant grenadier has a pelagic juvenile stage, with settlement to benthic habitats thought to coincide with the onset of maturity (Noikov 1970). This life history strategy may protect immature giant grenadiers from fishing pressure (Burton 1999).

Pacific grenadiers are approximately one-half the size of the giant grenadiers. They are a benthopelagic mid-slope species, usually found in a depth range of 155 to 2500 m, that may wander off slope bottoms into midwater (Ambrose 1996). Pacific grenadier are oviparous, with a planktonic larval stage (Ambrose 1996). According to research near the Oregon and California coasts, spawning depth is not known. Larval stages, however, have been captured in the water column in waters less than 200 m, while older larvae and juveniles are known to occur deeper. Pacific grenadier of the northeast Pacific ocean appear to be a relatively sedentary species, as no migrations have been documented. Iwamoto and Stein (1974) noted that larger Pacific grenadier are found in deeper water off the coast of Oregon, suggesting that the species may move to deep water as they grow.

Popeye grenadier are a benthopelagic species, usually found between 225 and 2,832 m in depth, whose size is approximately two-thirds that of the Pacific grenadier. Because there are no current age and growth information for the popeye grenadier, it is assumed that it has a lifespan similar to the giant grenadier, based on preliminary information (J. Hoff, AFSC, personal communication). Grenadiers dominate the biomass in many deep-sea habitats and are suspected to play an important ecological role in energy transfer, either as pelagic predators, benthic predators, and/or as scavengers on detritus. There is much to learn about grenadier ecology.

Grenadier life history is summarized in Table 3.5-66. There are no distribution maps to date for the grenadier, but there are documented harvest areas for the sablefish, a species with which grenadier bycatch is primarily associated in the GOA (see discussions following). Since the two species share similar habitats and ranges (bathydemersal, deep water, GOA) it can be inferred that the distribution of grenadiers in the GOA would mimic the distribution of sablefish in the harvest area map from the east Yakutat area to the western GOA area (Figure 3.5-34).

Trophic Interactions

Grenadiers that inhabit the upper continental slope generally prey on locally abundant fish and invertebrates and scavenge for carcasses (Okamura 1970, Pearcy and Ambler 1974, Drazen *et al.* In press). The popeye grenadier is the most numerically abundant grenadier in this region (Bohle 1988), and it likely has this type of feeding strategy. The giant grenadier feeds on myctophids, squid, and a variety of benthic and mesopelagic animals in the EBS (Novikov 1970): eelpouts, other fish, and shrimp were identified as its dominant prey from samples taken in the 1980s (Brodeur and Livingston 1988). Pacific grenadier feed on small fish, euphuasiids, prawns, amphipods and cephalopods (Cohen *et al.* 1990). Cannibalism is not uncommon in Pacific grenadier off the coast of Oregon, according to Stein (1978), and may be responsible for high larval and juvenile mortality.

Predators of the grenadier include sablefish (*Anaplopoma fimbria*) and skates (*Bathyraja maculata*), both bathydemersal fishes like the grenadier.

Grenadier Management

There is currently no management or monitoring of grenadiers in either the BSAI or GOA. This complete lack of reporting requirements and protection within the existing non-specified species category can lead to overexploitation of the species. The Pacific grenadiers may be extremely vulnerable to unregulated fishing due to the species' very low resilience, the minimum population doubling time is more than 14 years (Cohen *et al.* 1990).

The original GOA FMP (1978) included three management categories: target species, prohibited species, and other species. The other species category contained all species that are in the current other species category, plus all that are now in the non-specified species category. Each category, including other species, had a MSY/OY cap. It became clear that the inclusion of grenadiers in the other species category could cause the MSY/OY cap for other species to be reached before foreign fisheries had caught their allocations of target species, because bycatch of grenadiers was high even then. In 1979, GOA FMP Amendment 5 established a separate management category and TAC of 13,200 mt for grenadiers to avoid premature closure of target fisheries due to grenadier bycatch. However, they were moved to the non-specified species FMP category in 1980 (Amendment 8), where they have remained ever since. Within the non-specified species FMP category, there are no requirements for reporting catch of grenadiers, and their catch is not monitored, but retention of grenadiers is permitted. Unfortunately, the highest observed catches of non-target species are within the categories receiving the least intensive management under the status quo: other species and non-specified species.

Right now, grenadiers are taken only as bycatch in fisheries directed at target species; consequently, catches of grenadiers are dependent on the distribution and limitations placed on target fisheries. In deep-water longline fisheries, the catch of non-specified species may approach that of target species, due solely to the bycatch of grenadiers (Table 3.5-67), the species which accounts for the higher proportion of non-target species catch in the GOA (Figure 3.5-35). Only PSCs are limited by status quo management of non-target species. At the November 1999 GOA Plan Team meeting, GOA grenadier catches were reviewed, and there was interest in initiating management for grenadier species, at least as part of the other species category. This action is being considered within the revision of the proposed FMP amendment to change the management of sharks, skates, and the rest of the other species category (NPFMC 1999a).

It was attempted to determine which species were likely to be caught in the fisheries by combining species distribution information from surveys with the observed fishery catch information from 1997 to 1999. In this case, information on depth distribution of grenadier species from surveys separated species more clearly than location of catch, because all three species appear to be distributed all along the GOA slope. This depth distribution information is only useful if the depths are known where fisheries catch grenadiers. Fortunately, there is average depth information available associated with each observed catch location which may indicate which species are caught.

Because observers are not trained to identify individual species of grenadiers, the majority (100 percent in 1997–1998 and 90 percent in 1999) of grenadier catch is reported as "grenadier unidentified." The other 10 percent of grenadier catch from 1999 were identified as giant grenadier, (*A. pectoralis*). All available catch information is summarized for aggregated grenadier species, including annual catch and location of catch. Fishery data were examined from 1997–1999 to determine total grenadier catch, and catch in different gear types and target fisheries (Table 3.5-68), and the location and depth of grenadier catch were observed (see latter test regarding spatial analysis). Unlike skates, grenadiers are almost all killed when caught and brought to the surface from the depths they inhabit.

If all grenadier species are caught in proportion to their estimated biomass in the GOA, then bycatch would remove approximately 3.4 percent of the biomass of each grenadier species. The available information on the maximum age of grenadier species indicates that the natural mortality rate M for each species might be 0.074 for giant grenadier (*Albatrossia pectoralis*) and 0.057 for the Pacific grenadier (*Coryphaenoides acrolepis*). The life history of the popeye grenadier (*C. cinereus*) was assumed to be most similar to the giant grenadier, and M was estimated accordingly at 0.074 for this species. If these estimates are correct for each species, current management Tier 5 criteria for establishing ABC would allow taking up to 5.5 percent of the biomass of giant and popeye grenadiers, and the OFL would be reached if 7.4 percent of the biomass of each species were caught in groundfish fisheries, because OFL = $M \times$ biomass, and ABC is 75 percent of OFL. Similarly, the ABC for Pacific grenadier would be reached when 4.3 percent of biomass was removed by fishing, and the OFL would be reached at 5.7 percent of estimated biomass.

The information available on the depth distribution of fisheries as compared to survey estimates of the depth distribution of grenadier species from the 1999 GOA trawl survey indicates that the fisheries likely catch giant grenadiers much more frequently than any other grenadier species. Therefore, the proportional catch assumption may be reasonable for grenadiers. However, the least common grenadier species according to our surveys, the Pacific grenadier (*C. acrolepis*), is also the longest lived, and, therefore, has the lowest OFL of 5.7 percent of biomass. The proportional catch assumption would mean that 2 percent of the grenadier catch is Pacific grenadiers, but if this proportion increased slightly to only 4 percent of catch, the take of Pacific grenadiers would increase to 6.8 percent of estimated biomass, over what we would establish as an OFL for this species using current management Tier 5 criteria. More extreme assumptions about disproportional catch would, of course, result in even higher estimated rates of fishing mortality relative to OFL for the rarer grenadier species.

If a disproportional catch assumption about the species composition of the grenadier complex catch in the GOA is true, then there would be very different impacts on each grenadier species. The impact on the common species in the complex, the giant grenadier (*Albatrossia pectoralis*), would be non-significant because the catch would not even approach the OFL based on $M = 0.074$. However, the catch of the less common species in the complex, the Pacific grenadier (*Coryphaeniodes acrolepis*), could be at or above the OFL based on current management Tier 5 criteria; therefore, the impact could be significantly adverse for this species. The actual proportion of each species in the catch is unknown, and in this case there is additional uncertainty associated with the biomass of Pacific grenadiers. Unfortunately, even with very good recent biomass data from the GOA, it has been impossible to determine whether Pacific grenadiers are truly rare in the GOA, or if the survey simply did not sample deep enough habitats to fully assess the population size of Pacific grenadiers. Given the longevity of the species and the unregulated nature of grenadier catch in general, the impacts of current management would be conditionally significantly adverse for Pacific grenadiers in the GOA.

Past/Present Effects Analysis

The geographic scope for the grenadier past/present effects analysis includes the Bering Sea, Aleutian Islands, and GOA. The temporal scope for this analysis begins in 1978 when the original GOA FMP was initiated and ends in 2002.

A discussion of the direct/indirect effects, external human controlled and natural events, and internal groundfish fishery events for the past effects analysis is presented in Section 3.1.4 of this Programmatic SEIS, Table 3.5-69 provides a summary of the grenadier past effects analysis presented below. The following direct and indirect effects were identified as potentially having population level effects on grenadiers:

- Mortality due to bycatch (direct effect)
- Reduced recruitment due to spatial/temporal concentration of bycatch (indirect effect)

The following past/present effects determined to be applicable to the grenadier past effects analysis include the following:

- Past/Present External Effects
  - Foreign groundfish fisheries (pre-MSA)
  - State of Alaska groundfish fisheries
- Past/Present Internal Events
  - Foreign groundfish fisheries (post-MSA)
  - JV groundfish fisheries
  - Domestic groundfish fisheries
- Past/Present Management Actions
  - Bilateral agreements
  - Industry initiated actions
  - FMP groundfish fisheries management
  - Lack of information

External Mortality: Bycatch in the pre-MSA Foreign Fisheries

Pre-World War II foreign fisheries were relatively small with an expansion of large scale fishing operations in the post-war period, ultimately leading to increases in the catches of groundfish in the BSAI and GOA. By 1979, grenadier bycatch comprised as much as 66 percent of the total foreign fishery sablefish catch in the GOA and was recognized as a significant bycatch problem (GOA FMP Amendment 5, see Appendix D). By 1985, the JV operations and growing U.S. domestic fleet had entered the scene and continued the harvest of groundfish species.

External Mortality: State of Alaska Groundfish Fisheries

State sablefish fisheries do not keep records of grenadier (ADF&G, personal communication). However, since grenadier bycatch is associated with the federal sablefish fisheries, it is inferred that grenadier bycatch would also be associated with the state sablefish fisheries.

Internal Mortality: Foreign, JV and domestic Groundfish fisheries (post-MSA)

Federal groundfish fisheries have been prosecuted by an all-domestic fleet since 1987 in the GOA and since 1991 in the BSAI. Information is lacking with regard to mortality effects on grenadiers from post-MSA groundfish fisheries. Bycatch of grenadier is primarily associated with the sablefish and Greenland turbot longline fisheries on the outer shelf and continental slope regions of the Aleutian Islands and EBS. Bycatch estimates of grenadier have ranged between 2,675 mt (in 1992) and 8,885 mt (in 1993) (Gaichas 2000). Bycatch of grenadiers is higher in the GOA than the catch of all species in the other species category combined (Gaichas *et al.* 1999).

During the period 1997 to 1999, the average estimated bycatch of grenadiers from the GOA sablefish fishery was 92 percent of the total average of grenadier bycatch for all 16 target species fisheries included in the study. The bycatch of grenadiers from the BSAI sablefish and turbot fisheries combined was 84 percent of the total average of grenadier bycatch for all 16 target species fisheries during this same period (Table 3.5-68). In the GOA, grenadiers comprised approximately 55 percent by weight of the total estimated non-target groundfish catch during 1997 and 1999. As has been discussed previously, since grenadier bycatch is not recorded by species, there is the potential for a species to become overexploited.

Internal Reduced Recruitment: Foreign, JV and Domestic Groundfish Fisheries

Since it has been found that the giant grenadier forms sex-specific aggregations (Novikov 1970, as referenced in Burton 1999), there is a potential for fisheries to overexploit a certain sex, thus possibly leading to reduced recruitment. Although bycatch composition estimates the impact on the common species, impact on giant grenadier would be non-significant because the catch would not approach the OFL based on $M = 0.074$. However, if it is found that the long-lived, rarer Pacific grenadier also forms sex-specific aggregations, this species may be more vulnerable to fishery-related impacts.

Grenadier Comparative Baseline

The reliability of grenadier biomass estimates depends on whether AFSC bottom trawl surveys included sampling of deep water strata. Deep strata were sampled in the EBS in 1979, 1981-1982, 1985, 1988, and

1991; in the Aleutian Islands in 1980, 1983, and 1986; and in the GOA in 1984, 1987, and 1999. Aggregate biomass estimates were reported from these bottom trawl surveys only, as others may severely underestimate the biomass of these deep water species. Recent biomass estimates are available for all three common grenadier species from the 1999 GOA bottom trawl survey (Table 3.5-70).

According to the observed depth distribution of biomass from the 1999 GOA survey, almost all grenadiers caught shallower than 700 m are giant grenadiers. This depth distribution also suggests that the surveys do not sample deep enough to fully assess all three common grenadier species found in the GOA; for example, there are indications that the maximum density of Pacific grenadiers occurs at a depth of approximately 1,500 m (Andrews *et al.* 1999). Catch by average depth and gear type indicates that all three species may be caught in longline fisheries, but the predominant catch in trawl fisheries in the GOA is most likely the giant grenadier, (*Albatrossia pectoralis*). The depth distribution of longline catch suggests that much of this catch may also be giant grenadiers; however, the interpretation of the longline depth data is complicated by the use of an average depth without any indication of the potential depth range. It is possible for a longline set at an average depth of 400 to 500 m to extend into waters deep enough to catch species other than giant grenadiers.

There had been no slope surveys in the EBS since 1991 and none in the Aleutian Islands since 1986. A few studies were conducted recently, beginning in 1997 to present. Sablefish longline surveys were conducted in deeper water strata (approximately 200 to 1,000 m) of the GOA and EBS annually from 1997 to 2001. The 2002 bottom trawl survey in the EBS and upper continental slope were also conducted in deep water strata (approximately 200 to 1,000 m). The 2000 and 2002 bottom trawl surveys in the Aleutian regions, however, were conducted in much shallower waters; the depths ranged from approximately 20 to 471 m. While these recent Aleutian studies confirmed the presence of giant grenadiers (grenadier biomass 2000: 219,693 mt, 2002: 22,851 mt) , the sampling most likely did not occur at depths great enough to fully assess all three grenadier species of interest in this document, and so will not be discussed. The results of the sablefish longline and 2002 EBS studies are outlined below.

The sablefish longline surveys were conducted annually from 1997-2001 at approximately the same depths (200 to 1,000 m) using the same sampling stations from year to year. The combined results from both the GOA and EBS areas showed that giant grenadier consistently accounted for 22 percent of the total number of fish caught and recorded (average of 232,000 fish). The giant grenadier followed only the sablefish (35 to 40 percent of the catch) as the second-most frequently caught species (1997-2001).

The 2000 bottom trawl survey of the Aleutian Islands region (western, central, and eastern Aleutians and southern Bering Sea) groundfish resources also resulted in grenadier catch as well. However, the bottom trawl survey was conducted in much shallower water than the sablefish survey with a depth range from 20 to 471 m. The giant grenadier was the third most abundant species (219,693 mt) of the 12 species captured in the four sample areas combined; following only the Atka mackerel (512,511 mt) and Pacific ocean perch (511,706 mt). The giant grenadier was most abundant in the eastern Aleutian region, where its biomass estimate was 203,727 mt, and non-existent in the southern Bering Sea area (AFSC 2000). According to groundfish assessment surveys in the Aleutian region, the catch of giant grenadier has increased approximately eight fold from 1991 to 2000, from an estimated 24,594 to 219,693 mt. This upward trend may have been influenced by survey factors such as improved sampling techniques and possibly survey timing; the 2000 survey was conducted 3 weeks earlier than the 1997 and 1994 surveys, which were 7 weeks earlier than the 1991 survey (AFSC 2000).

The 2002 bottom trawl survey of the EBS upper continental slope groundfish resources was conducted along the EBS from Akutan Island northwest to the International boundary, between depths of 200 and 1,200 meters. The giant grenadier was the dominant species in overall biomass collected, with a total biomass of 81.5 mt. Pacific ocean perch weighed a total of 13.0 mt followed by the popeye grenadier total of 9.2 mt.

The 2002 bottom trawl survey of the Aleutian Islands region was conducted in approximately the same areas and at the same depths as the 2000 study. The giant grenadier was the fifth most abundant species in the three Aleutian areas, following the Atka mackerel, Pacific ocean perch, northern rockfish, and the walleye pollock, respectively. There were no grenadier found in the southern Bering Sea area. The grenadiers are again most abundant in the eastern Aleutian region, where their biomass estimate was 20,908 mt, compared with the combined biomass total in all three Aleutian regions being 22,851 mt.

The species most commonly encountered in the trawl surveys mentioned above was the giant grenadier (*Albatrossia pectoralis*). The Pacific grenadier (*Coryphaenoides acrolepis*) and the popeye grenadier (*Coryphaenoides cinereus*) were also present, but with much lower estimated biomass in all years. Survey coverage of deeper strata is particularly important to grenadier biomass estimates; therefore, the 1990-1996, 2000, and 2002 bottom trawl survey estimates are considered to be of little use for detecting trends in grenadier abundance. Because the 2000 sablefish longline survey and the 2002 bottom trawl surveys were both conducted in deeper strata, the data may be helpful in determining grenadier abundance.

BSAI and GOA Grenadier Cumulative Effects Status

Reliable biomass estimates are limited for grenadier, and species-specific information within the complex is almost non-existent. Since grenadier bycatch is not recorded by species, there is the potential for a species to become overexploited by fishing activities. This lack of information prevents discussion of the mortality effects of grenadiers due to post-MSA groundfish fisheries. Due to the potential vulnerability of this species group to overfishing, they will be brought forth for cumulative effects analysis.

3.6 Habitat

MSA provisions call for the description of measures to avoid, mitigate, or offset adverse effects to EFH. EFH is defined in the MSA as "those waters and substrate necessary to fish for spawning, breeding, feeding or growth to maturity" (16 USC 1802 3, 104-297). Consistent with these provisions, this analysis focuses on the following question: Do the alternative management policies result in conditions that offer protection to and minimization of adverse impacts to EFH? For Alaska groundfish, this includes the habitat for all target groundfish species, non-target species, prohibited species, other species, and their prey. When viewed in aggregate, across all species, EFH is all pelagic and benthic habitat in the Alaska EEZ. The EFH definitions for all managed species are currently being reviewed by the NPFMC and NOAA Fisheries through its EFH amendment process. A decision on the Alaska EFH definitions will be made by the end of 2004. For purposes of this Programmatic SEIS, we provisionally defined EFH generally, as all benthic habitat.

As explained above, this analysis focuses on benthic habitat, which is generally believed to be at greater risk to the impacts of fishing than non-benthic habitat in the water column. In addition, much of the analysis focuses on the impacts of bottom trawling. It is recognized that fixed gear (longlines, pots, and jigs) or pelagic trawl gear that comes in contact with the sea floor can disturb benthic habitat. Pelagic trawls are fished "lightly on the bottom," and fishing on the sand and mud flats of the Bering Sea during daytime tends to involve a higher percentage of limited bottom contact involving the "fishing line" and leading edge of the first row of meshes. In some types of habitat, fixed gear may cause an impact due to its ability to be more easily fished on rougher substrates (e.g., boulders with coral) than bottom trawl gear. However, most scientific studies of gear impacts have dealt with bottom trawls and dredging because this gear is the most controversial (Auster and Langton 1999, Jennings and Kaiser 1998, Hall 1999a, NRC 2002).

In this analysis, benthic habitat is further divided into two categories: living and non-living. Living substrate is composed of biological communities. Non-living substrate is comprised of boulders, cobbles, sand waves and other seabed features organisms may colonize. The primary components of non-benthic habitat include the biological, physical, and chemical properties of the water column. The biological component of non-benthic habitat consists of non-benthic groundfish prey. HAPC is defined as a subset of EFH, described as habitat types or areas that may require extra protection; HAPC is designated using specific criteria (see Section 3.6.2). In Alaska, HAPC is specifically defined as: "living substrate in shallow and deep water, and freshwater areas used by anadromous fish."

In October 1996, the U.S. Congress reauthorized the MSA through the Sustainable Fisheries Act. The Final Rule EFH provisions of the MSA (50 CFR Part 600) was promulgated in January 2002. The intended effect of the rule is to promote the protection, conservation, and enhancement of EFH. Among other conservation measures, the Final Rule broadly defines EFH as those waters and substrate necessary for fish to spawn, feed or grow to maturity. The Final Rule also includes provisions requiring Regional Fishery Management Councils (RFMCs) to amend their FMPs to describe and protect EFH, and to mitigate for any adverse impacts potentially caused by fishing activities. The Final Rule requires that FMP components include mitigation for the adverse effects of fishing. Fishery management options may include, but are not limited to: fishing equipment restrictions, time area closures, and harvest limits.

At present, environmental and human variables that could affect habitat quality are addressed in the FMPs for both the BSAI and GOA (NPFMC 1999c). However, The EFH EA and FMP Amendments 55/55/8/5/5, along with similar actions prepared by five other RFMCs, were challenged by a coalition of seven environmental groups and two fishermen's associations. The plaintiffs' challenge was twofold. The U.S. District Court for the District of Columbia found that NOAA Fisheries evaluation of fishing gear impacts on EFH in the FMP amendments was in accordance with the MSA. The supporting EAs, however, failed to comply with the requirements of NEPA and the regulations promulgated by the CEQ and NOAA Fisheries. The court determined that the EAs did not consider the full range of relevant alternatives, nor did they fully explain the environmental impact of the proposed action and alternatives. In addition, the EAs failed to address any mitigative efforts to reduce adverse effects from fishing activities.

The Assistant Administrator of NOAA Fisheries determined that NOAA Fisheries would prepare new regional EISs to include all FMPs covered by the EAs. The following are several key areas of guidance provided in his determination:

- The selected range of alternatives should be developed by taking into account comments NOAA Fisheries receives during the scoping process, and that the EIS must evaluate a reasonable range of alternatives for developing the mandatory EFH provisions of the affected FMPs.

- For the designation of EFH, the analysis should include alternative ways of identifying EFH.

- For the identification of HAPC, the analysis should discuss alternative areas or different approaches that could be used to designate HAPCs.

- For the minimization of fishing impacts, the alternatives analysis should identify a range of approaches that could be taken to minimize the adverse effects of fishing on EFH. If information is lacking on the effects of specific fishing practices on EFH, the analysis should examine alternatives that could be taken in the face of uncertainty.

- To the extent feasible, NOAA Fisheries should use the NEPA process as the vehicle for reviewing and revising the information contained in the original EFH FMP amendments. Such a review should include information regarding the description and identification of EFH, threats to EFH from fishing and non-fishing activities, and measures that could be taken to minimize those threats.

The proposed action to be addressed in the EFH EIS is the development of the mandatory EFH provisions of all five FMPs of NPFMC: the BSAI groundfish; GOA groundfish; BSAI king and Tanner crab; scallop fishery off Alaska; and salmon fisheries in the EEZ off the Coast of Alaska. At present NOAA Fisheries and NPFMC are identifying feasible alternatives for analysis in the EIS and for selection of a preferred alternative. The Alaska Groundfish Programmatic SEIS is not intended to replace or supercede the EFH EIS, but will provide overarching policy guidance for EFH and set the stage for future FMP actions.

3.6.1 Identification of Essential Fish Habitat

The 1996 re-authorization of the MSA mandated that NOAA Fisheries and the RFMCs specifically describe and identify EFH within the FMPs. The MSA also required that FMPs minimize to the extent practicable adverse effects on EFH caused by fishing. NOAA Fisheries and NPFMC prepared one EA and a comprehensive set of Habitat Assessment Reports to address the new EFH requirements of the MSA

(NPFMC 1998a, 1998b, and 1998c). EFH FMP amendments for the five FMPs were submitted to the Secretary of Commerce in October 1998; these amendments were reviewed and approved by the Secretary of Commerce and took effect on January 20, 1999 (64 FR 20216). These FMP amendments identified EFH for 80 individual species including target and other fish, and for five species groups incorporating a total of 115 individual species. In cases where information was available, EFH was identified by each particular life stage for a given species (34 of the 80 individual species fell into this category).

According to the Final Rule implementing the EFH provisions of the MSA (50 CFR Part 600), to identify EFH basic information is needed to understand the usage or various habitats by each managed species. Pertinent information includes the geographic range and habitat requirements by life stage, the distribution and characteristics of those habitats, and current and historic stock size as it affects occurrence in available habitats. Temporal and spatial distribution of each life history stage is necessary to understand each species' relationship to, or dependence on, its various habitats. Data summarizing all environmental and habitat variables that control or limit distribution, abundance, reproduction, growth, survival, and productivity of the managed species should be provided.

RFMCs must obtain this information to describe and identify EFH from the best available sources, including peer-reviewed literature, unpublished scientific reports, data files of government resource agencies, fisheries landing reports and other reliable sources. The scientific rigor of the reports, and species-specific data gaps and potential deficits in data quality should be taken into consideration.

In order to analyze habitat information, the EFH Final Rule specifies the following for organizing the data necessary to describe and identify EFH:

- **Level 1:** Distribution data are available for some or all portions of the geographic range of the species. Distribution data may be derived from presence/absence sampling and/or may include opportunistically collected information on species and life stages. In the event that distribution data are available for only portions of the geographic area occupied by a particular life history stage of a species, habitat use can be inferred on the basis of distributions among habitats where the species has been found and on anecdotal information about its habitat requirements and behavior. Habitat use may also be inferred from information on a similar species or another life stage.

- **Level 2:** Habitat-related densities of the species are available. At this level, quantitative data (i.e., density or relative abundance) are available for the habitats occupied by a species or life history stage. Because the efficiency of sampling methods is often affected by habitat characteristics, strict quality assurance criteria should be used to ensure that density estimates are comparable among methods and habitats. Density data should reflect habitat utilization, and the degree that a habitat is utilized is assumed to be indicative of habitat value. When assessing habitat value on the basis of fish densities in this manner, temporal changes in habitat availability and utilization should be considered.

- **Level 3:** Growth, reproduction, or survival rates within habitats are available. At this level, data are available on habitat-related growth, reproduction, and/or survival by life history stage. The habitats contributing the most to productivity should be those that support the highest growth, reproduction, and survival of the species (or life history stage).

- **Level 4:** Production rates by habitat are available. At this level, data are available that directly relate the production rates of a species or life history stage to habitat type, quantity, quality, and location. Essential habitats are those necessary to maintain fish production, consistent with a sustainable fishery and the managed species' contribution to a healthy ecosystem.

RFMCs should strive to obtain data sufficient to describe habitat at the highest level of detail (i.e., Level 4). If scientists and managers have no information on a given species or life stage and habitat use cannot be inferred from other means, EFH should not be designated.

The EA for Amendments 55/55/8/5/5 identified EFH information levels for groundfish, crab, scallops, and salmon in the Alaska region. Level 2 data are available for some adult life history stages of groundfish, crabs, and shellfish. Level 2 data are also available for some stocks of red and blue king crab, tanner and snow crab stocks in some regions, at the egg, larval, late juvenile, and adult stages. The remainder of the data for all other crab stocks is either at Level 1 or unknown. Level 1 data are available for the eggs, larvae, early juvenile, and late juvenile stages of pollock, and for the late juvenile stages of most other groundfish species. Even minimal (Level 1) data are not available for forage fish at all life stages, so distribution and habitat use is considered to be unknown. Salmon EFH data are highly variable and crosses Levels 1 through 4 depending on species, stock, and life stage. The majority of the data available for adults in the freshwater stage ranges from Levels 1 to 3. The information levels for all EFH are continually being refined and updated and will be presented in the EIS currently being developed for EFH.

3.6.2 Identification of Habitat Area of Particular Concern

As defined above, HAPC are habitat types or areas that may require extra protection. While HAPC is managed in the non-specified species category (per BSAI and GOA amendment 65), these areas are included with EFH for description and impacts discussions in this Programmatic SEIS. HAPC is defined by the following criteria.

Ecological importance is defined as the value of a habitat type to a species at a particular life stage, based on ecological function. Where there are few studies and observations of ecological function, the ecological importance of a particular habitat type may need to be inferred from the presence of species life stages. When limited data are available about a species presence or absence, ecological importance may need to be inferred from the shelter or food items the habitat is capable of providing.

Sensitivity is defined as the degree to which a habitat feature is susceptible to degradation by exposure to activities, events, or conditions. The sensitivity of a given type of habitat to a disturbance regime depends on its ecological resistance (the ability to resist change during a disturbance) and resilience (the ability to return to its predisturbance condition). Several factors contribute to ecological resistance: 1) redundancy in function of component species; 2) tolerance to environmental fluctuations; 3) physical and chemical buffering capacity or flushing characteristics; and 4) proximity of the system to its ecological limits. Resilience has four components: elasticity, amplitude, hysteresis, and malleability. Elasticity is the time required for recovery, amplitude defines the level of disturbance that allows recovery, hysteresis describes the "path" of recovery, and malleability is a measure of the plasticity of the system (i.e., its capacity to persist in an altered state). Habitat types with low resistance and resilience have high environmental sensitivity, and habitats with high resistance and resilience have low environmental sensitivity.

Exposure is defined as the probability that a habitat feature will be exposed to activities, events, or conditions that may adversely affect it. These activities were discussed in the environmental assessment/regulatory impact review (EA/RIR) to the EFH amendments (NMFS 1998a). In the marine environment, numerous land-based activities expose nearshore habitat to potentially adverse impacts. The most obvious marine activity that affects habitat, and the one activity both NOAA Fisheries and NPFMC are most accountable for, is fishing.

Rarity is defined as how uncommon the habitat feature is relative to other available habitats. In Alaska, little is known of the geographic extent and distribution of many habitat features and types, particularly in the marine environment.

Vulnerability is determined by a combination of the above factors, the area or habitat type and the priority it will be assigned for consultations. Vulnerable habitat can be defined as habitat that is susceptible to perturbation by natural or human events or activities. Such perturbation would include physical damage to or removal of features, or more general degradation of the condition or quality of an area. Physical damage and removal could be caused, for example, by anchors dragging through submerged aquatic vegetation. Degradation of quality could be caused, for example, by activities that negatively affect water quality, which, in turn, could have repercussions such as impeding the reproductive success of submerged aquatic vegetation.

Three habitat types in Alaska that meet all of the above criteria as specified in the interim Final Rule are: living substrates in shallow water, living substrates in deep water; and freshwater areas used by anadromous fish. As such, these three types were adopted as part of the five EFH amendments to Alaska's Fishery Management Plans.

These habitat types have important ecological functions, are sensitive and vulnerable to human impacts, and are relatively rare. The first two types are described below, but given that this Programmatic SEIS is concerned with the groundfish fishery, freshwater areas used by anadromous fish are not discussed further.

3.6.2.1 Living Substrates in Shallow Water

HAPCs include nearshore areas of intertidal and submerged vegetation, rock, and other substrates. These areas provide food and rearing habitat for juvenile groundfish and spawning areas for some species, such as Atka mackerel and yellowfin sole, and may have a high potential to be affected by shore-based activities.

Shallow nearshore areas (less than 50 m depth) provide important structural habitat for early juvenile instars of red king crab. Early juvenile instars are cryptic and occupy the protective refuges provided by high-relief habitat or coarse substrate, such as boulders, cobble, shell hash, and living substrates (macroalgae, bryozoans, stalked ascidians, etc.) (Sundberg and Clausen 1977). Adult red king crabs also use highly structured shallow water habitat during the mating period and will use macroalgae as cover during this period (Stone *et al.* 1993).

All nearshore marine and estuarine habitats used by fish, such as eelgrass beds, submerged aquatic vegetation, emergent vegetated wetlands, and certain intertidal zones, are sensitive to natural or human-induced environmental degradation, especially in urban areas and in areas near intensive development activities.

Juvenile rockfish are known to use eelgrass beds (Murphy *et al.* 2000). Herring also require living substrates in shallow water for reproduction. Spawning takes place near the shoreline between the high tide level and 11 m depth. Herring deposit their eggs on vegetation, primarily rockweed (*Fucus spp.*) and eelgrass (*Zostera spp.*). These seaweeds are found along much of the Alaska coastline, but they often occur in discrete patches.

3.6.2.2 Living Substrates in Deep Waters

HAPCs include offshore areas with substrates of high microhabitat diversity that serve as cover for groundfish and other organisms. These can be areas or habitat types with rich epifaunal communities (e.g., coral, sponges, anemones, bryozoans), or with large particle size (e.g., boulders, cobble). Since many deep water areas are characterized as stable environments dominated by long-lived species, the impacts of fishing can be substantial and long-term (Auster and Langton 1999).

Coral, for example, is a living substrate in deep water that has been defined as a type of HAPC. Coral is a common name for a number of diverse invertebrate species within the phylum Coelenterata. Five major taxonomic groups and at least 34 species of coral occur in waters off Alaska (Cimberg *et al.* 1981): Alcyonacea (soft corals), Gorgonacea (sea fans, bamboo corals, and tree corals), Scleractinia (cup corals or stony corals), Stylasterina (hydrocorals), and Antipatharia (black corals). Heifetz (2002) analyzed the distribution and abundance of corals based on trawl survey data collected during 1975-1998. Soft corals were most frequently encountered in the Bering Sea, while in the Aleutian Islands, gorgonian corals were most common; the Aleutian Islands also were found to have the highest diversity and abundance of corals. In the GOA, gorgonian corals and cup corals were dominant.

Some corals grow upright and branch out, whereas other species are low-growing encrusting forms. In Alaska, gorgonian corals, particularly members of the genera *Primnoa* (red tree coral) and *Paragorgia*, may be especially valuable as fish habitat due to their longevity and large size–they grow up to 3 m high and 7 m wide. Heifetz (2002) found certain fish groups to be associated with particular types of coral. For example, rockfish and Atka mackerel were the most common fish captured with gorgonian, cup, and hydrocorals, while flatfish and gadids were the most common fish captured with soft corals.

Gorgonian corals are colonies of animals composed of individual polyps that deposit a tree or fanlike skeleton that supports the colony. In general, corals are very slow-growing organisms. Some species of gorgonians may live to be over 100 years old (Risk *et al.* 1998, Andrews *et al.* 2002). Large *Primnoa* colonies may be hundreds of years old; a 5 cm diameter specimen of *Primnoa reseda* from Nova Scotia, Canada was estimated at 500 years, using isotope dating (Risk *et al.* 1998). The habitat created by these gorgonians may be occupied by communities with high biodiversity and may provide shelter for fish (Risk *et al.* 1998, Fossa *et al.* 1999). Given their size and longevity, gorgonian corals may be especially vulnerable to fishing impacts and may take over 100 years to recover (Andrews *et al.* 2002). Although scientists have limited understanding of its importance as fish habitat, deep water coral clearly provides vertical structure for fish to use for protection and cover. This has been observed in Alaska during submersible dives (Krieger and Wing 2002).

3.6.3 Management History

Passage of the MSA in 1976 marked the beginning of efforts to integrate habitat considerations into the fishery management process. The MSA directs the RFMCs to recommend management plans for commercial and recreational species of fish occurring in the EEZ. For the most part, the individual states have responsibility for managing fisheries within the territorial sea. Although some early efforts were made to address significant fishery habitat issues, the RFMCs and the NOAA Fisheries concentrated largely on ocean harvest during the first decade after passage of the MSA.

In 1983, NOAA Fisheries adopted a National Habitat Conservation Policy, uniting its MSA authority with its advisory responsibilities and authority under the Fish and Wildlife Coordination Act and NEPA. The Habitat Conservation Policy provides guidance to NOAA Fisheries regarding interactions with the RFMCs and with federal and state agencies. It also focuses NOAA Fisheries' habitat conservation efforts on specific habitat impacts potentially affecting fishery resources, marine mammals, and endangered marine species. Although the policy notifies other agencies and the RFMCs of NOAA Fisheries' intent, it does not clarify the RFMCs' role in fishery related habitat issues.

In 1986, Congress amended the MSA, essentially codifying elements of the NOAA Fisheries Habitat Conservation Policy and giving the RFMCs new authority and responsibility to include "readily available" habitat information in all FMPs. The amendments to the MSA direct the RFMCs, with guidance from NOAA Fisheries, to evaluate any effects that habitat changes may have on managed fisheries. Furthermore, the 1986 amendments give the RFMCs the opportunity to recommend habitat management measures for ongoing and proposed federal and/or state activities that could potentially adversely affect fishery resources. Federal agencies are required to respond specifically and substantively to NPFMCs recommendations within 45 days. The amendments also encourage the RFMCs to monitor state activities and to comment on those activities that could adversely affect NPFMC-managed fishery resources.

In September 1988, NPFMC adopted a policy to guide the review of habitat issues:

> *The Council shall assume an aggressive role in the protection and enhancement of habitats important to marine and anadromous fishery resources. It shall actively enter federal decision-making processes where proposed actions may otherwise compromise the productivity of fishery resources of concern to NPFMC Recognizing that all species are dependent on the quantity and quality of their essential habitats, it is the policy of the NPFMC to:*
>
> *Conserve, restore, and maintain habitats upon which commercial, recreational and subsistence marine fisheries depend, to increase their extent and to improve their productive capacity for the benefit of present and future generations. (For purposes of this policy, habitat is defined to include all those things physical, chemical, and biological that are necessary to the productivity of the species being managed.)*
>
> *This policy shall be supported by three policy objectives which are to:*

(1) Maintain the current quantity and productive capacity of habitats supporting important commercial, recreational and subsistence fisheries, including their food base. (This objective will be implemented using a guiding principle of no net habitat loss caused by human activities).

(2) Restore and rehabilitate the productive capacity of habitats which have already been degraded by human activities.

(3) Maintain productive natural habitats where increased fishery productivity will benefit society.

In light of these policy objectives, NPFMC and NOAA Fisheries have enacted certain measures that are consistent with protecting habitat and ecosystem components from potential negative impacts of fisheries. These measures include gear restrictions, time and area closures, and harvest restrictions. Of these three measures, the most widely used is closure of areas to certain gear types. A chronology of management measures undertaken by NPFMC with the primary intent or secondary effect of protecting habitat is provided in Table 3.6-1. Figure 3.6-1 depicts the groundfish closures presently enacted in Alaska's EEZ.

3.6.4 Effects of Fishing on Habitat

Benthic habitat encompasses seafloor habitat that is generally believed to be at greater risk to the impacts of fishing than non-benthic habitat in the water column. Therefore, the focus of the following analysis of past and present effects is on impacts to benthic habitats. However, discussions concerning the primary components of non-benthic habitat (physical, biological, and chemical properties of the water column) are provided. For example, Section 3.3.1 considers the effects of fishing on the physical and chemical properties of the water column; biological components are discussed in Section 3.5.4, 3.5.5 (discussion forage fish and non-specified species, respectively) and Section 3.10 (ecological relationships including predator-prey relationships and energy removal and flow between target species and other species).

In order to assess the potential effects of fishing gear on benthic habitat it is first important to characterize the type of fishing gear used, the intensity of fishing as determined by trawling patterns, and the type of substrate fished or encountered. The following subsections describe these different factors and their relative importance in predicting effects.

3.6.4.1 Gear Types

Three main classes of fishing gear are used in the Alaskan fisheries: otter trawls, longlines, and pots. Each gear type has several components or characteristics that determine its overall effect on the benthic environment. Effects of the gear are also dependant on the vulnerabilities of the substrate and organisms.

Otter Trawls

Otter trawls pull conical nets through the water; fish that encounter the open forward end are gathered into a restricted bag (codend) at the back of the net. Otter trawls have four main components that can contact the seabed: doors, sweeps, footrope, and netting.

Doors are flattened metal structures that ride vertically in the water column; their weight and force through the water act to horizontally spread the net open and force it down into the water. Some bottom trawl doors use contact with the seafloor to accomplish the spreading and downward pull. On pelagic trawls the net is pulled above the seafloor and the doors are unlikely to contact the bottom. Trawl doors used in Alaska are typically less than 9 ft long.

Sweeps are steel, fiber or combination steel and fiber cables which connect the doors to the trawl net. The cables pass over the bottom at a narrow angle from the direction of travel and herd near-bottom fish toward the net. When used on bottom trawls, these cables commonly contact the seafloor and often have protective disks strung on them. Lengths of the sweeps will vary with target species fished, substrate, and individual vessel preference. A large vessel targeting flatfish on smooth bottom may use 1,000 ft of sweeps, while a small rockfish trawler on rough bottom may only use 100 ft.

The footrope of the trawl is a cable or chain connected along the bottom edge of the trawl net and is designed to contact the seafloor on bottom trawls. The footrope usually has rubber cones, spheres or disks, collectively known as bobbins, strung along its entire length. The bobbins serve to limit damage to the netting and reduce bycatch of crabs and other invertebrates. Alternately, tire gear is used in the center net section, particularly in the Atka mackerel fishery and in the GOA fisheries for cod, rockfish and Dover and rex sole. Tire gear consists of vehicle tires or sections of tires linked side-by-side to form a continuous cylinder. This gear is effective at protecting the netting and allows fishing in areas of rough substrates where fishing would not otherwise be possible.

The netting is the least likely component of bottom trawls to directly contact the seafloor. The bobbins or tire gear act to raise the netting so that only very prominent seafloor features touch the netting without entering the trawl. The codend can contact the seafloor, particularly when it contains rocks, substrate, or numerous fish. In order to allow the net to be pulled up the stern ramp of the vessel, the codend is usually no more that 8 ft in diameter, thereby limiting the amount of bottom potentially impacted by this part of the net. The size of vessel determines the width of the trawl net fished and whether a high opening, or wide, low trawl is selected. Typically bottom trawls range in width from 36 to 90 ft across.

The pelagic trawl is a specially modified otter trawl that is designed for harvesting fish that inhabit the waters above the seabed. These trawls, which are very important in the Alaska groundfish fisheries, have very large mesh opening in the forward sections and the doors are fished above the bottom. By regulation, these trawls must not use bobbins or other protective devises, so the footropes are small in diameter, and typically consist of bare chain. Since they are fished with the doors above the seafloor, the doors have no effects on substrate. The footrope is unprotected; therefore, these trawls are not used on rough or hard substrates and are less likely to contact some of the most vulnerable habitats (Rose In preparation). Night fishing tends to be more "off-bottom" than day fishing, and fishing in high-relief hard bottom areas is all "off bottom."

Longlines

Demersal longlines consist of two buoy systems that are situated on each end of a mainline to which leaders (gangions) and hooks are attached. The mainline is usually made of sinking line and can be several miles long and have several thousand baited hooks attached. Small weights may be attached to the mainline at intervals. At the bottom of each buoyed end is a weight or an anchor. A vessel may set a number of lines, depending on the area, fishery, and site. The principal components of the longline that can contact the seabed are the anchors or weights, the hooks, and the mainline (ICES 2000 as referenced in NMFS 2001b).

In Alaskan waters, longline gear is fished on the bottom. Some vessels attach weights to the longline, especially on rough or steep bottoms so that the longline stays in place and on the bottom. Average set length in 1996 was 6 miles for the sablefish fishery, 10 miles for Pacific cod, and 4 miles for Greenland turbot. The gear is baited by hand or by machine with smaller boats tending to bait by hand. Circle hooks are usually used; however J-hooks are more common with machine baiters. The gear is deployed from the stern of the vessel while traveling at 5 to 7 knots.

Pots

Pots are enclosures that retain entering fish. Pots used in the Alaska cod fishery are generally modified from the designs developed for the crab fishery and include one-way entrances that are modified to prevent fish escape. The most common design is a rectangular frame approximately 6 ft by 6 ft by 3 ft, constructed of welded steel rods with entrances on opposite walls. Pots weigh between 500 and 700 pounds, and the weight is not greatly reduced by immersion in water. In Alaska, regulations require that each pot have its own buoyed line, so there are no underwater lines connecting adjacent pots. Each pot is sufficiently heavy that no additional anchors are required.

3.6.4.2 Trawling Patterns

Bering Sea

The continental shelf and slope region off the coast of Alaska comprises one of the most extensive fishing grounds in the world (NRC 2002). Bottom trawling in the Bering Sea began in 1929 with a Japanese operation and continued through the 1930s and early 1940s, recommencing in the 1950s after World War II. Soviet and other distant water trawl fishing operations intensely fished the Bering Sea and GOA through the 1960s and 1970s. Domestic bottom trawling began as joint ventures in the Bering Sea in 1978 after passage of the MSA in 1976. These U.S. trawl activities grew rapidly during the 1980s and had displaced foreign fishing by the end of the 1980s. Presently the groundfish fleet is divided into catcher vessels and catcher processors. In 1999, the catch was almost equally divided between the two sectors (NMFS 2001a).

Therefore, virtually all areas of the Bering Sea have experienced some degree of exposure to bottom trawls (Figure 3.6-2). However, the intensity of exposure, measured in trawls made per unit area, varies substantially. These patterns reflect the non-random behavior of fishing fleets, which is based on historical patterns of performance and regulatory restrictions. Relatively heavy trawling has occurred in three places: along the shelf edge, along the Alaska Peninsula near Unimak Island, and in Togiak Bay. The primary composition of the catch in these three areas, respectively, was pollock, Pacific cod and Greenland turbot; Pacific cod and pollock; and yellowfin sole (Fritz *et al.* 1998).

Bottom trawling in the Bering Sea during the early 1990s was most intense on the slope and shelf area north of the Aleutian Islands (NRC 2002). The Alaska peninsula in the area of Unimak Island, east of the Pribilofs west of Bristol Bay and off of Cape Constantine, was also heavily fished. However, large areas of the Bering Sea have no trawling activity because of closed management areas, less productive fishing grounds, or unobserved tows. However, both the spatial extent and intensity of fishing effort decreased in the 1990s. Over large parts of the Bering Sea there were either no observed bottom trawls or only about four tows averaged over two years (NRC 2002). Also see: http://www.afsc.noaa.gov/race/groundfish/habitat/hist_trawldata.htm for additional information.

GOA and Aleutian Islands

Coon *et al.* (1999) described the spatial and temporal patterns of bottom trawl effort in the GOA and Aleutian Islands from 1990 to 1998 by analyzing domestic observer data. The greatest bottom trawl effort in the GOA has taken place in the Kodiak Island region (Figure 3.6-3), where directed fisheries have targeted Pacific ocean perch, Pacific cod, and flatfish. In the Aleutian Islands, intense bottom trawl effort (Figure 3.6-4) has been directed at Atka mackerel and Pacific ocean perch. There has been a significant reduction in the geographic extent and intensity of trawling in the Aleutian Islands and the GOA also. The number of tows in the region was reduced by about half due to management area closures and general reductions in fishing effort associated with fisheries management and reduction of TAC. In considering the fishing effort distribution, it is important to consider that, even within depth-area strata, fishing effort is not evenly distributed. Some areas are rarely fished and some are fished frequently.

3.6.4.3 Type of Substrate Fished

Most bottom fishing off the coast of Alaska takes place on the continental shelf and upper slope in water depths of less than 500 m. The seafloor affected, or potentially affected, covers a wide range of habitats, from relatively featureless sand and mud, to more complex rocky areas, or areas of HAPC. Hard substrates and rocky areas provide the most habitat complexity for the benthic community and are likely to be more vulnerable to fishing disturbance.

NOAA Fisheries and the AFSC are currently conducting research to map limited areas of the Alaska EEZ for geographic characterization. During 2001, 900 km^2 of seafloor near Kodiak were mapped using a high-resolution multi-beam echo-sounder. In July 2002, an additional 500 km^2 of seafloor near Yakutat were mapped. Survey depths ranged from 100 m to 760 m and the seafloor consisted of irregular seabed with mixed sediments (sand, mud, gravel) and high-relief areas consisting of boulders. The mapping of the area allows habitat characterization to be compared to fishing intensity for analysis of impacts. See: http://www.afsc.noaa.gov/Quarterly/jas2002/divrptsABL2.htm for additional information on the results of this study.

Four habitat types in the Bering Sea shelf were defined by (Rose, in preparation) using habitat sediment data in Smith and McConnaughey (1999). Figure 3.6-5 depicts these habitat strata. The first, situated around the shallow eastern and southern perimeter of the shelf and near the Pribilof Islands, consists of sand substrates with a small amount of gravel.

The second lies across the central shelf out to the 500 m contour and is composed of mixtures of sand and mud. This sand/mud habitat of the EBS is subject to a high level of effort from a variety of fisheries, pollock fishing accounts for the largest effort with substantial contributions from trawling for flathead (and other) sole, yellowfin, and rock sole and a lesser proportion from cod trawling (Rose, in preparation).

A third strata, west of a line between St. Matthew and St. Lawrence Islands, is composed primarily of mud (silt) substrates with some sand mixed in. The fourth strata is found north and east of St. Lawrence Island including Norton Sound and consists of a complex mixture of substrates that are not easily separated out or defined; however, this areas is subject to very little fishing effort.

A similar compressive substrate data set does not exist for the GOA and Aleutian Islands. Compared to the Bering Sea, the GOA has relatively weaker currents and tidal action near the seafloor and, therefore, a variety of seabed types such as gravely-sand, silty-mud, and muddy to sandy gravel, as well as areas of hardrock are found there (Hampton *et al.* 1986). For both of these areas, sufficient data to describe the spatial distributions of these substrates does not exist. However, data collected from AFSC groundfish surveys regarding "trawlability" were compiled to approximate percentages of hard substrate in the following depth strata (Rose, in preparation):

- Shallow waters (1-100 m) - 19 percent hard substrate.
- Deeper areas on the shelf (gullies; 100-300 m) - 5 percent hard substrate.
- Upper slope (200-500m) - 10 percent hard substrate.

These areas are also depicted on Figure 3.6-5. However, the percentages of hard bottom substrate as derived from "trawlability" data are limited in interpretation due to several factors:

- A standard trawl may function well on hard substrate consisting of smoother pebbles and cobbles.
- Trawlable bottom may be found in areas of mostly hard substrate.
- Patches of soft bottom may exist in otherwise untrawlable areas.

Investigations of the northeast GOA shelf (less than 200 m) have been conducted between Cape Cleare (148°W) and Cape Fairweather (138°W) (Feder and Jewett 1987). The shelf in this portion of the GOA is relatively wide (up to 100 km). The dominant shelf sediment is clay silt that comes primarily from either the Copper River or from the Bering and Malaspina Glaciers. When the sediments enter the Gulf, they are generally transported to the west. Sand predominates nearshore, especially near the Copper River and the Malaspina Glacier.

Most of the western GOA shelf (west of Cape Igvak) consists of slopes characterized by marked dissection and steepness. The shelf consists of many banks and reefs with numerous coarse, clastic, or rocky bottoms, and patchy bottom sediments. In contrast, in the vicinity of Kodiak Island, the shelf consists of flat, relatively shallow banks cut by transverse troughs. The substrate in the area from Near Strait and the vicinity of Buldir Island, Amchitka, and Amukta Passes is mainly bedrock outcrops and coarsely fragmented sediment interspersed with sand bottoms.

The relative significance of seabed disturbance by mobile and other fishing gear must be considered in light of the magnitude and frequency of seabed disturbance due to natural causes. DeAlteris *et al.* (1999) found that in a shallow, sand substrate where natural processes are disturbing the seabed regularly, recovery of the substrate from gear-related disturbance was almost immediate. However, in deep, mud substrates the analyses indicated that natural processes are rarely capable of disturbing the seabed; therefore recovery from gear-related disturbance was slow. Many studies summarized by NRC (2002) and NMFS (2002c) indicate that more stable, biogenic, gravel and mud habitats experience the greatest impacts from trawling and have the slowest recovery rates. By comparison, those areas with less consolidated, coarse sediments that also typically experience high rates of natural disturbance, show fewer impacts. These habitats tend to be populated by opportunistic species that recolonize the area rapidly, thereby reducing recovery times.

3.6.4.4 Fishing Effects

It is important to distinguish between the direct and indirect effects of trawling and dredging on marine habitat (NRC 2002). Direct and immediate effects of fishing gear potentially include the following:

- Mortality either as part of the catch or incidentally by killing benthic and demersal species or increasing their vulnerability to predators.

- Increased food availability for scavengers due to discarded fish, fish offal and dead benthic organisms.

- Loss of habitat due to scraping and plowing thereby destroying seafloor habitat.

Indirect effects are removed in space and/or time from the actual fishing activity. These effects include post-fishing mortality, and reductions in total biomass of target fish. The reductions in biomass could subsequently affect predators, prey, competitors of the targeted species, and the overall benthic community structure. Indirect effects also could also be realized at the ecosystem level due to potential changes in energy flow and shifts in the processes of primary production, primary consumption, and secondary production (NRC 2002).

Therefore, the following are types of potential effects from fishing gear on habitat:

- Alteration of the physical structure.

- Direct mortality of benthic organisms.

- Sediment suspension.

- Physical and chemical modifications to the water column.

- Benthic community changes.

- Ecosystem changes.

Alteration of Physical Structure

Physical effects of fishing gear such as ploughing, smoothing of sand ripples, removal of stones, and turning of boulders can act to reduce the heterogeneity of the sediment surface. Boulder piles, crevices, and sand ripples can provide fish and invertebrates hiding areas and a respite from the need to swim against currents (Rose, in preparation). Removal of taxa such as worm tubes, corals, and gorgonians that provide relief and the removal or shredding of submerged vegetation can also occur, thereby reducing structures available to biota as habitat (see NMFS 2002c, Kaiser *et al.* 1998, Lindebloom and de Groot 1998, Auster and Langdon 1999).

Any type of fishing gear that is towed, dragged, or dropped on the seabed will disturb the sediment and the resident community to varying degrees. The intensity of disturbance is dependent on the type of gear, sediment type, and frequency of disturbance. Heavy gear such as the shellfish dredge and the flatfish beam trawl disturb the seabed intensely. Lighter gear, such as the otter trawl predominately used in Alaska, also cause disturbance mostly due to the trawl doors and foot ropes which can leave tracks or trenches up to several meters wide and can remove or displace boulders (Hall 1999b). There are no studies of fishing gear effects that use gear directly comparable to Alaskan pelagic trawls.

Penetration into soft mud will be considerably greater than into hard-packed sands, and effects on infauna would occur accordingly. For example, Churchill (1989) estimated that coarse sand was typically penetrated to a depth of 1 cm by otter boards whereas the penetration for fine and muddy sand was as much as 2 cm. In a summary of the effects of bottom trawls in muddy substrates, NMFS (2002c) concluded that tracks made by trawl doors can remain visible for up to 18 months. However, in shallow sandy bottom sites, tracks were no longer visible after a few days. Other researchers have determined that parts of mobile gear can penetrate up to 30 cm into the substrate (Drew and Larson 1994 as referenced in the NMFS 2001b).

Specifically, Freese *et al.* (1999) conducted experimental trawling using an otter trawl over a cobble/boulder (93 percent pebble) habitat in the eastern GOA (water depth 206-274 m). The researchers found tire marks from the trawls to be visible as disturbance to substrate or to overlying silt. On compact substrate with more cobble, the trawl path was visible as a darker band because the layer of lighter colored silt was removed. On less compact substrate the trawl path was visible as furrows ranging from 1-8 cm deep. This work concluded that a single trawl pass can displace boulders and remove or damage large epifaunal invertebrates. In a subsequent study conducted at the same site, Freese (2003) found that furrows in the substrate were still prominent after one year. Boulders that had been moved by the trawl in 1996 were also easily identified.

A number of papers describe trawl marks on substrate, including Gilkinson *et al.* (1998), who describe the scouring process in detail as part of a model door study. It is not known if the trenches might compensate for the sediment smoothing actions of other gear (NMFS 2002c). The actions of roller gear trawls can replace one type of natural sediment structures (hummocks, biogenic features, and sand ripples) with other, anthropogenic forms (door, footrope, and roller tracks). In habitats with an abundance of such natural structures, this can represent a decrease in habitat complexity, while in naturally smooth areas, an increase in complexity would be apparent.

Very little information exists regarding the effects of longlining on benthic habitat. The principal longline components that can produce seabed effects are the anchors weights, hooks and mainline (ICES 2000). Rose (in preparation) If very light weight lines are used with longline gear, effects on substrate and benthic organisms would be limited to the impact of anchors and weights (Rose in preparation). These make up less than 1/500th of the total length of the gear, so effects on the soft bottoms should be very small. However, effects in hard bottom areas could be realized through snagging on smaller boulder piles and other emergent structures.

In a report presented by NPFMC (1992b), the authors determined that setline gear often lies slack and can meander for a considerable distance along the bottom, a phenomenon confirmed by observations of halibut gear made by NOAA Fisheries scientists during submersible dives off southeast Alaska. During the retrieval process, the line sweeps the bottom for considerable distances before ascending. It snags on objects in its path, including rocks and corals. Smaller rocks are upended, hard corals are broken; however, soft corals appear unaffected by the passing line. Invertebrates and other lightweight objects are dislodged and pass over or under the line. Fish, halibut in particular, frequently moved the groundline numerous feet along the bottom and up into the water column during escape runs, disturbing objects in their path. This line motion was noted for distances of 50 ft or more on either side of the hooked fish.

Although little research has been conducted to document the impacts to physical structure from pot gear, it is likely that benthic structures (both living and non-living) could be impacted as the pots are dropped or dragged along the bottom. Eno *et al*. (2001) observed that impacted sea pens were able to recover within 72 to 144 hours of the pots being removed. The study concluded that the use of pots and traps had no lasting effects on three different habitat types. However, this study used gear much smaller and lighter than that used in Alaska waters, so the results are not directly applicable. Alaska pots have mesh bottoms that are suspended 2.5 to 5 cm above the weight rails that initially contact the substrate (Rose in preparation). Therefore, the greater weight of the pots is concentrated in a smaller area beneath the pot. Also of concern is the incidence of bottom disturbance by the weight rails as the pot is dragged across the seafloor by bad weather, currents, or during hauling. Rose (in preparation) assumes that the average pressure applied to the seafloor along the rails would be sufficient to penetrate into most substrates during lateral movement. This effect was speculated to be most similar to the effects of pelagic trawls.

Direct Mortality of Benthic Organisms

In addition to effects on the physical habitat, fishing gear can cause direct mortality to emergent epifauna. In particular, erect, foliose fauna or fauna which build reef-like structures have the potential to be destroyed by towed gear, longlines, or pots (Hall 1999b). Within the trawl tracks that could range up to several meters wide, epifauna such as sponges, corals, or gorgonians are often removed, crushed, or broken (Van Dolah *et al.* 1987). Freese *et al.* (1999) found during experimental trawling studies in the GOA that no motile invertebrates showed reductions in density as a result of trawling. The researchers also note that apparent damage to echinoids, holothurians, molluscs, and arthropods was less than 1 percent. However, substantial quantities of broken sponges and other material were brought up by the trawl, but the numbers of individuals impacted could not be enumerated.

In addition to mobility, the physical structure of the biota determines their ability to withstand and recover from the physical impacts of fishing gear. For example, thinner shelled bivalves and seastars often suffer higher damage than solid shelled bivalves (Rumohr and Krost 1991). Animals that can retract below the penetration depth of the fishing gear and those that are more elastic and can bend upon contact with the gear also fare much better than those that are hard and inflexible (Eno *et al.* 2001).

Specifically, Freese *et al.* (1999) conducted trawling impact studies in the GOA in 1996. A total of 29 taxa were identified from video transects. "Vase" sponges accounted for most of the invertebrate biomass because of their large size and high density. These sponges were especially susceptible to trawl damage. Other sponges were damaged by being knocked over onto the substrate when the cobble and pebbles to which they were attached were rolled by the trawl tire gear; individuals attached to boulders usually escaped damage. The only other large erect sessile invertebrate observed in the transects was the reticulate anemones *Arctinauge verelli* and sea whips *Stylea* sp. Over half of the sea whips were either broken or had been pulled out of the substrate, while there was no evidence of trawl damage to *A. verelli.* In a subsequent study done one year later, Freese (2003) revisited three of the transects observed in 1996. He found no new colonization of sponges to be apparent in any of the observed trawl paths, and that unlike sponge communities in warm shallow waters, communities at this site in the GOA did not appear to have the ability to return to pre-trawl population-levels after one year, nor do individual sponges have the ability to recover quickly from wounds suffered from trawl gear. However, since the study only covered a one-year period, recovery rates for these cold water species may be in excess of several years and not enough information exists at present to predict actual long-term recovery rates.

Sediment Suspension

Resuspension of sediment can occur as fishing gear is pulled along or immediately above the seafloor (NMFS 2002c). The resuspension is not unique to mobile fishing gear and can occur with longlines and pots also. The chronic suspension of sediments and resulting turbidity can affect aquatic habitat by reducing available light for photosynthesis, burying benthic biota, smothering spawning areas, and causing negative effects on feeding and metabolic rates. If occurring over large areas, resuspension can redistribute sediments having implications for nutrient budgets by burying fresh organic matter and exposing deeper anaerobic sediments (Messieh *et al.* 1991, Black and Parry 1994, Mayer *et al.* 1991, and Pilskaln *et al.* 1998).

Species' reactions to turbidity depend on life history characteristics of the organism. Effects are likely to be more significant in waters that are normally clear as compared with areas that typically experience high naturally induced turbidity (Kaiser 2000). Mobile organisms can move out of the affected area and quickly return once the turbidity dissipates (Coen 1995). Even if species experience high mortality within the affected area, those with high levels of recruitment or high mobility can repopulate the affected area quickly. Sessile or slow-moving species would likely be buried and could experience high mortality. If effects are protracted and occur over a large area relative to undisturbed area, recovery through recruitment or immigration will be hampered. Furthermore, chronic resuspension of sediments may lead to shifts in species composition by favoring those species that are better suited to recover or those that can take advantage of the additional nutrient supply as the nutrients are released from the seafloor to the euphotic zone (Churchill 1989).

Chemical Modifications to the Water Column

Disturbance due to fishing gear can cause changes in the chemical composition of the water column overlying impacted sediments. In shallow water, the impacts may not be noticeable relative to mixing effects caused by tidal and storm surges, and wave action. However, in deeper, calmer areas with more stable waters, the changes in chemistry may be evident (Rumohr 1998 as referenced in NMFS 2002c). Increases in ammonia content and decreases in oxygen have been observed in the North Sea waters, along with pulses of phosphate. Although these changes have been documented, it is not clear how they affect fish populations. Increased incidence of phytoplankton blooms could occur during seasons when nutrients are typically low. The increase in primary production could have a positive effect on zooplankton communities and on organisms up the food chain. Eutrophication, often considered a negative effect, could also occur. However, it is important to note that these releases of nutrients to the water act to recycle existing nutrients and thereby make them available to benthic organisms rather than add new nutrients to the system (ICES 1992). The recycling is thought to be less influential in the eutrophication process than the input of new nutrients from rivers and land runoff.

Changes to the Benthic Community and Ecosystem

Benthic community structure can be impacted due to direct mortality of benthic organisms potentially causing a shift in the community from low-productive long-lived species (k-selected species) to highly-productive, short-lived, rapidly-colonizing species (r-selected species). Motile species that exhibit high fecundity and rapid generation times will recover more quickly from trawl-induced disturbance that non-mobile slow-growing organisms leading to a potential community shift in chronically trawled areas (Levin 1984, NMFS 2002c).

Those organisms with long-lived larvae were only available for successful recolonization if the timing of disturbance coincided with periods of peak larval abundance; however, these species were able to colonize over much larger distances.

Specifically, McConnaughey *et al.* (2000) examined the effects of chronic trawling on soft-bottom benthos of the EBS. They found that overall species diversity and niche breadth of sedentary taxa were greater in unfished areas, but there were mixed responses within the motile groups. Lower diversity in heavily fished areas was the direct result of greater dominance by the sea star *Asterias amurensis*. To determine niche breadth for the 36 taxa that co-occurred in the heavily fished and unfished areas, the taxa were placed into three functional groups (motile, n = 16; sedentary, n = 13; infaunal, n = 7). Statistically significant differences were observed between the heavily fished and unfished areas for sedentary and infaunal organisms, but not for motile epifauna. The results indicate a more patchy distribution for the attached or non-motile members of the epibenthic community in the heavily fished area. For infaunal organisms (mainly bivalves), niche breadth was consistently greater in the heavily fished area. The authors conclude that macrofaunal biomass was higher in the heavily fished area, but the differences were not statistically significant.

Freese *et al.* (1999) postulate that reducing the number of sponges and associated invertebrate taxa also reduces the shelter value of the invertebrate community. The authors acknowledge that it is not known whether the change produces a measurable response in recruitment for any taxon and subsequent changes in the overall community. The authors conclude that these species (sponges and sea whips) are especially vulnerable to trawl damage, and extensive trawling over wide areas could impact spatial patterns of invertebrate diversity. Freese *et al.* (1999) also found an increase in the density of scavenging organisms in trawl tracks due to a chumming effect from damaged organisms.

As described above under *Direct Mortality*, the physical structure and/or mobility of biota often determines their ability to avoid, or withstand and recover from, the physical impacts of fishing gear. Therefore, a switch in dominant species based on these avoidance and survival traits could be evident in chronically trawled areas.

A potential problem that does occur with longline gear is ghost fishing of lost gear. Lost longline gear may continue to catch fish as long as bait exists on the hooks. Fish caught on the hook, may itself become a form of bait for subsequent fish. This lost gear will not stop fishing until all of the hooks are bare. The extent to which this occurs and its effects on community structure have not been analyzed.

Increased fishing pressure in a given area can also lead to changes in species distribution; changes could be evident in benthic, demersal, and even pelagic species (i.e., localized depletion). Authors have also speculated that mobile fishing may lead to increased populations of opportunistic feeders in chronically trawled areas.

3.6.5 Past and Present Effects Analysis

This section presents a discussion of the direct and indirect effects, external human controlled and natural events, and internal groundfish fishery events used for the past effects analysis. Table 3.6-2 provides a summary of the past effects analysis conducted specifically for EFH.

The past effects discussion focuses on specific direct and indirect effects of fishing on habitat that will be used to model the predicted effects for each alternative in Chapter 4 (Rose in preparation). The six types of potential effects on habitat as summarized in the literature and discussed in Section 3.6.4 are cross referenced to the effects to be modeled as follows:

Direct/ Indirect Effect Discussed from Literature	Corresponding Direct/Indirect Effect to be Modeled
Alteration of the physical structure	Changes to non-living habitat (1)
Direct mortality of benthic organisms	Changes to living habitat (2)
Sediment suspension	Changes to non-living habitat (1)
Physical and chemical modifications to the water column	Changes to non-living habitat (1)
Benthic community changes	Changes to living habitat (2) Epifaunal and infaunal prey effects (3)
Ecosystem changes.	Changes to living habitat (2) Epifaunal and infaunal prey effects (3)
Not applicable	Changes in distribution of fishing effort (4)

These effects are shown on Table 3.6-2. The following subsections describe the external and internal events and management actions applicable to the effects.

3.6.5.1 Past and Present Events

Events are described as activities or occurrences that have or had the potential to induce one or more of the effects listed above. Events can either be external or internal to the groundfish fishery. In addition, external events can either be human controlled or natural. As shown on Table 3.6-2, the following events which occurred both external to the groundfish fisheries and within these fisheries have been identified:

Dredging The action of bringing up sediment, either to deepen channels for navigation purposes, or to remove shellfish such as clams and scallops has the potential to change non-living and living habitat, and to affect epifaunal and infaunal prey. Dredging activities also resuspend large amounts of sediment and can potentially change the chemical and physical composition of the water column. If widespread and chronic these actions can cause overall changes to the benthic community.

Bottom Trawling The effects of bottom trawling and other mobile fishing gears on the physical structure of the benthos, sediment suspension, the chemical and physical composition of the water column, and benthic biodiversity (community structure) have been documented for Alaska (see Section 3.6.4), thereby changing living and non-living habitats and potentially affecting prey. External events related to bottom trawling include foreign fisheries pre-and post-MSA. These fisheries are described in more detail in Appendix B. There is also a small amount of bottom trawling conducted in the state fisheries (past and present). Internal events include the post-MSA JV fisheries and the domestic groundfish fisheries for pollock, rockfish, Atka mackerel, Pacific cod, and various flatfish.

Longline and Pot (fixed gear) Longline and pot fisheries have impacted living and non-living benthic physical structure, caused direct mortality of benthic organisms, resuspended sediment, and if extensive, could have modified epifaunal and infaunal prey in localized areas. It is unlikely that these fisheries would have caused ecosystem-wide effects. External activities or events employing fixed gear include: the IPHC-managed halibut fishery, State of Alaska managed crab fisheries, state shrimp pot fishery for spot shrimp (mainly in PWS, but was more extensive in the past), and subsistence fisheries. Fixed gear fisheries managed within the FMPs include Pacific cod, sablefish, and rockfish.

Offal Discharge This discharge has occurred both externally to the groundfish fisheries and within these fisheries. Offal discharge can alter physical structure of the benthos, cause direct mortality of benthic organisms through smothering, and resuspend sediment, alter the chemical and physical composition of the water column, and if extensive cause impacts to the benthic community or ecosystem. The latter two effects are more likely in a closed bay or system where water circulation is impeded. Significant amounts of deposition could decrease the oxygen available to benthos, creating anoxic conditions in which only a few species (mainly polychaetes) could survive. Examples of this have been observed in the past at Captain's Bay in Dutch Harbor. However, improvements in offal pre-treatment and discharge regulations in recent years have reduced impacts and potentially improved conditions.

Vessel Groundings Within and externally to the groundfish fishery, vessel groundings have impacted the physical structure of the benthos and caused direct mortality of benthic organisms; these impacts if extensive could lead to changes in the benthic community on a very localized scale. It is unlikely that ecosystem impacts would be realized due to vessel groundings, and there are no documented impacts on EFH.

Port Construction and Development The construction and development of ports has occurred in coastal GOA and Aleutian Island regions. Development has likely caused the following impacts on the benthic community: alteration of physical structure, direct mortality, sediment resuspension, chemical and physical modification of the water column, and localized changes in community structure. It is unlikely that the overall ecosystem would not have been affected due to the localized nature of these events.

Petroleum Exploration and Facilities Minimal exploration and development of petroleum facilities has occurred in the GOA. Impacts are likely similar to those described above for Port Construction and Development (particularly in the Port of Valdez). While localized community changes have occurred (i.e., Port of Valdez), extensive ecosystem changes cannot be attributed to these activities.

Oil and/or Hazardous Materials Releases Releases of pollutants into both the BSAI and GOA environments have occurred. These range from small (< 10 gallon) spills to the EVOS incident that impacted areas of the GOA. Large spills cause direct mortality, alter the chemical composition of the water column, and cause changes to the structure of the benthic community. If very large, spills or incidents have the potential to impact the entire ecosystem.

Exotic Species Bilge or ballast water could introduce exotic species to new locations. Should the species survive, community impacts could be realized. It is unlikely that ecosystem impacts could occur unless the introduction was extensive, or other factors are involved. However, impacts on EFH have not been documented and are therefore unknown.

Toxic Algal Blooms These blooms have occurred in localized areas. These external events alter the physical and chemical composition of the water column and can cause mortality to benthic and pelagic organisms. "Toxic algal blooms" applies not only to toxic microscopic algae but also to non-toxic macroalgae (seaweeds) which can grow out of control and cause such ecological impacts as displacing indigenous species, altering habitat suitability, and depleting oxygen. However, long-term community and ecosystem changes are not likely since the community is adapted to their occurrence and unless already stressed by other factors can rebound. If unable to rebound, impacts include: alterations of marine food chains through adverse effects on eggs, young, and adult marine invertebrates (e.g., corals, sponges), sea turtles, seabirds, and mammals.

Storm Surges and Wind Generated Waves These external events have likely impacted EFH through physical alteration of the bottom structure and chemical and physical modification of the water column. Unless these events are long-term and extremely severe, or occur in conjunction with other events to stress the environment, community and ecosystem changes are not expected.

Climate Effects Regime shifts, and large-scale environmental fluctuations associated with ENSO and La Niña events have been identified as having impacts on both the physical and biological systems in the North Pacific Ocean (NMFS 2001a).

Volcanic Eruptions Impacts to EFH from volcanic eruptions that have occurred in the Aleutian chain, would only be realized if lava or ash reached the water. If so, impacts to the chemical composition of the water column, and indirect impacts to benthic and pelagic communities would have occurred; however, these impacts have not been documented for the BSAI or GOA. Ecosystem changes are only possible if the event was of a long duration or covered an extremely large area.

Earthquakes and Underwater Landslides Earthquakes and landslides have occurred in the GOA and Aleutian Islands. Impacts to benthic community could have occurred through burial and/or changes in the chemical composition of the water column. However, as with volcanic eruptions, impacts have not been documented for the BSAI or GOA. Ecosystem changes are only possible if the event was of a long duration or covered an extremely large area.

3.6.5.2 Past and Present Management Actions

Management actions are specific management decisions that have been determined to have had the potential to mitigate one or more of the direct/indirect effects shown on Table 3.6-2. External management actions are those determinations or regulations that have been enacted by agencies or governments outside of the jurisdiction of NOAA Fisheries and NPFMC. Nevertheless, these actions have been determined to have the potential to affect EFH in either a positive or negative manner. Internal management actions are those regulations internal to the BSAI and GOA FMPs.

External Actions

U.S. Multi- and Bi-Lateral Agreements

A detailed discussion of U.S. fisheries management prior to the MSA is presented in Appendix B. The U.S. had virtually no authority to impose regulations beyond its territorial sea (3 miles prior to 1966, then expanded to 12 miles by public law) and relied primarily on multilateral and bilateral international agreements. For example, in 1973, a bilateral agreement between the U.S. and Japan and the USSR included annual catch quotas, which reduced the catch of walleye pollock to 1.2 million mt by 1976. However, each country was still responsible for monitoring its catch quotas, the only internationally acceptable arrangement at the time. With the passing of the MSA and the increase of U.S. and JV groundfish fisheries, groundfish catch in the Bering Sea had dropped below 1 million mt by 1985 (NPFMC 2002a). Since these fisheries employed bottom trawling for the most part, it can be assumed that impacts to benthic habitat were reduced.

Circa 1980 Closures

The GOA groundfish FMP was implemented in 1978. The BSAI groundfish FMP was implemented in 1980. Both of these management plans were among the first produced under the MSA and reflect an early approach to federal fisheries management. For purposes of this Programmatic SEIS, and to assist in the description of the affected environment, a set of Circa 1980 maps was produced for two gear specific types: trawl gear (Figure 3.6-6) and fixed gear (e.g., hook-and-longline and pot gear; Figure 3.6-7). These figures illustrate a combination of spatial measures that were in effect at around that time.

The trawl map (Figure 3.6-6) is shown with three different closures types:

Blue:	No foreign groundfish fishing
Red:	No foreign groundfish trawling

Red Hatching: Seasonal no foreign groundfish trawling

Although the seasonal closures are illustrated consistently (with the exception of the darker more restrictive seasonal closures around Kodiak Island) some of these seasonal trawl closures existed for the greater part of the year.

Trawl Gear	Percent of Fishable Area: *11.5%	Percent of EEZ *4.3%

* Does not include seasonal closures

The NOAA Fisheries Reporting Areas were not in affect at this time and are for reference only.

The fixed gear map (Figure 3.6-7) is shown with three different closures types:

Blue: No foreign groundfish fishing
Green: No foreign hook and line or pot fishing
Blue Hatching: Seasonal no foreign hook and line fishing

Fixed Gear	Percent of Fishable Area: *21.0%	Percent of EEZ *7.8%

* Does not include seasonal closures

The NOAA Fisheries Reporting Areas were not in effect at this time and are for reference only.

These measures only regulated the foreign fishery conducted under a Governing International Fishing Agreement in the fishery and conservation zone seaward of the State of Alaska. Domestic vessels were not restricted by these spatial regulations. During the late 1970s and early 1980s, there was little domestic fishing for groundfish species. Most of the restricted areas were implemented to restrict foreign fishing areas and times so they would not conflict with domestic fisheries through bycatch of species important to U.S. fishermen and to reduce the potential for grounds preemption and gear conflicts. With the exception of the sablefish longline and pot fishery, and the halibut longline fishery, most domestic fishing effort focused on crab, salmon, and herring. Figures 3.6-6 and 3.6-7 illustrate that back in 1980, there were more restrictions placed on foreign fixed gear fisheries than trawl fisheries. This again was due to the need to give priority to the domestic fisheries that used similar gear and fishing grounds.

Figures 3.6-6 and 3.6-7 only show the spatial restrictions and do not take into account the other regulations affecting the foreign fishery. In 1980, other measures were used including direct allocations of OY to foreign nations and specific gear restrictions. In 1980 the federal and state management of herring was still being developed, but by August 1980 the 35-mile-wide by 30-mile-long ADF&G statistical-reporting areas had been created.

<u>Self-Monitoring of the Foreign Fishery in the EBS</u>

Japan instituted some conservation and management measures independently including a LLP and area restrictions to ease U.S. and Canadian concerns about the Japanese trawl fisheries impact on Pacific halibut (Appendix B). Benthic habitat likely benefitted from these area restrictions.

Industry Self-Imposed Actions: Gear Restrictions

Preliminary FMPs banned bottom trawling in pollock spawning grounds (pre-MSA). Due to intensive bottom trawling by the foreign groundfish and JV groundfish fisheries, a bottom trawling ban was initiated in pollock spawning habitats by the 1977 BSAI Preliminary FMP. Several of the foreign groundfish fisheries also self-imposed regulations in order to reduce their effects on pollock spawning habitats.

Clean Water Act

Growing public awareness and concern for controlling water pollution led to enactment of the Federal Water Pollution Control Act Amendments of 1972. As amended in 1977, this law became commonly known as the Clean Water Act. The Act established the basic structure for regulating discharges of pollutants into the waters of the U.S. The Act made it unlawful for any person to discharge any pollutant from a point source into navigable waters, unless a permit was obtained under its provisions. A goal of the Act is to provide for the protection and propagation of fish, shellfish, and wildlife.

Oil Pollution Act of 1990

In the wake of the spill of the Exxon *Valdez*, Congress passed the Oil Pollution Act of 1990. The Oil Pollution Act of 1990 sets forth an extensive liability scheme that is designed to ensure that, in the event of a spill or release of oil or other hazardous substance, the responsible parties are liable for the removal costs and damages that result from the incident. A responsible party includes an owner, operator, or demise charterer of a vessel. A responsible party may be liable for removal costs and damages to natural resources, real or personal property, subsistence use, revenues, profits and earning capacity, and public services.

International Laws Regarding Marine Pollutants

The International Maritime Organization is the United Nations specialized agency responsible for improving maritime safety and preventing pollution from ships. Pollution of the marine environment by ships of all types, including fishing vessels, is strictly controlled by the International Convention for the Prevention of Pollution from Ships (known as MARPOL 73/78). MARPOL 73/78 is the main international convention covering prevention of pollution of the marine environment by ships from operational or accidental causes. It is a combination of two treaties adopted in 1973 and 1978 respectively and updated by amendments through the years.

Any violation of MARPOL 73/78 within the jurisdiction of any party to the Convention is punishable either under the law of that party or under the law of the flag state. In this respect, the term "jurisdiction" in MARPOL 73/74 should be construed in the light of international law in force at the time MARPOL 73/78 is applied or interpreted. With the exception of very small vessels, ships engaged on international voyages must carry on board valid international certificates which may be accepted at foreign ports as evidence that the ship complies with the requirements of MARPOL 73/78.

Internal Actions

Groundfish management measures intended to protect habitat, or that indirectly protect habitat by reducing fishing effort are described below:

Fishing Equipment Restrictions

Seasonal and Areal Restrictions on the Use of Specified Equipment

Many gear types and fisheries are prohibited seasonally or in some areas (see Table 3.6-1). For example, trawl fisheries are closed by regulation from January 1 to January 20 (BSAI Amendment 19, GOA Amendment 24). Longline fisheries for sablefish are prohibited from January 1 to March 15. Nonpelagic trawl (e.g., bottom trawl) gear has been prohibited in the directed pollock fishery in the BSAI (BSAI Amendment 57). Figure 3.6-1 shows existing BSAI and GOA areas closed to groundfish trawling. As shown on Table 3.6-1, both the BSAI and GOA had increased trawl area closures beginning in 1994.

Equipment Modifications

Some modifications have been done to equipment to allow escapement of particular species or life stages. Pots that are used to harvest groundfish are required to have a minimum mesh size or rings to reduce the capture of juveniles and female crabs (BSAI Amendment 16, GOA Amendment 21). Escape panels have been used for trawl gear to reduce the capture of halibut and pollock. Although a proposal for trawl mesh restrictions was evaluated several years ago, it was not implemented due to enforcement difficulties and other concerns. Recent research suggests that because many pollock that escape from trawls may have delayed mortality (Alaska Fisheries Development Foundation 1999), a regulation specifying a minimum mesh size may be counter productive.

Prohibitions on Anchoring or Setting Equipment in Sensitive Areas

No anchoring (or fishing) by vessels holding a Federal fisheries permit or by vessels engaged in commercial or sport halibut fishing is allowed in a 2.5 nm^2 area surrounding the pinnacles off Cape Edgecumbe (GOA Amendment 59). Other sensitive areas have been closed to trawling to protect habitat from potential adverse effects (see Time and Area Closures below).

Prohibitions on Fishing Activities that Cause Physical Damage

Many fishing methods (including chemicals, explosives, hydraulic dredges, bottom gillnets, etc.) have been prohibited to protect habitat from physical damage. By regulation, only specified gear types (pot, longline, trawling, jig) may be used.

Time and Area Closures

Seasonal Closures

Seasonal closures have been primarily adopted to reduce the impacts of fisheries on prohibited species and marine mammals. Seasonal time and area closures also provide added protection to the habitat within the closure area. The following paragraphs describe in detail the existing closure areas summarized in Table 3.6-1.

Area 516 exhibits a seasonal closure (BSAI Amendment 12a 1989) in order to protect red king crabs from trawls when the crabs are molting. Area 516 encompasses about 4,000 nm^2.

The Chum Salmon Savings Area was established to limit the amount of chum salmon that can be taken incidentally by trawl gear (BSAI Amendment 35). This hotspot area is closed during the month of August, and remains closed if a trigger is reached. The area encompasses about 5,000 nm^2.

The Chinook Salmon Savings Areas were designated based on high bycatch rates of chinook salmon taken in the pollock fishery. The total area encompasses about 9,000 nm^2. The areas were first established in 1995 (BSAI Amendment 21b), then later modified when the bycatch limit was reduced in 1999 (BSAI Amendment 58). The trigger limit was reduced as follows: 48,000 salmon in 1999, 41,000 in 2000, 37,000 in 2001, 33,000 in 2002, and 29,000 in 2003. Accounting for the cap begins January 1 and continues year-round. Non-pollock fisheries are exempt from the closure, and those fisheries' chinook PSC bycatch is not counted toward the cap because observer data have shown that few chinook salmon are taken by the other fisheries.

Three herring savings areas were established to limit the amount of herring taken as bycatch in trawl fisheries (BSAI Amendment 16a). Two of these areas are closed in the summer months, and one in the winter. These areas were established based on seasonal abundance of herring in given areas. Together, the herring savings areas encompass about 30,000 nm^2.

Two bycatch limitation zones (Zone 1 and Zone 2) were established to limit the amount of Tanner crab taken incidentally in trawl fisheries. These zones were first established under BSAI Amendment 10, then modified under Amendment 12a. Each zone is closed to trawling in designated target fisheries when a specified amount of bycatch is taken in those fisheries. Tanner crab bycatch zones encompass about 80,000 nm^2.

The Opilio Tanner Crab Bycatch Limitation Zone is closed when a limited amount of these crabs is taken incidentally in specified trawl fisheries (BSAI Amendment 40). This area encompasses about 90,000 nm^2.

During the summer months, all fishing vessels are prohibited within 12 nm of the three major Pacific walrus haulouts in Bristol Bay (BSAI Amendment 17).

On July 19, 2000, all trawl fishing was enjoined by court order within Steller sea lion critical habitat area (as defined in 50 CFR 226.202) in the BSAI and the GOA west of 144°W, pending development of a comprehensive biological assessment. Before this order, a complex set of seasonal and area closures was already in place to reduce the interactions of pollock fisheries and sea lions.

Year-Round Closures

Year-round closure areas have been established to protect habitat, reduce bycatch, and reduce competition with marine mammals (Figure 3.6-8). These closure areas may be considered marine protected areas under common usage, in that the habitat is partially protected from trawl gear impacts. However, the National Research Council (NRC) has adopted a narrower definition (NRC 2001), under which a marine protected area is "a spatially defined area in which all populations are free of exploitation." Under that definition, none of these closure areas would entirely qualify.

The nearshore Bristol Bay closure area encompasses 19,000 nm^2 (BSAI Amendment 37) and expanded upon the area 512 closure enacted under BSAI Amendment 10 in 1987. This area meets all HAPC criteria in that it contains rare habitat types (bryozoans and other living substrates); it is important ecologically, that is, the ecosystem for young-of-the-year red king crab survival structure is necessary for young-of-the-year red king crab survival (McMurray *et al.* 1984, Rounds *et al.* 1989, Rodin 1989); and it is a habitat type thought to be vulnerable and highly sensitive to fishing gear damage (Auster and Langton 1999). The closure area also encompasses areas where red king crab pod, a behavior that occurs when the crabs grow and move away from the epifaunal structure (Dew 1990). For a review of how this area was evaluated as a marine protected area, refer to Ackley and Witherell (1999).

The Pribilof Islands Habitat Conservation Area encompasses 7,000 nm^2 (BSAI Amendment 21a). This area meets all HAPC criteria in that it contains rare habitat types (shell hash); it is important ecologically, and it is needed for juvenile blue king crab survival (Armstrong *et al.* 1985); and it is vulnerable to damage from bottom trawls via crushing, burying, and siltation. Other gear types probably do not significantly alter or impact this habitat.

The Red King Crab Savings Area covers 4,000 nm^2 (BSAI Amendment 37). This area does not meet all HAPC criteria, but contains a known concentration of adult red king crab. It contains primarily a sand/silt substrate, which does not appear as sensitive to the impacts of fishing gear as some other substrates.

The red king crab protection zones around Kodiak Island were established under GOA Amendment 26 to reduce crab bycatch and unobserved crab mortality, and, to a lesser extent, provide habitat protection. Trawling is prohibited in some areas year-round, whereas other areas are closed on a seasonal basis. The year-round areas encompass about 1,000 nm^2.

The southeast Alaska no-trawl area covers about 52,600 nm^2. This area contains a vast amount of deep water living substrates, including red tree coral. This prohibition of trawling east of 140° was adopted as part of the license limitation program (GOA Amendment 41).

The Sitka Pinnacles Marine Reserve covers 2.5 nm^2 (GOA Amendment 59). It is an unusually productive area that contains great concentrations of spawning lingcod and a variety of rockfish species, which find shelter in the algae and anemones along the rock walls. The ADF&G and NOAA Fisheries worked together to close the area to commercial fishing for groundfish and halibut, or anchoring by groundfish or halibut vessels. Commercial and recreational salmon fishing remains open.

Amendment 60 prohibits non-pelagic trawling in Cook Inlet. The purpose is to control crab bycatch mortality and protect crab habitat in an area that has depressed king and Tanner crab stocks. The area to be protected covers about 7,000 nm^2, including state waters, where consistent restrictions have been imposed by the Alaska Board of Fisheries.

Year-round closures to pollock trawling extending out to 10 nm have been implemented around 71 Steller sea lion rookeries and haulouts (46 in GOA, and 25 in the BSAI; Figure 3.6-9). It is assumed that one half of the total closed area indicated in the figure is comprised of land, resulting in approximately 22,000 nm^2 of area covered by water being closed to pollock trawling (NMFS 2001b). These closures were implemented by regulatory amendments in 1992: BSAI Amendment 20 and GOA Amendment 25.

The entire Aleutian Islands management area is closed to pollock fishing year-round to reduce interactions of Steller sea lions and trawl fisheries targeting pollock.

Southeast Trawl Closure Areas - the year round closure, adopted as part of the LLP, prohibits all trawling east of 140°W and closes about 53,000 nm^2, of which about 2,000 nm^2 is located on the shelf.

Internal Management Summary

Adequate habitat is essential for maintaining the productivity of fishery resources, and some species or life stages require particular habitats for food, reproduction, and shelter from predators. Numerous fishery closures and/or limitations that protect benthic habitat exist in the BSAI and GOA (see Table 3.6-1 and Figure 3.6-1). The existing management measures protecting habitat include fishing seasons and area quotas, fishing gear restrictions, time and area closures, and prohibited species restrictions. The primary focus of these past regulations has been to prevent potential damage to vulnerable crab habitat from bottom trawl gear. Some of the trawl closures are in effect year-round while others are seasonal (see Table 3.6-1). In general, year-round trawl closures have been implemented to protect vulnerable benthic habitat. Seasonal closures are used to reduce bycatch by closing areas where and when bycatch rates had historically been high. Additional measures to protect the declining western stocks of the Steller sea lion began in 1991 with some simple restrictions based on rookery and haulout locations, to specific fishery restrictions 2000 and 2001. Most of the areas listed on Table 3.6-1 allow fishing by gear other than trawl gear; however, ten sites shown on Table 3.6-1 lasting protection for part or all of the natural resources on a year-round basis.

Existing closures include three large areas in the Bering Sea (Red King Crab Savings Area, Nearshore Bristol Bay encompassing Area 512, and Area 516), together encompassing 27,000 nm^2. These areas, along with the Pribilof Islands closure area (7,000 nm^2) and the Opilio/Tanner Crab Bycatch Limitation Zone are closed to groundfish trawling and/or other specified fisheries such as scallop dredging on a seasonal or trigger basis to reduce potential adverse impacts on king crabs and crab habitat. The shallow areas in particular contain complex living and non-living substrates, which are essential for juvenile crab survival and are potentially sensitive to bottom trawling. The Chum and Chinook Salmon Savings Areas, the Herring Savings Area, and the Zones 1 and 2 areas are trigger closures that protect EFH for several species. While not year round, they encompass a total of nearly 125,000 nm^2. The Walrus Islands seasonal closures and the Steller sea lion critical habitat and trawl exclusion zones, and state waters (0-3 nm) are also closed to bottom trawling.

In the GOA, several discrete trawl closure areas (Kodiak No-Trawl Zones) covering about 1,500 nm^2 are set around Kodiak Island to reduce crab bycatch, but also serve to protect crab habitat. In addition, fishing with all gear types has been prohibited in an area around two nearshore pinnacles identified as supporting rare, vulnerable, and ecologically important habitat (Sitka Pinnacles Marine Reserve). The year round southeast trawl areas closure adopted as part of the LLP prohibits all trawling east of 140°W and closes about 53,000 nm^2, of which about 2,000 nm^2 is located on the shelf. Steller sea lion critical habitat and trawl exclusion zones are also identified in the GOA and will continue under Alternative 1. A proposal to close Cook Inlet to bottom trawling was approved by NPFMC in September 2000 to protect that area's crab habitat.

Putting the closure in perspective, the areas closed in the Bering Sea encompass more than twice the size of Georges Bank off the east coast of the U.S. The GOA closures encompass about 47,000 nm^2 (140,200 km^2), but a vast majority (80 percent to 90 percent) of this area is off the continental shelf, in extremely deep water.

3.6.6 Essential Fish Habitat Comparative Baseline

In general, the overall comparative baseline for habitat is generally adversely impacted in many areas, but unknown in others. Physical benthic information is limited to site-specific investigations. Existing information includes recent Bering Sea sampling grid efforts, older Outer Continental Shelf Environmental Assessment Program investigations for a portion for the central GOA, and no specific physical mapping effort for the Aleutian Islands. A complete representation of the physical benthic environment for Alaska does not exist. However some comparative conclusions can be drawn for each of the impacts in the three regions.

Non-Living Habitat Baseline

<u>Physical Characteristics: Bering Sea</u>

- Large, relatively shallow (<100m) plain consisting of mud, sand, sand and mud, and gravels. Boulders and smaller rock are scattered.
- Bedrock and gravel shelf break relatively far offshore, as compared to the Aleutian Islands.
- Non-living shell hash is common.

<u>Aleutian Islands</u>

- Volcanic island system consisting of higher relief and vertical rock wall bedrock ledges with numerous rock and gravel passes, canyons, and trenches.
- Shelf break relatively nearshore.

<u>GOA</u>

- Diverse rock, cobble, gravel, sand, and mud slope extending to bedrock shelf break consisting of canyons, banks, and flats. Non-living habitats have been historically exposed to fishing activity.

Generally, theses habitats can be categorized into hard substrates (bedrock, boulders), coarse substrates (cobble, gravel) and soft substrates (sand, mud). Harder substrates are considered static with some local relocation of smaller boulders. Softer and coarse substrates are thought to be altered in some degree, but the extent of these alterations is not well known.

Living-Habitat Baseline

Bering Sea

- Diverse benthic community consisting of infauna and epifauna such as sponges, soft and hard corals, anemones, and bryozoans.

Aleutian Islands

- Rich, diverse, concentrated benthic bio-structures such as sponges, soft corals, tree corals, and anemones.

GOA

- Diverse benthic community consisting of infauna and epifauna such as sponges, tree corals, soft corals, anemones, and bryozoans.

Benthic habitats have been exposed to fishing in larger areas of the Bering Sea, smaller areas in the GOA, and in more discrete locations in the Aleutian Islands. Benthic community diversity has been altered in these areas. However, the direct association of the fishing intensity and the degree of diversity alteration remains relatively unknown. Information suggests that areas subject to high disturbance notice some change in species diversity, as compared to similar habitats or historical species distribution. For this reason we rate the comparative baseline as conditionally significant adverse.

Habitat impacts modeling indicates that biostrucure has been reduced in these locations. In the Bering Sea, impacts to biostructure range from 1.8 to 9 percent of the fishable EEZ and 8.2 to 41.9 percent of the fished area. In the Aleutian Islands, baseline impacts ranged from 1.1 to 6.8 percent of the fishable EEZ and 5.4 to 32.6 percent of the fished area. In the GOA, baseline effects averaged over the entire fishable EEZ range from 0.9 to 6.9 percent and 3.8 to 29 percent of the fished area.

Long-lived corals and sponges are more prevalent in the Aleutian Islands. These organisms have life history traits that make them very susceptible to fishery-induced mortality. Past fishing practices have likely had lingering effects on these species. Distribution maps of living habitat based on survey data are provided in Heifetz (2001) and Malecha *et al.* (2003).

Distribution of Fishing Effort Baseline

Bering Sea

- Bottom trawl fisheries mainly target shallow and deepwater flatfish, Pacific cod, and rockfish.

- Pelagic fisheries mainly target walleye pollock and Atka mackerel.
- Pot gear fisheries mainly target Pacific cod and sablefish.
- Longline fisheries mainly target sablefish and rockfish.

<u>Aleutian Islands</u>

- Bottom trawl fisheries mainly target Pacific cod, Atka mackerel, and Pacific ocean perch.
- Pelagic fisheries mainly target walleye pollock.
- Pot gear fisheries mainly target Pacific cod, sablefish, and crab.
- Longline fisheries mainly target sablefish and rockfish.

<u>GOA</u>

- Bottom trawl fisheries mainly target Pacific cod, flatfish, and rockfish.
- Pelagic fisheries mainly target walleye pollock and Atka mackerel.
- Pot gear fisheries mainly target Pacific cod, sablefish and crab.
- Longline fisheries mainly target sablefish and rockfish.

FMPs for the BSAI and GOA distribute effort to specific fishery management units with the plan. Areas are seasonally and permanently closed to a particular gear type, during certain times, to afford protection of habitats. In the GOA, there exists a large area permanently closed to a specific gear type and a mixture of seasonal closures. In the Bering Sea there is a mixture of open fishing areas adjacent to areas closed to fishing. In the Aleutian Islands, closure areas exist for a limited number of fishing types and there are no permanent closure areas for all fishing activities.

3.6.7 Essential Fish Habitat Cumulative Effects Analysis Status

Even though at this time it is difficult to state a definitive baseline status for EFH in the BSAI and GOA, the topic will be brought forward for cumulative effects analysis. However, the following external events will not be brought forward since the impacts on EFH have not been directly observed or documented, or are likely to be minimal or have no lingering impacts:

- Vessel groundings.
- Introduction of exotic species.
- Toxic algal blooms.

- Volcanic eruptions.

- Earthquakes/underwater landslides.

All other internal and external events and management actions depicted on Table 3.6-2 will be brought forward for cumulative effects analysis.

3.7 Seabirds

The purpose of this chapter is to describe the baseline condition of seabirds as they relate to the federally managed groundfish fishery in Alaska. This baseline condition includes a description of the pertinent natural history for each species and an assessment of the various natural and anthropogenic factors that have shaped the status of each species in Alaskan waters. These accounts summarize the human and natural impacts on each species, to the extent that they are known, and thus provide the historical and scientific basis for analyzing the potential impacts of the alternative FMPs in Chapter 4.

The geographical and temporal scope of material presented in this chapter is not consistent between different species because of the wide variety in their distributions and the incompleteness of historical information. For some species, like the short-tailed albatross, the defining events that pertain to their present status in Alaska may be well known but took place many years ago in distant waters. For other species, like many of the auklets, there are few historical records of impacts and basic biological parameters such as population trends and winter distribution are still not known. The intent is to provide as much relevant information as possible for each species. In order to minimize redundancy in the individual species accounts, general information on seabird biology and the types of effects that may impact seabird populations are described below. Information pertinent to only one species or species group will be presented in the individual species accounts.

The USFWS is the lead federal agency for managing and conserving seabirds. Its Ecological Services Program addresses fish and wildlife conservation, endangered species, and contaminants issues through the review of federally permitted, licensed or constructed projects. USFWS biologists evaluate effects of land and water resource development projects and recommend mitigation measures to the developer or responsible federal agency. The USFWS Office of Migratory Bird Management is responsible for monitoring migratory seabird populations, and their distribution and abundance. Its goals are 1) to conserve migratory bird populations and their habitats in sufficient quantities to prevent them from being considered as threatened or endangered and 2) to ensure continued opportunities to enjoy both consumptive and non-consumptive uses of migratory birds and their habitats. Data are collected annually for selected species of marine birds at geographically dispersed breeding sites along the entire coastline of Alaska. Twelve sites, located roughly 300 to 500 km apart, are scheduled for annual monitoring, and a number of other sites are monitored every three years (Figure 3.7-1). Systematic monitoring provides long-term, time series data from which biologically-significant changes may be detected, and has alerted NOAA Fisheries to negative trends in individual seabird populations (USFWS 1999a).

Seabirds spend the majority of their life at sea rather than on land. Species from two Orders account for the vast majority of seabirds discussed in this document. The albatrosses, shearwaters, fulmars, and storm-petrels belong to the Order *Procellariiformes* and are commonly called "tubenoses." The Order *Charadriiformes* has two families of birds that make up another large part of Alaskan seabirds, the gulls (family *Laridae*), and the alcids (family *Alcidae*), which include the puffins, murres, auklets, and murrelets. Other bird groups contain pelagic members, including the loons, grebes, sea ducks, and phalaropes, but only those species that regularly interact with the federally managed groundfish fisheries will be discussed.

Thirty-eight species of seabirds breed in Alaska. More than 1,600 colonies have been documented, ranging in size from a few pairs to 3.5 million birds (Figure 3.7-2). The USFWS has compiled population estimates of seabirds from many researchers at many colonies throughout Alaska (USFWS 1998a). This database is now called the Beringian Seabird Colony Catalog and is updated on the Internet as new information becomes available. Although it is the best source of information that we have on Alaska seabird numbers, many of the estimates are rated as "poor" or "fair" in quality and the resultant population totals cannot be considered reliable for anything but the most generalized discussions. They are certainly not sufficient for documenting anything but the most extreme changes in population-levels. Breeding populations are estimated to contain 36 million individual birds in the BSAI and 12 million in the GOA (Table 3.5-62). Total population size (including subadults and non-breeders) is estimated to be approximately 30 percent higher. Five additional species that do not breed in Alaskan waters but occur in Alaska during the summer months contribute another 30 million birds (Table 3.5-63).

Assessment of Population-Level Effects

In order to monitor population trends, the USFWS has established sample plots for different species in various locations, as described above. Population monitoring has been reasonably good for 5 to 20 years for most seabird species that nest on cliffs, and for some that nest on flat ground or in burrows. Information with which to estimate population trends is lacking for some open- and burrow-nesters and for almost all crevice-nesters. Groups whose populations are not monitored adequately enough to estimate population trends anywhere in Alaska include jaegers, all gulls except for glaucous-winged, terns, auklets, horned puffins, and rhinoceros auklets. Groups for which population trends are known only in a few small areas include storm-petrels, cormorants, and pigeon guillemots. The inability to estimate seabird population trends prevents analysis of past effects of fisheries management or environmental change on the seabird species. Population trends for those species that can be monitored are presented in an annual report entitled, "Breeding Status, Population Trends, and Diets of Seabirds in Alaska," published by the USFWS (Dragoo *et al.* 2001). Trends vary for different species and in different areas of the state and are summarized in the individual species accounts.

There are actually many other sources of seabird abundance and distribution information from various at-sea transect surveys over the years, including many from the Outer Continental Shelf Environmental Assessment Program (OSCEAP) in the 1970s and early 1980s. These data have been essentially unavailable to researchers because of the many different formats and parameters used to record data. A major interagency effort to standardize and compile this data in a searchable database was recently initiated and spearheaded by the USFWS and the U.S. Geological Survey (USGS)/Biological Resource Division. The North Pacific Pelagic Seabird Database is presently under development and will be made available to the public upon completion.

Seabirds are characterized by low reproductive rates, low adult mortality rates, long life span, and delayed sexual maturity—traits that make populations extremely sensitive to changes in adult survival and less sensitive to fluctuations in reproductive effort (Ricklefs 1990, Russell *et al.* 1999, Saether and Bakke 2000, Ricklefs 2000). For this reason, Russell *et al.* (1999) caution against relying on productivity studies to reach conclusions about population dynamics. However, it is much more difficult to obtain long-term demographic data on seabirds to measure survival rates than it is to measure their reproductive success. As a practical matter, reproductive data are often collected in conjunction with population trend data and it is thus tempting to use reproductive data to "explain" population trends. The problem with attributing population changes to specific impacts is that, because seabirds are long-lived animals, it may take years or decades before relatively small changes in survival rates result in observable impacts on the breeding population. One study, which modeled impacts of the loss of juvenile wandering albatross from longline incidental take, estimated it would take 5 to 10 years to detect the decline in breeding populations and 30 to 50 years for the population to stabilize after conservation measures were taken (Moloney *et al.* 1994).

3.7.1 Past and Present Effects on Seabirds

Direct Mortality from Intentional Take

Some seabird species have been hunted by Alaska Natives for thousands of years and continue to be an important source of both meat and eggs in certain communities (Denlinger and Wohl 2001). Seabirds have also been used for clothing and decoration and are important in many cultural contexts. The impacts of subsistence hunts are concentrated during the breeding season and on the colonies most accessible to Native communities.

Commercial harvests of seabirds for meat, eggs, and feathers have not been widespread in Alaska, but there are historical accounts of specific colonies and species that have suffered major impacts (Veniaminov 1840). The commercial harvest of the once abundant short-tailed albatross on its breeding colonies in Japan during the early 1900s nearly wiped out the species, a situation from which it is still recovering (USFWS 1999b). In some cases, seabird nesting sites and breeding adults have been intentionally destroyed in an attempt to displace the birds from military facilities and airport runways, such as the Laysan albatross on Midway Island (NMFS 2001e).

Direct Mortality from Incidental Take in Fisheries

Seabirds are caught incidentally in all types of fishing operations. The risk of seabirds getting caught in fishing gear varies with the density and behavior of the bird species around the fishing vessel, the type of fishing gear used, and the techniques and devices used, if any, to deter or avoid the birds. Many factors contribute to the abundance and distribution of birds at sea, including the availability of natural prey, but many species are attracted to fishing vessels in order to forage on bait, offal, discards, and natural prey disturbed by the fishing operation. The sight and sound of swarming birds can attract other birds from many miles around. For some fishermen, watching the birds is an enjoyable part of their work at sea but mostly fishermen are too preoccupied with fishing to pay them much attention. Even among those who are interested in birds, only some can distinguish one species from another, especially immature birds and very rare species like the short-tailed albatross. Relying on self-reported seabird interactions would therefore underestimate the numbers of birds taken and lead to erroneous conclusions regarding the extent of biological impacts. The first step in getting reliable data is to have trained, dedicated personnel on-board fishing vessels to actually note which species are present and how many are caught. This is not an easy task on a busy commercial fishing vessel.

The definition of "take" in the Migratory Bird Treaty Act of 1918 is "to pursue, hunt, shoot, wound, kill, trap, capture, or collect, or attempt to pursue, hunt, shoot, wound, kill, trap, capture, or collect" (50 CFR 10.12). In a fishery context, "take" refers to birds killed or injured during commercial fishing operations, whether in fishing gear or by striking some part of a vessel. Under the Migratory Bird Treaty Act of 1918, take of migratory birds is illegal, even if it is accidental or inadvertent, unless permitted through regulations (such as hunting regulations or permit exemptions). Thus far, only certain forms of intentional take have been legalized in these ways. There are currently no regulations to allow unintentional take. The USFWS and Department of Justice are vested with enforcement discretion, which has been used in lieu of a permitting program. Enforcement has focused on those who take birds with disregard for the law and the impact of their actions on the resource, particularly where effective conservation measures are available but have not been applied ("Fact sheet" on Migratory Bird Treaty Act of 1918, K. Laing, USFWS). Executive Order 13186 (66 FR 3853-3856), "Responsibilities of Federal Agencies to Protect Migratory Birds", which was signed by the President on January 10, 2001, directs federal agencies to develop and implement a "Memorandum of Understanding" with the USFWS to promote the conservation of migratory birds affected by their actions, including mitigation of activities that cause unintentional take. NOAA Fisheries and USFWS are currently developing this framework document which will incorporate seabird protection measures designed for specific fisheries (K. Rivera, NOAA Fisheries National Seabird Coordinator, personal communication).

In addition to the Migratory Bird Treaty Act, the Bald Eagle Protection Act (16 U.S.C. 668(a)) specifically prohibits the taking of bald eagles. In February 2001, the USFWS surveyed the pollock shoreside fish processing facilities in Unalaska regarding interactions with bald eagles. Anecdotal information indicated that eagles were attracted to the pollock vessels delivering shoreside, with birds entering the ship holds and becoming caught in the hoppers as fish were being delivered. Occasionally an injured bird would be sent to the Bird Treatment and Learning Center in Anchorage, Alaska for rehabilitation. The Bird Treatment and Learning Center maintains a database recording information about the nature and cause of each bird's injury, but many birds received from Unalaska are not accompanied by information on the cause of the injury. The current database contains no birds reported as injured by groundfish fishing activities (Bird Treatment and Learning Center, personal communication).

The application of the ESA to the case of the endangered short-tailed albatross has had a major impact on the longline sector of the BSAI and GOA groundfish fisheries. The history of these ESA deliberations and management actions is detailed in the species account for short-tailed albatross (Section 3.7.4). On a global level, the Food and Agriculture Organization of the United Nations Committee on Fisheries called for increased research and mitigation of seabird take, among other species taken incidentally in worldwide fisheries, in its *Code of Conduct for Responsible Fisheries* (FAO 1995). NOAA Fisheries developed a national Bycatch Plan that addressed these issues in a document entitled, *Managing the Nation's Bycatch: Programs, Activities, and Recommendations for the National Marine Fisheries Service* (NMFS 1998b). The management actions taken to protect short-tailed albatross in the groundfish fishery have instituted the recommendations in these documents, including monitoring and mitigation, and provide substantial protection for other species as well.

Observer Program and Estimation of Incidental Take

NOAA Fisheries began to collect data on seabird/groundfish fishery interactions in 1992 and expanded those efforts through the existing North Pacific Groundfish Observer Program in 1993, 1999, and 2000 (BSAI FMP Amendments 13, 27, 37 and GOA FMP Amendments 18 and 30). The Observer Program also collects data for a wide variety of fishery management and research purposes (see Section 2.5). A major change in 1993 was to train observers in seabird identification and provide group or species identifications of incidentally caught seabirds. NOAA Fisheries coordinated with the USFWS to update the seabird section of the NOAA Fisheries observer manual and to incorporate a standardized format for reporting sightings of sensitive species. Observers began providing information on seabird avoidance measures being used by hook-and-line vessels in 1997. The information collection was expanded in early 1999 to incorporate more detailed information about the frequency of measures used during a fishing trip and specific characteristics of different avoidance measures. In 2000, observers began to record the type of seabird avoidance measures used by longliners on a haul-by-haul basis. Recently, NOAA Fisheries and USFWS have developed and distributed an improved species identification guide for seabirds that focuses on feet and bills, often the only identifiable body parts remaining when a bird is retrieved onboard.

The seabird incidental take estimation methods and procedures, developed by USFWS in consultation with NOAA Fisheries, are described in a report using 1993-1997 data from the longline fishery (Stehn *et al.* 2000). Standard statistical procedures ("separate ratio estimators" of stratified random sampling; Cochran 1977) for estimating a population total from a sample were used. USFWS and NOAA Fisheries calculated rates and estimates for all seabird species or species groups in each stratum of all fishing gears, statistical fishing areas, regions (BSAI or GOA), vessel types (processors, motherships, and catcher-only vessels), and time periods (annual or each of 13 four-week periods in a year) (Stehn *et al.* 2000). As requested by USFWS, the following eleven groups of seabirds were chosen for analysis: short-tailed albatross, black-footed albatross, Laysan albatross, unidentified albatross, fulmars, gulls, shearwaters, unidentified tubenoses, alcids, other bird species, and unidentified seabirds (those not identified to one of the other ten groups). The Observer Program data actually includes some records of birds that are identified to species but which are included in a species group for statistical and analytical purposes.

Incidental catch estimates were based on the number of seabirds by species in samples from observed hauls and the total commercial fish catch as estimated by the NOAA Fisheries blend program. The NOAA Fisheries method utilized two measures of fishing effort: total tons of groundfish catch per haul or set for the trawl fishery (NOAA Fisheries blend program), and the number of hooks or pots per set for both the longline and pot fisheries (estimated for the unobserved fishery in the NOAA Fisheries blend program using the average number of hooks or pots, respectively, in the observed fishery). The NOAA Fisheries Observer Program data is incorporated into the NORPAC database which records the number and weight of the fishery catch by species in the species composition samples and the estimated weight of the entire catch (all species combined) in the whole haul or set. NORPAC also records the number of hooks or pots in the sample and the estimated number of total hooks or pots in the whole set. The number of observed birds in a species composition sample per effort (tons or hooks or pots) of that sample was used to extrapolate the number of seabirds to the whole haul or set, and similarly upwards to the whole fishery, including the unobserved effort. Both the catch rate of birds (number of birds per weight of fish, or birds per 1,000 hooks) and the catch rate of fish (total weight of all fish species per hook/pot/net) were assumed to be equal for observed and unobserved hauls of the same gear, area, and time period. These assumptions may not hold, not necessarily because the presence of the observer may change the fishing practices of the skipper or crew, but rather because, for some other operational reason, the smaller (unobserved) vessels may have different catch rates than the large or mid-sized vessels. The constant catch rates for birds and/or fish among vessel size categories are untested and critical assumptions. If different catch rates do exist for different vessel size categories, then the average area catch rates and the estimates of the total seabird incidental catch number may be overestimated or underestimated.

In some fisheries around the world, observer data have not accounted for birds that are hooked on longlines as they were deployed but fell off before they were retrieved on board. One study from Australia (Gales *et* *al.* 1998) indicated that 30 percent to 95 percent of the birds coming out of the water fell off or were shaken off the gangions before being hauled aboard and were thus missed by observers. However, that study was based on an observer program that did not actively watch the groundline as it was retrieved. In the North Pacific Groundfish Observer Program, observers actually watch the groundline as it is retrieved and do tally birds that fall off before being retrieved on board. This accounts for some of the "unidentified seabird" data (S. Fitzgerald, NOAA Fisheries, North Pacific Groundfish Observer Program, personal communication).

Direct Mortality from Incidental Take on Longlines

At a global level, concerns about the incidental catch of seabirds on longlines led to the development of the *International Plan of Action for Reducing the Incidental Catch of Seabirds in the Longline Fisheries*, a voluntary plan endorsed by the Food and Agriculture Organization of the United Nations Committee on Fisheries (FAO 1999). The plan applies to countries in whose waters longline fishing is being conducted by domestic or foreign vessels, and countries which conduct longline fishing on the high seas and in the EEZ of other countries. The international plan calls for individual countries to develop distinct national plans of action. Consequently, in addition to the local action taken by NPFMC and the NOAA Fisheries Alaska Regional Office, NOAA Fisheries and the USFWS have developed a *National Plan of Action for Reducing the Incidental Catch of Seabirds in the Longline Fisheries* (NMFS 2001d). The purpose of the plan is to reduce seabird incidental take in those U.S. longline fisheries where incidental take is determined to be a problem by a regional fishery management council. While not prescribing specific mitigation measures, the plan provides a framework of actions that the agencies can use within their area of authority. It is intended to give NPFMCs additional flexibility to incorporate local, fishery-specific measures. The national plan calls for the regional councils to assess the extent of incidental take in their fisheries on a regular basis, mitigate problems quickly, and cooperate with national and international agencies to address more widespread issues. NOAA Fisheries Alaska Region provides an annual assessment of seabird incidental take in all three groundfish gear sectors in the "Ecosystem Considerations" section of the annual Stock Assessment and Fishery Evaluation report (NPFMC 2002c, SAFE, available from the website: http://www.fakr.noaa.gov/npfmc/safes/safe.htm.

Seabirds are hooked on longline gear as they attempt to capture the bait or scavenge fishery wastes, mostly while the line is being deployed but sometimes as it is hauled aboard. With the closure of the international high-seas driftnet fisheries in 1992, longline fishing has grown tremendously and is now considered the most serious global threat faced by albatrosses and other tubenoses (Brothers *et al.* 1999a). The impacts of longline mortality on particular species are discussed in the separate species accounts.

Estimates of the annual seabird incidental take in the groundfish longline fisheries, based on 1993 to 2001 data, indicate that approximately 14,400 seabirds were taken annually in the BSAI at an average rate of 0.09 birds per 1,000 hooks (Table 3.7-1). The species composition of these birds is: 60 percent fulmars, 19 percent gull species, 12 percent unidentified seabirds, 4 percent albatross species, 3 percent shearwater species, and 2 percent all other species (Table 3.7-2, Figure 3.7-3). In the GOA, about 1,030 birds were estimated to be taken annually between 1993-2001 at an average rate of 0.03 birds per 1,000 hooks. The species composition of these birds is: 46 percent fulmars, 35 percent albatrosses, 11 percent gull species, 4 percent unidentified seabirds, 3 percent shearwater species, and less than one percent all other species (Table 3.7-3, Figure 3.7-3).

In the following species accounts, data on the incidental take in the groundfish fisheries are reported for each species or species group. In an effort to evaluate the effectiveness of the seabird protection measures that have been enacted (see below), the average take from 1993-1996 is compared to the average take from 1997-2001. However, these comparisons should be viewed with caution for several reasons. First, many longline fishermen began using a variety of seabird deterrence techniques of their own design before the techniques were required in regulations. In fact, many of the techniques that are included in the regulations came from the longline fleet's initiative in developing effective measures. There are no data on which techniques were used or how many vessels used them, but the data from 1993-1997 are clearly not a "no deterrence" baseline. Second, many variables influence the effectiveness of a given deterrence technique, including the quality of the deployment. One factor not under the control of the fishermen is the behavior of the birds. Many fishermen and observers have reported instances where flocks of birds swarmed the vessel and appeared to be unusually aggressive and persistent in going after bait, ignoring all attempts to deter them. These birds were assumed to be under great nutritional stress due to an area-wide shortage of natural food and the fishing vessel provided the only source of food available. Certain years, like 1997 and 1998, have anomalously high incidental take rates for many species groups which indicates that these years may have had widespread food shortages, at least for certain periods during the longline seasons. Since the data set compares a group of four years (1993-1996) with a group of five years (1997-2001), one or two high years can dominate an average take level. Again, these comparisons should be viewed with these caveats in mind.

It is difficult at this time to make valid comparisons of bird incidental catch rates between regions. It is difficult to discern whether the differences between the BSAI and GOA estimated incidental catch rates are due to vastly different levels of fishing effort in each region, different vessel types used in each region (small catcher vessels in the GOA and large catcher processors in the BSAI), different distribution and abundance of birds, or some other factor. It may be possible to use the Observer Program database to make a statistical comparison of incidental catch rates from different areas but this work would require some new budgetary resources.

As a result of ESA Section 7 consultations with the USFWS and their resulting BiOp on the protection of short-tailed albatross, NOAA Fisheries required the BSAI and GOA groundfish longline fleet to employ specified seabird avoidance measures to reduce incidental take in 1997 (62 FR 23176). Prior to 1997, avoidance measures were not required but observer information indicates that some vessel operators used mitigation measures voluntarily. In order to protect short-tailed albatross in other North Pacific fisheries, NOAA Fisheries required seabird avoidance measures to be used by vessels fishing for Pacific halibut and sablefish in U.S. EEZ waters off Alaska in 1998 (63 FR 11161) and for the Hawaii pelagic longline fleet in 2002 (67 FR 34408). The Alaska longline seabird avoidance regulations have been changed several times to reflect improvements in techniques and the need to evaluate the effectiveness of those techniques in reducing incidental take. The U.S. Coast Guard is responsible for at-sea enforcement of these and other regulations and regularly checks for compliance during at-sea boardings. Reports of these compliance checks are made in the Coast Guard's report to NPFMC at each meeting. NOAA Fisheries Enforcement currently is investigating several cases involving alleged violations of seabird avoidance regulations and other seabird-related issues (T. DuBois, NOAA Fisheries Enforcement, personal communication).

As of the 2002 season, all vessel operators using hook-and-line gear to fish for groundfish and Pacific halibut must conduct fishing operations as follows:

- Use baited hooks that sink as soon as they are put in the water.

- Discharge offal in a manner that distracts seabirds from baited hooks (if discharged at all during the setting or hauling of gear).

- Make every reasonable effort to ensure that birds brought on board alive are released alive.

In addition, all applicable hook-and-line vessels at or more than 26-ft length overall, must employ one or more of the following four measures:

- Set gear at night (during hours specified in regulation);

- Tow a streamer line or lines during deployment of gear to prevent birds from taking hooks.

- Tow a buoy, board, stick, or other device during deployment of gear at a distance appropriate to prevent birds from taking hooks;

- Deploy hooks underwater through a lining tube at a depth sufficient to prevent birds from settling on hooks during the deployment of gear.

Fishermen currently are provided some flexibility to choose the most appropriate and practicable methods for their vessel size, fishery, and fishing operations and conditions.

In September of 1998, two short-tailed albatross were taken by longline vessels that were using required avoidance measures in the BSAI cod fishery. However, at least one of these takes was the result of a poorly deployed avoidance technique. Concerned that the incidental take threshold for short-tailed albatross could be exceeded, the longline fleet petitioned NPFMC to improve the seabird avoidance measures and to specify performance standards for their deployment. In 1999, NPFMC recommended revising the existing regulations to make the most effective avoidance techniques mandatory. They also recommended that NOAA Fisheries undertake for the first time a comprehensive scientific study to experimentally determine the effectiveness of seabird deterrent measures. This research, conducted by the Washington Sea Grant Program in 1999 and 2000 in the IFQ halibut and sablefish fishery and in the BSAI Pacific cod freezer-longliner fishery, was a cooperative effort funded by NOAA Fisheries, USFWS, and the Washington Sea Grant Program, with major support by the North Pacific Groundfish Observer Program and the longline industry. It was the largest study of its kind in the world with over 1.2 million hooks set in the sablefish fishery and over 6.3 million hooks set in the cod fishery.

The results of the study were presented to NPFMC in October 2001 in its final report, "Solutions to Seabird Bycatch in Alaska's Demersal Longline Fisheries" (Melvin *et al.* 2001). The study found that paired streamer lines of specified performance and material standards successfully reduced seabird incidental take in both years, regions, and fleets by 88 to 100 percent relative to controls with no deterrent. Single streamer lines of specified performance and material standards were slightly less effective than paired streamer lines, reducing seabird incidental take by 96 percent and 71 percent relative to controls with no deterrent in the sablefish and cod fisheries, respectively. While the study participants took special precautions when short-tailed albatross were sighted and none of these birds were caught during the study, the dramatic reduction of incidental take of similar-feeding species with the use of paired streamer lines indicates that the risk of incidental take to the endangered species would be greatly reduced if this avoidance measure was widely adopted. However, despite their effectiveness in reducing overall take, single streamer lines were five times more likely to take Laysan albatross compared to paired streamers. The Washington Sea Grant study did not recommend use of single streamers to reduce the potential for taking short-tailed albatross.

Based on the results of their research (Melvin *et al.* 2001), the Washington Sea Grant Program, USFWS, and NOAA Fisheries jointly developed recommended changes to the existing seabird avoidance regulations required in the groundfish and halibut hook-and-line fisheries off Alaska. At its October and December 2001 meetings, NPFMC reviewed these recommendations, made some changes, and requested NOAA Fisheries to implement the necessary regulations. NPFMC's recommendations include the following:

- Vessels over 55 ft (16.8 m) LOA using hook-and-line gear in the EEZ would be required to use paired streamer lines of specified performance and materials standards.

- Vessels over 26 ft (7.9 m) LOA to 55 ft (16.8 m) LOA using hook-and-line gear would be required to use less stringent measures such as a buoy bag line or single streamer line—each with its own specified performance and materials standards. The requirement would depend upon fishing location ['Inside' or EEZ, where 'Inside' is PWS (NOAA Fisheries Area 649), southeast inside district (NOAA Fisheries Area 659), and state waters of Cook Inlet], vessel type (if masts, poles, or rigging are on vessel), and gear type (if snap gear is used).

- The performance and material standards for measures required on smaller vessels would be guidelines for an interim one-year period, at which time they would become required.

- Directed discharge (through chutes, pipes, or other similar devices suited for purpose of offal discharge) of residual bait or offal from the stern of the vessel while setting gear would be prohibited.

- Prior to offal discharge, embedded hooks would be removed from offal.

- A Seabird Avoidance Plan would be required onboard the vessel.

- Vessels less than or equal to 32 ft (9.8 m) LOA fishing for halibut in IPHC Area 4E within 0 to 3 miles of shore would be exempt from seabird avoidance measures.

- Vessels less than or equal to 26 ft (7.9 m) LOA would continue to be exempt from seabird avoidance measures.

The proposed seabird avoidance measures would apply to the operators of vessels using hook-and-line gear for:

- Pacific halibut in the IFQ and CDQ management programs (0 to 200 nm).

- IFQ sablefish in EEZ waters (3 to 200 nm) and waters of the State of Alaska (0 to 3 nm), except waters of PWS and areas in which sablefish fishing is managed under a State of Alaska limited entry program (Clarence Strait, Chatham Strait).

- Groundfish (except IFQ sablefish) with hook-and-line gear in the U.S. EEZ waters off Alaska (3-200 nm).

The longline fleet has been proactive in adopting these techniques and most vessels may already be in compliance in advance of the forthcoming regulations. At its March 2002 meeting, the Alaska Board of Fisheries approved a proposal that will change state groundfish regulations to parallel federal regulations governing seabird avoidance measure requirements for operators in hook-and-line fisheries.

NOAA Fisheries published the proposed regulations in February 2003 (68 FR 6386) and final regulations on January 13, 2004 (69 FR 1930). These regulations are in effect as of February 2004 and vary by length of vessel, area fished, type of gear, and other factors. They are available at NOAA Fisheries website http://www.fakr.noaa.gov/protectedresources/seabirds.html.

NOAA Fisheries attempted to incorporate the most current information as possible into this Final Programmatic SEIS document. Seabird avoidance measures are discussed throughout the following species accounts in Chapter 3 and in the analysis of alternatives in Chapter 4. Due to the timing of the publication of the Final Programmatic SEIS document and the newest regulations published in January 2004, only the Preferred Alternative analysis specifically references the new seabirds BiOps. However, the analyses of seabird impacts under Alternatives 1 through 4 in the Final Programmatic SEIS were written anticipating the adoption of these new regulations and therefore, no changes to significance ratings were necessary. The interested reader is directed to NOAA Fisheries website for the most recent fishing regulations that concern seabirds.

Direct Mortality from Incidental Take in Trawls

On trawl vessels only, observers may use any one of three different sample sizes of groundfish catch to monitor incidental take of birds in a haul. Observers are currently advised to use the largest of the three sample sizes whenever possible. However, observers do not record the sample size choice for monitored hauls which have no observable seabird take. Thus, it has been necessary to calculate two alternative sets of estimates for incidental take in trawls based on the smallest and largest sizes of sampling effort recorded. In each of these two alternative calculation methods, a "separate ratio estimator" was used to bind the results of the catch ratios and variances of data from the three different sample sizes into arbitrary equal samples which were then extrapolated to the total catch effort of the NOAA Fisheries blend program. Although, it is not known with certainty which of the two sets of estimates is more accurate, the level of seabird bycatch on trawl vessels during the 1990s probably lies somewhere between the two sets of estimates. Observer Program data on the numbers and species composition of incidental take in the combined BSAI and GOA trawl fisheries is currently available for 1997 through 2001 (Table 3.7-4). During this time period, an estimated average of between 961 to 9,687 seabirds were taken in trawls each year. Based on the means of the high and low estimates for each species group, the species composition of these birds is approximately: 58 percent fulmars, 15 percent shearwaters, 8 percent unidentified seabirds, 5 percent gulls, 5 percent alcids, 5 percent other species, 2 percent unidentified tubenoses, and 2 percent Laysan albatross.

Diving species, including some alcids, are taken more frequently in trawls than they are on longlines. However, trawls actually take many more individuals of the surface-feeding and shallow-diving species than they do of deep-diving species. Many of these birds are probably caught in trawls as they attempt to scavenge processing wastes or capture escaping fish as the net is being retrieved, rather than while it is actively fishing at depth. NOAA Fisheries analysis of 1997 to 2001 observer data indicates that trawl gear accounted for 6 to 35 percent of the total average annual incidental take of seabirds in the BSAI and GOA groundfish fisheries, depending on the trawl sampling methodology used (Figure 3.7-4).

Direct Mortality from Incidental Take in Pot Gear

Pot gear is the cleanest type of fishing as far as seabird incidental take is concerned. It accounts for only a small fraction of the total numbers of seabirds taken in the BSAI and GOA groundfish fisheries (Figure 3.7-4). Observer Program data on the numbers and species composition of incidental take in the combined BSAI and GOA pot fisheries are currently available for 1993 through 2001 (Table 3.7-5). During this time period, an estimated 48 birds were taken in pot gear per year, about 70 percent of which were northern fulmars. Many of these birds may have been killed by collisions with pot gear as it sat on deck, rather than as it was fishing.

Direct Mortality from Vessel Strikes

Seabirds sometimes strike vessels and fishing gear in flight. Some birds fly away without injury but others are injured or killed. The Observer Program records of bird-strikes from 1993-2000 have been entered into the Observer Notes Database (USFWS, Anchorage). Statistical analysis of the bird-strike data has not been completed but some preliminary summaries can be made (NPFMC 2002c). There are 120 definitive records of birds striking the vessel (n = 101) or the rigging (n = 19). The main species involved in vessel strikes were northern fulmars (564 birds in 38 incidents), Laysan albatross (21 birds in 15 incidents), storm-petrels (631 birds in 19 incidents), crested auklets (1,305 birds in seven incidents), and sooty shearwater (526 birds in six incidents), with almost half of the birds being killed or injured. As the last two records indicate, collisions of large numbers of birds occasionally occur. In one historical account, approximately 6,000 crested auklets were attracted to lights and collided with a fishing vessel near Kodiak Island during the winter of 1977 (Dick and Donaldson 1978). Bird strikes are probably most numerous during the night and during storms or foggy conditions when bright deck lights are on, which can cause the birds to become disoriented. From the limited number of observer records that included weather observations (n = 53), most of the bird-vessel interactions occurred when it was snowing (83 percent), with some occurring during rain (10 percent) or fog (seven percent). The proximity of the vessels to seabird colonies during the breeding season is also a factor (V. Byrd, USFWS, personal communication).

Many trawl vessels deploy a cable ("third wire") from the vessel to the trawl net monitoring device (sonar transducers). There are 16 records of birds striking the "third wire" in the Observer Notes Database. These incidents involved 79 birds, mainly fulmars and Laysan albatross, with approximately 90 percent mortality. However, these cables are not typically monitored by groundfish observers and any birds killed by such collisions would not be likely to make their way into the trawl net and would therefore not be recorded in observers' haul samples. The distribution and extent of seabird mortalities or injuries by species are therefore unknown. NOAA Fisheries' AFSC is currently pursuing the possibility of using video technology to evaluate this issue. NOAA Fisheries and USFWS are presently trying to determine if this impact poses a threat to short-tailed albatross (USFWS 2000c). Solutions may be as simple as hanging streamers from the third wire (G. Balogh, USFWS, Anchorage – personal communication).

Indirect Mortality or Reduced Fitness

The following effects are classified as indirect because the impacts are removed in time and/or space from the initial incident. In some cases, individual birds may be killed outright by the effect. In other cases, individuals are affected in ways that may decrease their chances of surviving natural phenomenon or reproducing successfully. These sub-lethal impacts may thus decrease their overall "fitness" as individuals and may have population-level implications if enough birds are impacted.

Indirect Effects Through Changes in Prey Availability

Seabird species differ greatly from one another in their prey requirements and feeding behaviors, leading to substantial differences in their responses to changes in the environment. Diets consist largely of fish or squid less than 15 cm long and large zooplankton. Although they may take a wide variety of prey species during the year, most seabirds in a given area and time depend on one or a few prey species (Springer 1991b). Diets and foraging ranges are most restricted during the breeding season, when high-energy food must be delivered efficiently to nestlings, and are somewhat more flexible at other times of the year. Winter foraging ecology is not known for most species (Hunt *et al.* 1999b). Seabird diets have been summarized in Tables 3.5-62 and 3.5-63 and specific research results are cited in the following species accounts.

A major constraint on seabird breeding is the distance between the breeding grounds on land and the feeding zones at sea (Weimerskirch and Cherel 1998). Breeding success in most species varies among years, but in stable populations, poor success is compensated for by occasional good years (Boersma 1998, Russell *et al.* 1999). Adult non-breeding seabird survival is unlikely to be affected by the common interannual variability of prey stock because adults can shift to alternative prey or migrate to seek prey in other regions. In contrast, breeding birds are tied to their colonies and local fluctuations in fish availability can have a dramatic effect on seabird reproduction. If food supplies are reduced below the amount needed to generate and incubate eggs, or if the specific species and size of prey needed to feed chicks are unavailable, local reproduction by seabirds will fail (Hunt *et al.* 1996a). The natural factor most often associated with lower breeding success is food scarcity (Kuletz 1983, Murphy *et al.* 1984, Murphy *et al.* 1987, Springer 1991b, Furness and Monaghan 1987, Croxall and Rothery 1991, Cairns 1992). Reproductive success, therefore, is usually limited by food availability (Furness 1982, Croxall and Rothery 1991).

Some authors believe that food is more limited in winter than summer for many species (Croxall 1987). Outside the breeding season, diets, feeding habitats, energy requirements, and distribution have been studied only minimally for most seabird species. Limited information suggests that in winter months many seabirds consume a greater variety of fish as well as higher proportions of zooplankton and invertebrates (DeGange and Sanger 1986, Sanger 1987).

The availability of prey to seabirds depends on a large number of factors and differs among species and seasons. All seabird species depend on one or more oceanographic processes that concentrate their prey at the necessary time and place; these include upwellings, stratification, ice edges, fronts, gyres, and tidal currents (Schneider *et al.* 1987, Coyle *et al.* 1992, Elphick and Hunt 1993, Hunt and Harrison 1990, Hunt

1997, Hunt *et al.* 1999b, Springer *et al.* 1999). Oceanographic phenomena that influence seabird foraging habitat primarily are on the scale of hundreds of meters to hundreds of kilometers (Hunt and Schneider 1987). Favorable foraging conditions are likely to last for a relatively short time (hours to weeks) at one spot and for many seabirds foraging in shelf waters, small-scale physical processes that concentrate prey are very important for successful foraging (Hunt *et al.* 1999b). Prey availability may also depend on the ecology of food species, including productivity, other predators, food-web relationships of the prey, and prey behavior, such as migration of fish and zooplankton. Many factors that influence prey availability are completely unknown. Most critical is the lack of information on how events beyond a seabird's foraging range may influence the prey availability. Such factors may include environmental changes, fluctuations in regionwide stocks of forage and non-forage species, and commercial harvests.

Reductions in the availability of forage fish to seabirds have been attributed to both climatic cycles and commercial fisheries but a NRC study (1996) concluded that both factors probably are significant. Regime shifts are major changes in atmospheric conditions and ocean climate that take place on multi-decade time scales and trigger community-level reorganizations of the marine biota (Anderson and Piatt 1999). Two cycles of warm and cold regimes have been documented in the GOA in the past 100 years, with the latest shift being from a cold regime to a warm regime in 1977. The consequences of this shift on fish and crustacean populations have been documented, including major improvements in groundfish recruitment and the collapse of some high-value forage species such as capelin and Pacific sand lance (Anderson and Piatt 1999). Unfortunately, that is around the time that data on most Alaskan seabird populations began to be collected so the effects of regime shifts on seabird populations can only be surmised on general principles. Declines in the breeding success and populations of piscivorous (fish-eating) species in several areas of Alaska have been attributed to the general decline in certain forage fish species (Springer 1992, NRC 1996, Piatt and Anderson 1996, Kuletz *et al.* 1997, Francis *et al.* 1998, McGowan *et al.* 1998, Anderson and Piatt 1999, Agler *et al.* 1999). However, directed fisheries on forage fish can deepen and prolong their natural low population cycles (Duffy 1983, Steele 1991). In nations with directed forage fish fisheries, some stocks have been decimated due to a combination of climatic and fishery pressures, which led to local population declines in seabirds (Duffy 1983, Anker-Nilssen and Barrett 1991, Crawford and Shelton 1978).

Competition and predation may also influence seabird prey availability. Links between seabirds and other species could be direct or they could be extremely diffuse and indirect. Possible links include competition between seabird species (Mehlum *et al.* 1998, Hunt *et al.* 1999b); competition of piscivorous seabirds with other large marine predators such as marine mammals and fish (Harrison 1979, Hunt 1990, Obst and Hunt 1990); cannibalism by large pollock on the smaller pollock preyed on by some seabirds; competition for food among forage species, such as small pollock, capelin, Pacific sand lance, herring, myctophids, and squid; competition between planktivorous seabirds with whales or planktivorous fish (including forage fish of other seabird species); and even ecosystem links with groups such as jellyfish. Little information is available on the magnitude or direction of these potential links.

The fraction of total exploitable stocks in the EBS that are consumed by seabirds has been estimated at 3 percent for pollock and less than one percent for herring (Livingston 1993), which is similar to an estimate of 4 percent for Pacific sand lance in the North Sea (Furness and Tasker 1997). Seabirds, therefore, may account for a very minor proportion of forage fish mortality, even for the young age classes that they consume (Livingston 1993). Seabirds may have greater impacts on fish stocks within foraging range of seabird colonies, however, because the birds are concentrated there during summer (Springer *et al.* 1986, Roseneau *et al.* 1998, Birt *et al.* 1987). About 15 to 80 percent of the biomass of juvenile forage fish may be removed by birds near breeding colonies each year (Wiens and Scott 1975, Furness 1978, Springer *et al.* 1986, Logerwell and Hargreaves 1997). This suggests that food availability to birds may be limited, at least in a given season, by the size of the local component of fish stocks. Seabirds may, therefore, be vulnerable to factors that reduce forage fish stocks in the vicinity of colonies (Monaghan *et al.* 1994).

In April 1997, NPFMC adopted Amendment 36 to the BSAI FMP and Amendment 39 to the GOA FMP to prevent the development of commercial fisheries for forage fish. NOAA Fisheries published the final rule implementing the regulations on March 17, 1998 (63 FR 13009). Amendments 36/39 defined a forage fish species category and prevented the development of a commercial directed fishery for forage fish. The amendment established a 2 percent maximum retainable bycatch (MRB) amount in other directed fisheries and prohibited the selling, bartering, trading, or receiving any remuneration for forage fish species. However, within the 2 percent limit, forage fish could be reduced to fish meal and sold. Forage fish identified under this action include: capelin, smelt, lanternfish, deep-sea smelts, sand lance, bristlemouths, pricklebacks, gunnels, Pacific sandfish, and euphausiids. These amendments are presumed to have had beneficial impacts on the availability of prey to seabirds but no quantitative benefits have been demonstrated to date.

Indirect Effects Through Ingestion of Processing Wastes and Discards

Scavenging of fishery wastes can influence population trends in either direction. About 30 percent of the total food consumed by seabirds in the North Sea is estimated to be offal and discards (Tasker and Furness 1996). These foods are, therefore, of direct importance in sustaining populations of some seabirds. Processing wastes may not be adequate foods for successfully rearing chicks (Murphy *et al.* 1984, Baird and Gould 1986, Irons *et al.* 1986, DeGange and Sanger 1986), but abundant scavenging during winter may increase populations because survival of immature birds is enhanced (Patten and Patten 1982). On the other hand, if populations of the larger gull species increase, local populations of other species may be reduced through increased competition for nest sites and predation pressure on their young (Spaans and Blokpoel 1991, Furness 1999). Sudden withdrawal of discards might cause the predatory species to increase pressure on other species long before the predator populations decline to previous levels (Furness 1999). In the North Sea, numerous instances are cited showing potential relationships between discards in diets and changes in breeding populations of different species, some of which were beneficial and some adverse (Garthe *et al.* 1999). No data are available on these effects in Alaska.

The seabird species whose normal foraging behavior includes scavenging on dead material, including the tubenoses and gulls (Patten and Patten 1982, Furness and Ainley 1984, Gould *et al.*1997), are strongly attracted to the food provided by fishing vessels. While this may benefit individual birds, it also places them in danger from entanglement and incidental take in fishing gear. As discussed above, incidental take may have population-level impacts on some seabird species and is a continuing fishery management concern. The timing and method of disposing of fishery wastes is an important element in efforts to reduce incidental take. The net impact of fishery wastes on particular seabird species, whether beneficial or adverse, has not been demonstrated in Alaska.

Indirect Effects Through Disturbance by Fishing Vessels

Fishing vessels can affect seabird populations whether or not the vessels are engaged in fishing or processing activities. Many surface-feeding birds are attracted to vessels (Furness 1999), but others, such as marbled murrelets, may be displaced from forage areas by vessel activity (Kuletz 1996). The magnitude of the impact on such species depends on the location, timing, and frequency of vessel traffic and on how closely those factors coincide with important seabird foraging areas. While avoidance behavior has been observed in many areas, measurable impacts of vessel traffic on seabird survival or reproduction have not been demonstrated in Alaska.

There is some concern that fishing activity, especially trawling, may have detrimental impacts on seabirds by disrupting the schooling behavior of their prey and therefore decreasing their foraging success. Although the intensity and longevity of trawling impacts on the structure and distribution of forage fish schools are not known, improvements in hydroacoustic methods may allow such research to be conducted in the future. However, given the large number of variables that influence foraging success for different species and the ability of birds to search for prey over large distances, it is unlikely that any localized disruptions of the prey field could be demonstrated to have specific adverse effects on seabirds. On the other hand, there is evidence that some forms of trawling may make fish vulnerable to diving birds by disturbing or injuring the fish. Black guillemots (Ewins 1987) and great cormorants (*Phalacrocorax carbo sinensis*) in the North Atlantic Ocean (Camphuysen 1999) are two species that may have learned to take advantage of such disruptions.

Indirect Effects Through Contamination by Oil Spills

The threat of oil spills to seabirds is well-known. All types of oil and fuel are dangerous, and only a few drops of oil are enough, under some situations, to kill a seabird. Oil kills birds because it damages the feathers, which are necessary to insulate the bird from cold water, and also because the bird ingests toxic oil as it tries to clean its plumage and suffers damage to various internal organs and its immune system (Burger and Fry 1993). Oiled feathers also affect the bird's buoyancy and ability to dive and fly. Since the insulation value of the feather is reduced, energy demands increase, requiring the birds to feed more when they are least able to do so (Wiens 1995). Reproductive success can also be decreased through effects to the endocrine system, transferring oil to eggs which affects hatching success, and through the loss of mates (Fry *et al.* 1987). In addition to the direct pathways of exposure listed above, birds may be indirectly affected by oil through habitat loss (e.g., vegetation mortality), habitat degradation, and diminished food populations (Huguenin *et al.* 1996).

A dramatic accident like the *Exxon Valdez* oil spill may kill hundreds of thousands of seabirds and reduce local populations of vulnerable species for several years (Piatt *et al.* 1990, Piatt and Ford 1996). The types of oil spills most commonly associated with fishing vessels are the chronic small spills of refined oil products (less than 100 gallons) caused by accidents during routine activities such as fuel transfer operations and bilge cleaning. For instance, in Dutch Harbor between November 1997 and June 1998, 13 oil or fuel spills were reported. The largest spill was 47,000 gallons from the *M/V Kuroshima*; the remainder of the spills were 1 to 15 gallons each. In the winter of 1996, the freighter *M/V Citrus* collided with a crab processing vessel off St. Paul Island, spilling an unknown quantity of bunker oil, which killed over 1,700 birds (Flint *et al.* 1998). The overall risk of these threats also depends on the number and condition of all vessels in the area, many of which are not associated with the fishing industry. Due to the great number of variables, including spill type and volume, wind and ocean currents, and season, the overall risk of oil contamination has not been quantified for particular species or in specific ocean areas. A report of data from 1995-2001 from the Alaska Department of Environmental Conservation (ADEC) indicates that the number of spills and volume from all sources in the BSAI and GOA is greatest during the summer months (ADEC 2001).

Many field and laboratory studies have demonstrated the differences in the effects of oil on various groups of birds. The three most important factors affecting sensitivity are behavior, distribution, and reproductive rate (Huguenin *et al.* 1996). The species at most risk are diving seabirds, which spend more time resting on the water than do surface-feeders (King and Sanger 1979). More specifically, of all bird groups alcids are considered to be the most vulnerable to oil, followed by diving ducks. Surface feeding and plunge feeding pelagic seabirds (albatrosses, petrels, fulmars, shearwaters, skuas, and jaegers) are moderately sensitive to oil effects given their extreme reliance on open-water marine habitats for feeding and roosting, making them susceptible to incidents in these settings. Gulls and terns are usually oiled in low proportion to the exposed populations because they are readily able to avoid oil (Huguenin *et al.* 1996).

Indirect Effects by Introducing Mammalian Predators to Nesting Islands

Seabird colonies on nesting islands are extremely sensitive to introductions of exotic predators. Seabirds nest on inaccessible islands and steep cliffs because these habitats provide protection against predators such as arctic fox (*Vulpes fulva*), red fox (*Alopex lagopus*), and rats (*Rattus norvegicus*). These mammals attack eggs, chicks, and even adult birds. When Vitus Bering first discovered Alaska in 1741, most islands in the Aleutian chain, along the south coast of the Alaska Peninsula, and in the GOA were not inhabited by foxes (Bailey and Kaiser 1993). In contrast, arctic foxes and, on a few nearshore islands, red foxes were indigenous to the islands in the Bering Sea. Apparently, foxes did not occur on any of the central or western Aleutians. Starting in 1750 and continuing into the 1930s, it was the policy of the Russian and, later, U.S. governments to facilitate the introduction of foxes for commercial fur farming purposes. The intent was for the foxes to feed on the seabirds, which they did most efficiently. In some cases, rats and voles were introduced to serve as alternative prey for foxes, but they preyed on seabirds and their eggs. Burrow and cliff-nesting species as well as Aleutian Canada geese were especially hard hit. Concern for the seabirds (and crash of the fox market) finally put an end to the practice. The USFWS has actively exterminated foxes on many islands since then, except where they occur naturally (Bailey 1993), and the foxes have died out on many other islands after eliminating the birds. Auklets and other species have begun to recolonize some of those islands after the removal of the foxes but populations are probably still depressed from pre-fox levels (Bailey and Kaiser 1993).

Rats are not native to Alaska, but they have become established on 22 Alaskan islands, including Kodiak and some of the Aleutian Islands. Fishing vessels and other ships inadvertently transport rats to previously uninvaded islands when the rats jump ship at docks or after wrecks (Brechbill 1977, Jones and Byrd 1979, Bailey 1993). At present, rats pose the greatest introduced predator threat to seabirds breeding in Alaska. Rats are voracious predators and can burrow, enter crevices, and climb cliffs with great agility (Jones and Byrd 1979). They can also kill small adult birds (Bailey 1993). Rats are a major management concern and the USFWS in Alaska has an extensive program to reduce the threat of new rat invasions. Efforts include maintaining networks of poison-bait boxes at ports on rat-free islands; training local communities to monitor and counteract rats aboard ships and on land; conducting public outreach programs to encourage operation of rat-free vessels in Alaskan waters; and training emergency-response teams to attack rats when they are found at remote shipwrecks. These efforts are in early stages, however, and the threat of rat invasions from vessels remains very serious. It is not known what proportion of fishing vessels carry rats. The effects of rat invasions on local seabird populations are not known in Alaska, because no islands have been monitored before and after their arrival. However, for most islands in other parts of the world where rats have invaded, seabird populations have declined or gone extinct (Jones and Byrd 1979, Moors *et al.* 1992, Burger and Gochfeld 1994).

Indirect Effects Through Plastics Ingestion

The presence of plastic pollution in marine birds was first recorded in 1962, coinciding with the increase in production of plastic resin (Robards *et al.* 1997). Ingestion of plastic pollutants has been recorded in 80 species of marine birds from around the world (Sievert and Sileo 1993). Species feeding primarily by surface-seizing or pursuit-diving have the highest frequencies of plastic ingestion, including the tubenoses and the parakeet auklet, whereas gulls and most alcids ingest little or no plastic. Species feeding primarily on crustaceans or cephalopods have the highest frequencies of plastic ingestion, probably because certain sizes and colors of plastic resemble their natural prey. Subadult seabirds, because they are less experienced in discriminating food items, ingest more pieces of plastic than do adult seabirds (Day *et al.* 1985). Adult seabirds may pass plastics on to chicks by regurgitation (Robards *et al.* 1997).

Two classes of plastic are commonly found in seabirds; pellets and fragments. Pellets are the raw product of the plastic industry and most probably enter the marine ecosystem during transportation or via drainage systems. Plastic fragments or "user" plastics are small, weathered pieces of larger manufactured items that are discarded or lost at sea, particularly from fishing boats and marine shipping vessels (Robards *et al.* 1997). Ocean currents, winds, and the location of disposal influence the abundance and distribution of plastic in the North Pacific Ocean (Auman *et al.* 1997). The highest incidence of ingested particles in the subarctic North Pacific was in the Aleutian coastal waters. Densities of small plastic particles in the subarctic North Pacific and Bering Sea are 26 to 400 times lower, respectively, than in subtropical waters. Of small oceanic plastic particles found in the central North Pacific, 3.7 percent were pellets and 96.3 percent were user fragments (Robards *et al.* 1997). In contrast, seabirds in the subarctic North Pacific ingested mostly pellets (76 percent pellets, 22 percent user plastic, 2 percent unrecognizable plastic particles) (Robards *et al.* 1997). Some of the recognizable plastic objects are consistent with debris originating from dumping as opposed to fishing activities.

Available evidence suggests that plastics are damaging to seabirds when they are consumed in sufficient quantity to obstruct the passage of food or cause stomach ulcers. Other effects may include bioaccumulation of polychlorinated biphenyls, toxic effects of hydrocarbons, diminished feeding stimulus, reduced fat deposition, lowered steroid hormone levels, and delayed reproduction. However, at present, acute effects of plastic ingestion are rarely observed, and chronic effects on body condition are generally equivocal (Robards *et al.* 1997). It may not be possible to demonstrate direct cause-and-effect relationships between plastic ingestion and body condition in wild seabirds because of natural variability in the environment and the fact that affected birds may quickly disappear from sampled populations (Robards *et al.* 1997).

The Marine Plastic Pollution Research and Control Act of 1987 (33 USC §§ 1901 *et seq.*) implements the provisions relating to garbage and plastics of the International Convention for the Prevention of Pollution from Ships, 1973 as modified by the Protocol of 1978 relating thereto (MARPOL 73/78). These regulations apply to all vessels, regardless of flag, on the navigable waters of the U.S. and in the Exclusive Economic Zone of the U.S. It applies to U.S. flag vessels wherever they are located. The discharge of plastics into the water is prohibited, including synthetic ropes, fishing nets, plastic bags, and biodegradable plastics. In 1995, as part of their BiOp on the status of short-tailed albatross (USFWS 1995a), the USFWS recommended that NOAA Fisheries begin an education program to help fishers be aware of and comply with the laws against discarding plastic at sea, an effort that continues to the present time.

3.7.2 Black-Footed Albatross (*Phoebastria nigripes)*

Life History and Distribution

The black-footed albatross is a large, dark-plumaged seabird with a wingspan of up to 80 inches. Nearly the entire world population nests on the Hawaiian Islands National Wildlife Refuge, principally Laysan and Midway Islands. Breeding begins in early November. One egg is laid and both parents share incubation which lasts about 65 days. Chicks begin to hatch in mid-January and are fed by regurgitation from both adults. This high calorie, nutrient-rich regurgitate consists primarily of squid and stomach oil and can sustain a chick for a number of days while the parents forage for food at sea. Fledging occurs in June and July. Sub-adults return to their natal colony when they are three years of age but do not mate and nest until they are between 5 and 8 years old. USFWS banding studies on Midway Island indicate that individuals may live 40 years or more in the wild.

The historic range of the species is from the coasts of China, Japan, and Russia east to continental North America; and from the Sea of Okhotsk and the Bering Sea south to about 18°N in the central Pacific (Shuntov 1972). Although the central Pacific is considered to be the preferred wintering area for non-breeding adults, low numbers of black-footed albatross are found in the eastern temperate North Pacific Ocean throughout the entire winter, as far north as 55°N (McDermond and Morgan 1993). Black-footed albatross are more abundant over the outer continental shelf, especially at the shelf break, than elsewhere. Areas with strong, persistent upwelling and the boundaries of different water masses are also favored. Their concentration over the continental slope may in part be a result of the distribution of fishing vessels in these areas, to which they are strongly attracted by fish wastes and bait (McDermond and Morgan 1993). Black-footed albatross spend the summer (approximately May through September) in Alaskan waters, although some non-breeding birds may be encountered at any time. In Alaska, black-footed albatross are most abundant in the GOA.

The USFWS conducts census counts annually at the Hawaiian breeding colonies. The census data suggest that during the last decade the estimated numbers of breeding pairs of black-footed albatross in nesting colonies in the Northwest Hawaiian Islands have fluctuated between approximately 53,000 and 41,000, with the high estimate in 1993 and the low in 2000. The estimate increased in 2001 to approximately 45,000 pairs. However, the overall breeding population of black-footed albatross appears to be decreasing by as much as 1.3 percent annually (NMFS 2001e). Individual nesting colonies such as French Frigate Shoals and Midway Atoll have shown dramatic inter-annual fluctuations (NMFS 2001e). The reasons for these fluctuations are not clear. Breeding adults do not typically nest every year and may skip a year for various reasons, including for molting or possibly if they are nutritionally stressed. Mortality of adults and subadults at sea is also a factor in determining how many birds return to nest.

The most recent estimate for the number of black-footed albatross breeding pairs is 54,548 (NMFS 2001e). Since the number of sub-adult (i.e., non-breeding) albatross may be five to six times the number of breeding pairs (Pradel 1996), the total world population of black-footed albatross is approximately 300,000 (Cousins and Cooper 2000).

Trophic Interactions

Cephalopods play a major role in the diet of black-footed albatross (Cherel and Klages 1998). Squid from the families Ommastrephidae and Onychoteuthidae are the most important food items although the species eaten by black-footed albatross are poorly known. Few observations have been published of black-footed albatross feeding in the wild, other than by scavenging near fishing vessels. They take food in the upper 1 m of the ocean's surface by seizing and dipping while sitting on the water (Gould *et al.* 1998). In addition to squid, other food items include myctophids (lanternfish), other invertebrates, and fish. In one study prior to the cessation of the high-seas driftnet fisheries in 1992, squids were more important than fishes in the diets of non-breeding black-footed albatross (review in Gould *et al.* 1998). A study in Hawaii found that fish eggs were the main component of the diet of black-footed chicks (Harrison *et al.* 1983). Black-footed albatross, with their short, stocky bills, are better adapted to scavenging naturally occurring large carrion or refuse from ships than they are at retrieving small prey from surface waters (Gould *et al.* 1998). Because of this attraction to fish waste and bait, black-footed albatross are drawn to fishing vessels and are vulnerable to being caught by longlines. One recent study incorporated the use of immersion monitors to study the foraging behavior of Laysan and black-footed albatross (Fernandez and Anderson 2000). The data suggested that individuals split their time between nocturnal and diurnal foraging.

In 1998 and 1999, satellite telemetry studies indicated that black-footed albatross nesting in the northwestern Hawaiian Islands mixed short foraging trips near their nesting island with much longer trips that typically extended to the California, Oregon, and Washington State coasts but did not include the colder waters of the GOA (Hyrenbach *et al.* 2002).

Management Overview

Wildlife management responsibility for the black-footed albatross, established by the Migratory Bird Treaty Act (16 U.S.C. 703 *et.seq.*), falls under the jurisdiction of the USFWS. Most research on the species has taken place in their northwest Hawaiian breeding colonies (where 96 percent of the world population resides) which are predominately on National Wildlife Refuge lands. Black-footed albatross were recently assigned "vulnerable" status on the World Conservation Union's *Red List of Threatened Species* (IUCN 2000) because of reported declines in numbers on their breeding colonies. This criterion is used for species that are deemed to have a high risk of extinction in the wild in the medium-term future (60 years).

Past and Present Effects and Management Actions

<u>Direct Mortality: Harvest and Other Intentional Take</u>

Within historic time, black-footed albatross have experienced periods of heavy mortality at their breeding colonies from various human activities, including mass harvesting of adults for feathers at the beginning of the 20th century, warfare, intentional destruction of nest sites and breeding birds for airport runway construction, collisions with aircraft and communication towers, and contamination with lead paint and other toxic wastes left from 50 years of military use (NMFS 2001e). The impact of these mortality factors on the population has not been quantified.

Direct Mortality from Incidental Take in External Fisheries

Human impacts on albatross at sea are also substantial. High-seas driftnet fisheries for tuna, squid, and salmon have been identified as a major source of mortality for albatrosses in the past. The Japanese large-mesh driftnet fishery for tuna and swordfish dates back to 1905. This fishery peaked in 1982 with over 700 vessels but declined to only 70 vessels by 1991. There are no data on the incidental take of seabirds for most of this fishery except for the 1990-1991 season when over 3500 seabirds were estimated to be taken, including a large number of black-footed albatross (DeGange *et al.* 1993). Driftnet fisheries targeting *Ommastrephes* squid, one of the preferred prey of black-footed albatross, were started in the late 1970s by Japan, Korea, and Taiwan. At their peak in the late 1980s, these fisheries deployed millions of kilometers of driftnet. Rough estimates of the total number of seabirds killed by the squid driftnet fisheries were between 875,000 and 1,660,000 seabirds annually, including 2,000-5,000 black-footed albatross per year (DeGange *et al.* 1993). Due to the tremendous amount of waste and ecosystem damage associated with the high-seas driftnet fisheries, they were outlawed by international agreement through United Nations Resolution (46/215) in December of 1992 (Paul 1994). Because black-footed albatross are such a long-lived and slowly maturing species, high rates of mortality from the driftnet fisheries may have a lingering impact on the population growth rate at present.

Longline fishing is considered the most recent and potentially most serious global threat faced by albatrosses (Brothers *et al.* 1999a). Longlines catch surface-feeding seabirds when they attempt to capture the bait as the line is being set. Mortality of black-footed albatross occurs in Alaskan and Hawaiian longline fisheries as well as in North Pacific longline fisheries conducted by Japan, Taiwan, Korea, Russia, and China (Brothers *et al.* 1999). Estimates of incidental take in some of these fisheries may underestimate actual mortality because they are based on samples of birds brought on-board and do not account for birds that are hooked as the line is being deployed but fall from the hook before the lines are retrieved. When observers do not watch the groundline as it is retrieved, underestimates of incidental take may be as high as 30 to 95 percent (Gales 1998). However, observers in the North Pacific Groundfish Observer Program actually watch the groundline as it is retrieved and tally birds that fall off before being retrieved on board.

Based on 1994 through 1999 data, the estimated average annual total catch of black-footed albatross in the Hawaiian pelagic longline fishery is 1,743 birds (NMFS 2001e). Preliminary estimates of the number of both black-footed and Laysan albatross taken in non-U.S. fisheries in the north and central Pacific pelagic longline fisheries (swordfish and tuna) are about 34,700 birds per year (Cousins *et al.* 2001). It is not known what portion of these are black-footed albatross. An estimate of this mortality may be made if one assumes that the percentages of Laysan and black-footed albatross are about the same in foreign fishing waters as they are in the U.S. Black-footed albatross make up about 57 percent of the total albatross taken in the Hawaiian longline fishery (NMFS 2001e) and 60 percent in the GOA longline fishery (Table 3.7-3). Based on the assumption that the U.S. data are comparable to the foreign fisheries situation, where there are no data, the numbers of black-footed albatross taken in the foreign longline fisheries could be over 20,000 birds per year.

State-managed longline fisheries and IPHC halibut fisheries may contribute only relatively small amounts to the overall incidental take of albatross. The larger hooks used in the halibut fisheries presumably result in lower incidental catch rates although there is little data to support this. In 1998, incidental takes of 32 unidentified albatrosses were documented in the IPHC halibut fishery through interviews with fishermen (Trumble and Geernaert 1999). However, since the halibut and state-managed fisheries are not subject to the NOAA Fisheries Observer Program, there is no way to independently verify or quantify the numbers of particular species taken by these vessels. NOAA Fisheries and NPFMC are working with the IPHC to find new ways to provide oversight and monitoring of the bycatch from these fisheries, which set millions of hooks each year.

Direct Mortality from Incidental Take on Groundfish Longlines

Tables 3.7-2 and 3.7-3 list the estimated incidental take of various species of seabirds by longline fisheries in the BSAI and GOA for the period 1993-2001 (Observer Program data). In the BSAI, the estimated number of black-footed albatross killed by longlines varied between 4 and 66 birds per year with an average of 21 per year (95 percent confidence interval is 14-29 birds per year). There were also an average of 63 unidentified albatross caught each year in the BSAI. If we assume that the unidentified albatross occurred in the same proportion as the identified numbers of black-footed and Laysan albatross, the average number of unidentified albatross would translate into 2 more black-footed albatross caught in the BSAI every year. This gives an estimated average of 23 black-footed albatross taken in the BSAI groundfish longline fishery every year between 1993-2001. In the GOA, between 7 and 658 black-footed albatross were caught each year with an average of 190 per year (95 percent confidence interval is 144-236 birds). An average of 56 unidentified albatross were also taken each year. Black-footed albatross make up a higher proportion of the identified albatross caught in the GOA, so this translates into an additional 34 black-footed albatross caught. This gives an estimated average of 224 black-footed albatross incidentally taken in the GOA groundfish longline fishery every year between 1993-2001. In this time period, the estimated total take of black-footed albatross in the BSAI and GOA longline fishery was thus an average of 247 birds per year. No black-footed albatross were observed to be taken in the trawl or pot fisheries during this period (Tables 3.7-4 and 3.7-5).

Several factors are likely to affect the risk of seabird incidental catch, including: fishing effort (number of hooks per year), the distribution of effort by sub-area and season, the abundance and distribution of seabirds in the vicinity of fishing vessels, seabird nutritional condition (i.e., starvation), and the use of seabird deterrents in longline fisheries. The relative importance of these factors has not been fully studied. NOAA Fisheries analyzed the relationship between fishing effort and numbers of birds hooked in the BSAI and GOA and found that the relationship varies for different species groups (Figures 3.7-5 and 3.7-6, respectively). The data suggest that fishing effort (number of hooks set) does not play a strong role in determining how many albatross are caught.

NPFMC and NOAA Fisheries have addressed the issue of seabird bycatch in numerous ways over the years, including scientific research and regulations that require changes in fishing techniques. Although these efforts have been pursued largely to protect the endangered short-tailed albatross, the take reduction measures that have been enacted since 1997 should decrease take of all seabird species that are susceptible to capture by longlines, including black-footed albatross. (See Section 3.7.4 on short-tailed albatross for a discussion of research and regulatory measures taken to protect seabirds from longline take). Observer Program data (Tables 3.7-2 and 3.7-3) show an estimated average of 33 black-footed albatross taken every year in the BSAI from 1993-1996. From 1997-2001, this estimated yearly take decreased to 11 birds. In the GOA, estimated annual take of black-footed albatross averaged 233 birds between 1993-1996. From 1997-2001, that average dropped to an estimated 156 birds taken per year. In the recently completed Washington Sea Grant Project study, new avoidance techniques resulted in a reduction of 70-95 percent of all species caught and were especially effective for black-footed albatross and other species that do not dive deeply on baited lines (Melvin *et al.* 2001).

Assessment of Population-Level Effects

Recent evidence from population studies and modeling exercises suggests that the combination of domestic and foreign longline fisheries in the North and Central Pacific has had a negative impact on the black-footed albatross population (Cousins and Cooper 2000). One finding of the modeling exercises indicates that the sustained growth rate of an albatross population (without any fishing-related mortality) is in the range of zero to four percent. The model concluded that a total loss of 10,000 birds per year (natural and anthropogenic mortality sources combined) is about the maximum a population of 300,000 black-footed albatross could sustain and still remain stable (Cousins and Cooper 2000). The modeling also showed that the growth rate of the population may be reduced by an equivalent percentage of the total number of birds killed in the fisheries each year. Thus, if fisheries mortality is one percent of the total population (3,000 birds), then the population growth rate will be reduced by more than one percent (Cousins 2001). This estimated reduction in population growth is a robust estimate in that it is not sensitive to the ratio of juveniles to adults lost and thus includes the potentially greater impact of taking nesting adults.

Other Past and Present Effects

The following issues have been identified as having potential impacts on black-footed albatross, but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects is outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** Abundance and distribution of squid and other prey are greatly influenced by climatic and oceanic fluctuations. High-seas squid drift fisheries by several Asian countries may have impacted prey availability but these fisheries were outlawed in 1992 (Paul 1994). Impacts of groundfish and other fisheries on availability of squid and small fish to albatross are unknown. Ability of albatross to forage over huge areas is presumed to lessen the potential impact of localized depletion of prey.

- **Indirect effects through consumption of fishery discards.** Albatross are attracted to fishing vessels and processors to eat discards and offal. Benefits of the food source are countered by increased risk of incidental take on longlines. The net benefit or adverse impact of this effect has not been studied.

- **Indirect effects through plastics ingestion.** There are many sources of plastic pollution on land and at sea. Albatross are particularly attracted to small consumer products that resemble floating prey. Adults may suffer from swallowing sharp objects and excessive amounts of non-digestible material (Sievert and Sileo 1993, McDermond and Morgan 1993). Chicks fed regurgitated plastics are subject to physiological stress as a result of satiation and mechanical blockages which may affect chick survival when the volume of plastic ingested is high (Sievert and Sileo 1993, Auman *et al.* 1997).

Comparative Baseline

There are an estimated 300,000 black-footed albatross in the world as of 2001, but their breeding numbers have declined over the past ten years (NMFS 2001e). They are not listed under the ESA, but are listed as "vulnerable" according to international conservation criteria. The great majority of nesting occurs in Hawaii and is protected under the National Wildlife Refuge System. The species faces serious threats from incidental take in longline fisheries throughout its range, especially by foreign tuna and swordfish pelagic longline fisheries in the Central and North Pacific. The numbers of black-footed albatross taken in the BSAI and GOA groundfish longline fisheries are relatively small compared to the estimated take in foreign fisheries. Seabird avoidance measures instituted for the BSAI and GOA longline fleet in 1997 have reduced the numbers of black-footed albatross taken. The past and present effects on black-footed albatross are summarized in Table 3.7-6.

Status for Cumulative Effects Analysis

Incidental take of black-footed albatross is expected to continue under all alternatives and warrants consideration in the cumulative effects analysis. Because of the similarity of their fishery interactions and responses to management measures, black-footed albatross will be discussed in conjunction with Laysan albatross in the analysis of FMP Alternatives.

3.7.3 Laysan Albatross (*Phoebastria immutabilis)*

Life History and Distribution

The Laysan albatross, also known as "gooney bird," is a large white and black seabird with a wingspan that reaches 85 inches. More than 99 percent of Laysan albatross nest in the northwest Hawaiian Islands. They are monogamous and if one of the mates should die it may be several years before the survivor can make a new pair bond. Only one egg is laid per year beginning around mid-November, and incubation lasts about 65 days. Both parents share in incubation duties although females usually leave for a few weeks after egg-laying. Chicks hatch during late January to mid-February. Both parents will feed the chick by regurgitation and will often leave them for several days while they obtain food out at sea. Fledging occurs 5 to 6 months after hatching (mid-June through late July). Parents will often leave before the chicks have reached their full juvenile plumage. Sub-adults return to their natal nesting colony after spending 3 to 5 years at sea. Mating and first nesting usually occurs by age 6 to 8.

Laysan albatross occur throughout the North Pacific from the southern Bering Sea to the Hawaiian Islands (Shuntov 1972). Laysan albatross spend the summer (approximately May through September) in Alaskan waters, although some non-breeding birds may be encountered at any time. In 1989 and 1999, satellite telemetry studies indicated that Laysan albatross nesting in the northwestern Hawaiian Islands mixed short foraging trips near their nesting island with much longer trips primarily to the north, frequently reaching the Aleutian Islands and GOA. Thus, based on satellite telemetry data, breeding Laysan albatross are known to forage in waters off Alaska (Anderson *et al.* 2000, Hyrenbach *et al.* 2002). Since the 1970s, the Laysan albatross has greatly expanded its presence in the southeastern Bering Sea. At present, Laysan albatross are most abundant in the western Aleutian Islands but are increasingly encountered in and north of the passes through the Aleutian Islands, over the shelf north of the Alaska Peninsula, and along the shelf break as far as the Pribilof Islands; hence, these birds are likely to attend even more vessels than may have previously been the case (G. L. Hunt, Jr., University of California, Irvine, personal communication).

Laysan albatrosses are the most numerous of the North Pacific albatrosses, but the species was probably even more abundant before feather hunters decimated breeding colonies in the early 1900s. No systematic population estimates were made until the USFWS began to make population estimates in 1992. The current world estimate of the number of breeding pairs of Laysan albatross is 488,852 (NMFS 2001e). Since the number of sub-adult (i.e., non-breeding) albatross may be five to six times the number of breeding pairs (Pradel 1996), the total world population of Laysan albatross is approximately 2.4 million birds (Cousins *et al.* 2000). Given the relative abundance of this species compared to other albatross species, its status is generally considered to be relatively secure. However, the number of breeding pairs at the largest nesting site, Midway Atoll, has decreased substantially in the past decade, from approximately 429,300 pairs in 1992 to 285,600 pairs in 2001 (NMFS 2001e). At the second largest nesting site, Laysan Island, the number of breeding pairs decreased from approximately 200,000 pairs in 1997 to about 55,000 pairs in 2000. This downward trend changed in 2001 when the number of breeding pairs increased on Laysan Island to approximately 118,000 pairs (NMFS 2001e). It is not clear why these fluctuations have been so dramatic. Albatross tend to return to their same nest sites over the years so it seems unlikely that breeding pairs are moving to different islands. Breeding adults do not typically nest every year and may skip a year for various reasons, including for molting or possibly if they are nutritionally stressed. Of course, adult and juvenile mortality at sea is also a factor in determining how many birds return to nest.

Trophic Interactions

Cephalopods play a major role in the diet of Laysan albatross (Cherel and Klages 1998). Squid from the families Ommastrephidae and Onychoteuthidae are the most important food items although which species are eaten by Laysan albatross is poorly known. Few observations have been published of Laysan albatross feeding in the wild, other than of those birds scavenging near fishing vessels. They take food in the upper 1 m of the ocean's surface by seizing and dipping while sitting on the water (Gould *et al.* 1998). In addition to squid, other food items include myctophids (lanternfish), other invertebrates, and fish. In one study prior to the cessation of the high-seas driftnet fisheries in 1992, fishes were more numerous than squid in the diets of non-breeding Laysan albatross (review in Gould *et al.* 1998). A study in Hawaii found that squid was the main component of the diet fed to Laysan chicks (Harrison *et al.* 1983). Numerous studies have noted that Laysan albatrosses are more frequently observed seaward of the continental slope, over areas of strong, persistent upwelling, and at the boundaries between different water masses, presumably because of the natural concentration of their prey in those situations (review in McDermond and Morgan 1993). Laysan albatross have better night vision than black-footed albatross and may be more capable of rapid retrieval of small prey that are active in surface waters at night. (Gould *et al.* 1998). One recent study incorporated the use of immersion monitors to study the foraging behavior of Laysan and black-footed albatross (Fernandez and Anderson 2000). The data suggested that individuals split their time between nocturnal and diurnal foraging. Laysan albatross are also strongly attracted to fishing vessels where the birds may aggressively pursue bait and fish processing waste.

Management Overview

Wildlife management responsibility for Laysan albatross falls under the jurisdiction of the USFWS. The species is protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*). Most research on the species has taken place on their nesting grounds which are predominantly on National Wildlife Refuge lands.

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Early Aleut and Eskimo hunters apparently preferred albatross for their meals, because archeologists find hundreds of albatross bones in the remains of old houses and villages along the Bering Sea coast (Smithsonian's Arctic Studies Center 2002). Although these remains have not been identified to species, it may be an indication that albatross were once more abundant and widespread in the Bering Sea. No albatross were identified in recent Alaska Native subsistence hunts (Denlinger and Wohl 2001).

Within historic time, Laysan albatross have experienced periods of heavy mortality at their breeding colonies in the northwest Hawaiian Islands from various human activities, especially mass harvesting of adults for feathers at the beginning of the 20th century. At only one of the many breeding colonies that were subjected to massive hunts, Laysan Island, feather hunters killed at least 300,000 birds in 1909 alone (Dill and Bryan 1912). The species has also suffered from intentional destruction of nest sites and breeding birds for military airport runways, collisions with aircraft and communication towers, and contamination with lead paint and other toxic wastes left from 50 years of military use (NMFS 2001e). Since systematic population estimates were only begun in 1992 by USFWS, the impact of these past mortality factors on the population have not been quantified.

Direct Mortality from Incidental Take in External Fisheries

High-seas driftnet fisheries for tuna, squid, and salmon have been identified as a major source of mortality for albatross in the past. The Japanese large-mesh driftnet fishery for tuna and swordfish dates back to 1905. This fishery peaked in 1982 with over 700 vessels but declined to only 70 vessels by 1991. There are no data on the incidental take of seabirds for most of this fishery except for the 1990-1991 season when over 3500 seabirds were estimated to have been taken, including a "large number" of Laysan albatross (DeGange *et al.* 1993). The land-based Japanese salmon gillnet fishery was responsible for millions of seabird deaths between 1952-1987, including an estimated 921 Laysan albatross in 1977. By 1987, fishing effort had been reduced and an estimated 231 Laysan albatross were caught (DeGange and Day 1991). Between 1981-1984, the Japanese salmon driftnet mothership fleet killed an estimated average of 86 Laysan albatross each year (Jones and DeGange 1988). Driftnet fisheries targeting *Ommastrephes* squid, one of the preferred prey of Laysan albatross, were started in the late 1970s by Japan, Korea, and Taiwan. At their peak in the late 1980s, these fisheries deployed millions of kilometers of driftnet. Rough estimates suggest that the total number of seabirds killed by the squid driftnet fisheries ranged between 875,000 and 1,660,000 seabirds annually, including 50,000-108,000 Laysan albatross per year (DeGange *et al.* 1993). Due to the tremendous amount of associated waste and ecosystem damage, the high-seas driftnet fisheries were outlawed by international agreement through United Nations Resolution (46/215) in December of 1992 (Paul 1994). Because Laysan albatross are such a long-lived and slowly maturing species, high rates of mortality from the driftnet fisheries may have a lingering impact on the population growth rate at present.

Longline fishing is considered the most recent and potentially most serious global threat faced by albatrosses (Brothers *et al.* 1999a). Mortality of Laysan albatross occurs in both Alaskan and Hawaiian longline fisheries as well as in other North and Central Pacific longline fisheries conducted by Japan, Taiwan, Korea, Russia, and China (Brothers *et al.* 1999). Preliminary estimates suggest that the number of both black-footed and Laysan albatross taken in non-U.S. pelagic longline fisheries in the North and Central Pacific (swordfish and tuna) is about 34,700 birds per year (Cousins *et al* 2001). It is not known what portion of these are Laysan albatross. An estimate of this mortality may be made if one assumes that the percentages of Laysan and black-footed albatross are about the same in foreign fishing waters as they are in the U.S. Laysan albatross make up about 43 percent of the total albatross taken in the Hawaiian longline fishery (NMFS 2001e) and 39 percent in the GOA longline fishery (Table 3.7-3). Based on the assumption that the U.S. data are comparable to the foreign fisheries situation, where there are no data, the numbers of Laysan albatross taken in the foreign longline fisheries could be close to 15,000 birds per year.

Based on 1994 through 1999 data, the estimated average annual take of Laysan albatross in the Hawaiian pelagic longline fishery is 1,330 birds (NMFS 2001e). NOAA Fisheries established mandatory seabird protection measures for this Hawaiian fishery in 2002 (67 FR 34408).

State-managed longline fisheries, which are typically near-shore operations, and halibut fisheries may contribute only a small amount to the overall incidental take of albatrosses. The larger hooks used in the halibut fisheries presumably result in lower incidental catch rates but there is little data to support this claim. In 1998, incidental takes of 32 unidentified albatrosses were documented in the halibut fishery through interviews with fishermen (Trumble and Geernaert 1999). However, since the halibut and state-managed fisheries are not subject to the NOAA Fisheries Observer Program, there is no way to independently verify or quantify the numbers of particular species taken by these vessels. NOAA Fisheries and NPFMC are working with the IPHC to find new ways to provide oversight and monitoring of the bycatch from these fisheries which set millions of hooks each year.

Direct Mortality from Incidental Take on Groundfish Longlines

Tables 3.7-2 and 3.7-3 list the estimated incidental take of Laysan albatross in the BSAI and GOA longline fisheries between 1993-2001 (Observer Program data). In the BSAI, the estimated number of Laysan albatross killed by longlines varied between 234 and 1,431 birds per year with an average of 538 per year (95 percent confidence interval is 481-595 birds). There was also an average of 63 unidentified albatross caught each year in the BSAI. If we assume that the unidentified albatrosses occurred in the same proportion as the identified numbers of black-footed and Laysan albatross, the average number of unidentified albatross would translate into 61 more Laysan caught in the BSAI every year. This gives an estimated average of 599 Laysan albatross taken in the BSAI groundfish longline fishery every year between 1993-2001. In the GOA, between 40 and 217 Laysan albatross were caught each year with an average of 126 per year (95 percent confidence interval is 98-154 birds). An additional 45 unidentified albatross were also taken each year. Laysan albatross make up a smaller proportion of the identified albatross caught in the GOA so this translates into an additional 18 Laysan caught. This gives an estimated average take of 144 Laysan albatross in the

GOA groundfish longline fishery every year between 1993-2001. In this time period, the estimated total take of Laysan albatross in the BSAI and GOA longline fishery was thus an average of 773 birds per year.

In an effort to reduce the incidental take of seabirds on longlines, NOAA Fisheries instituted mandatory seabird avoidance measures for the groundfish fleet in 1997 (62 FR 23176). Prior to 1997, the average estimated number of Laysan albatross taken in the BSAI was 406 birds per year. Between 1997 and 2001, the estimated annual average take in the BSAI increased to 643 Laysan albatross per year. Most of this increased average take was due to an unusually high number of birds taken in 1998 (1,431 albatross). The reason this one year was so different than the others is not known but it may be related to nutritional stress. Starving birds appear to be much more aggressive in pursuit of food around fishing vessels and the numbers of fulmars, gulls, and shearwaters taken on longlines were also well above average in 1998, indicating a possible region-wide food shortage. In the GOA, the average take before and after the seabird avoidance measures were enacted remained essentially the same (129 albatross per year in 1993-1996 versus 124 birds per year in 1997-2001).

Direct Mortality from Incidental Take in Groundfish Trawls

According to 1993-2001 Observer Program data, the amount of estimated incidental take of Laysan albatross in BSAI and GOA groundfish trawls varied substantially between years (Table 3.7-4). From 1997-2001, the estimated average number of Laysan albatross taken every year was estimated to be between 46 birds (average low estimate) and 133 birds (average high estimate).

Direct Mortality from Vessel Strikes

According to the Observer Program records of bird-strikes from 1993-2000, Laysan albatross have been documented to strike vessels and rigging. Of the 120 recorded collisions, 21 Laysan albatross were involved in 15 incidents. Laysan's were also observed to collide with trawl "third wires". Monitoring these types of collisions is not part of the observer's normal duties so the true extent of this impact is not known. NOAA Fisheries is currently investigating the issue, especially as it relates to "third wires". During 2002, NOAA Fisheries evaluated the use of video as a tool to monitor "third wire" seabird interactions, and the report is in process. (NPFMC 2002c) NOAA Fisheries is investigating mitigation efforts for this problem, which may be as simple as hanging streamers from the wire (G. Balogh, USFWS, Anchorage, personal communication).

Assessment of Population-Level Effects

Recent evidence from population studies and modeling exercises suggest that the combination of domestic and foreign longline fisheries in the North and Central Pacific have had a negative impact on albatross populations (Cousins and Cooper 2000). Although the emphasis to date has been on the impacts of longline fishing operations on the black-footed albatross population, the modeling exercises can be applied to the Laysan albatross population and to all sources of anthropogenic mortality as well. One finding of the modeling exercises indicates that the sustained growth rate of an albatross population (without any fishing-related mortality) is in the range of zero to four percent. The modeling also showed that the growth rate of the population may be reduced by an equivalent percentage of the total number of birds killed in fisheries each year. Thus, if fisheries mortality is one percent of the total population (24,000 birds), then the population growth rate will be reduced by more than one percent (Cousins 2001). This estimated reduction in population growth is a robust estimate in that it is not sensitive to the ratio of juveniles to adults lost and thus includes the potentially greater impact of taking nesting adults.

Other Past and Present Effects

The following issues have been identified as having potential impacts on Laysan albatross but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** The impacts of groundfish and other fisheries on the availability of prey to Laysan albatross are unknown. The ability of albatross to forage over huge areas is presumed to lessen the potential impact of localized depletion of prey.

- **Indirect effects through consumption of fishery discards.** Laysan albatross are attracted to fishing vessels and processors to eat discards and offal. Benefits of the food source are countered by increased risk of incidental take on longlines.

- **Indirect effects through plastics ingestion.** Species feeding primarily by surface-seizing or pursuit-diving, including Laysan albatross, have the highest frequencies of plastic ingestion (Sievert and Sileo 1993). Studies on Midway Island found that ingested plastic probably does not cause significant direct mortality in Laysan albatross chicks, but likely causes physiological stress as a result of satiation and mechanical blockages (Auman *et al.* 1997) and may affect chick survival when the volume of plastic ingested is high (Sievert and Sileo 1993).

- **Indirect effects through contamination by oil spills.** Surface-feeding pelagic seabirds, including Laysan albatross, are moderately sensitive to oil effects given their extreme reliance on open-water marine habitats for feeding and roosting, making them susceptible to incidents in these settings (King and Sanger 1979).

Comparative Baseline

The Laysan albatross is the most numerous albatross species in the BSAI and is also common in the GOA with a total population estimated to be about 2.4 million birds. However, the recent decline in breeding pairs at their largest nesting colony in Hawaii is cause for concern. According to population modeling exercises, the impact of mortality from incidental take in fisheries, especially longlines, may be contributing to recent declines at nesting colonies. The amount of incidental take from the BSAI and GOA groundfish fishery is relatively small compared to the estimated mortality from foreign fisheries. Seabird avoidance measures instituted for the BSAI and GOA longline fleet in 1997 have not reduced the numbers of Laysan albatross taken. The past and present effect on Laysan albatross are summarized in Table 3.7-7.

Status for Cumulative Effects Analysis

Incidental take of Laysan albatross is expected to continue under all alternatives and warrants consideration in the cumulative effects analysis. Because of the similarity of their fishery interactions and responses to management measures, Laysan albatross will be discussed in conjunction with black-footed albatross in the analysis of FMP Alternatives.

3.7.4 Short-Tailed Albatross (*Phoebastria albatrus)*

Life History and Distribution

The short-tailed albatross is a very large seabird with narrow, seven-foot-long wings adapted for soaring low over the ocean. Young birds are chocolate brown, gradually turning white as they grow older. Adult short-tailed albatross have an entirely white back, white or pale yellow head and back of neck, and black and white wings. Their large pink bill is hooked at the end with a blue tip. Short-tailed albatross mate for life, returning to the same nest sites in the breeding colony for many years. Presently, these birds nest only on two islands in Japan, Torishima and Minami-kojima. Single eggs are laid in October or November, chicks hatch in December through February, and the young fledge from May to July. Immature birds wander across the North Pacific until they begin breeding at 6 to 9 years old (ADF&G 1994).

Relatively little is known about seasonal movements or factors determining marine distribution of the short-tailed albatross (McDermond and Morgan 1993). It is believed that the species was formerly common off China, in the Sea of Japan, the Sea of Okhotsk, the Bering Sea north to the Bering Strait, and throughout the entire temperate North Pacific Ocean, from Alaska to Baja California (McDermond and Morgan 1993, USFWS 1998b). Areas of high food productivity, such as along the Pacific coast of North America, in the Aleutian Islands, and in the Bering Sea, were favored (Hasegawa and DeGange 1982). Over 90 percent of records are sightings of one or two birds (mostly single birds) and these sightings have been reported in all months of the year. For those sightings that recorded age(s), four times more non-adults (juvenile, immature, and subadult) than adults were sighted. Past observations indicate that as with other albatross, older short-tailed albatross are present in Alaska primarily during the summer and fall months along the shelf break from the Alaska Peninsula to the GOA. Recent satellite telemetry studies indicate that, following the breeding season, the tagged short-tailed albatross moved north along the coast of Japan to the southern tip of the Kamchatka Peninsula and then east to the western Aleutians. Records of sightings from the Observer Program and fishing vessels have been compiled to indicate their present distribution in Alaskan waters (Figure 3.7-7) (NPFMC 2002c).

The North Pacific Ocean and Bering Sea once supported millions of short-tailed albatross but they were decimated by commercial hunters in the early 1900s. Volcanic eruptions also destroyed significant amounts of nesting habitat. By 1949, there were no short-tailed albatross breeding at any of the 15 historically known breeding sites, including Torishima Island, and the species was reported to be extinct. Fortunately, this report was premature and several birds returned from the sea in 1950 to nest on Torishima. By 1954 there were 6 breeding pairs and 25 total birds seen on the island. Japan designated the albatross a protected species in 1958, prohibiting hunting and limiting access to the breeding colonies. These protection measures and extensive habitat enhancement work on Torishima has allowed the species to increase steadily (Fadely, 1999). In addition, Japan has been working to reestablish breeding colonies in areas that are not so susceptible to volcanic eruptions and mudslides. Small numbers of short-tailed albatross have also been observed on a regular basis at Midway Atoll in the Hawaiian Islands and this may become a future colony site (Fadely, 1999). Based on egg counts from 1980 to 1998, the population on Torishima is increasing at an annual rate of 7 to 8 percent, a level that appears to be near its maximum biological potential (J. Cochrane, USFWS, Grand Marais, personal communication). Based on data from site visits to the two known breeding colonies in 2001 and estimates of the fraction of adult and sub-adult birds that do not visit the breeding colonies, the current world population of short-tailed albatross is estimated at 1600 to 1700 individuals (NPFMC 2002c). No confidence intervals for this estimate are available at this time. The great majority of nesting occurs on Torishima Island with small numbers at Minami-kojima Island (H. Hasegawa, personal communication, 2001).

Trophic Interactions

Albatross seize small fish (e.g., larval and juvenile pollock and sablefish), squid, and zooplankton from the surface of the water or just below it. Short-tailed albatross forage along the edge of the continental shelf and on the outer shelf where upwellings bring their prey to the surface. They may forage at night as well as in daylight (Sherburne 1993). Since they range widely over the ocean and are opportunistic feeders, their diet varies with local availability. Albatross are attracted to fishery wastes released from fishing vessels and processors and are thus vulnerable to being caught in fishing gear, especially on baited hooks in the longline fisheries.

Management Overview

Wildlife management responsibility for the short-tailed albatross is under the jurisdiction of the USFWS. The short-tailed albatross was originally designated as "endangered" under the Endangered Species Conservation Act of 1969 as a foreign-listed species (because they do not nest in U.S. territory). In 1973, when the ESA replaced the 1969 Act, the short-tailed albatross was included as a foreign species but not as a native species. This created an administrative error by listing its status as endangered elsewhere except in the U.S. The USFWS corrected this administrative error by extending the species endangered status to include its range within the U.S. (USFWS 2000c). The proposed and final rules contain extensive information on the species life history, demographics, and population status (USFWS 1998a, 2000c). Despite the listing oversight, the short-tailed albatross has been treated as an endangered species in the EEZ since 1970.

At the time a species is proposed for listing under the ESA, critical habitat can also be proposed. Habitats outside of the U.S. are not eligible for critical habitat designation. Because the North Pacific Ocean and Bering Sea once supported millions of short-tailed albatross, USFWS scientists believe that this species is nowhere near its habitat carrying capacity, and that it would be some time before any feature of its marine habitat becomes a critical limiting factor to population growth. Further, because the species' precarious situation derives entirely from historical harvest of the birds themselves, not from actions that caused habitat degradation, and because marine habitat loss does not appear to be a factor limiting current population growth rate, NOAA Fisheries determined that designation of critical habitat within the U.S. would not be beneficial to the short-tailed albatross (USFWS 1998a, 2000c).

Under the requirements of the ESA Section 7, the USFWS is responsible for determining whether proposed federal actions are likely to jeopardize the recovery of the species. The resulting BiOps may contain mandatory and/or recommended mitigation procedures and may set limits on the number of birds that can be taken incidental to the proposed action. In 1989, NOAA Fisheries had its first consultation with USFWS concerning the effects of the BSAI and GOA groundfish fisheries on the endangered short-tailed albatross. Although the 1989 BiOp identified several possible adverse effects of fishing activities, it concluded that the

BSAI and GOA FMPs were not likely to jeopardize the continued existence of the short-tailed albatross (USFWS 1998a and 1998b). It did, however, establish a threshold number of incidental takes (two birds per year) that would be allowed in the fishery based on historical take estimates. If this threshold number was exceeded, USFWS would immediately initiate a review of the fishery and possibly require mitigation measures under Section 7 of the ESA. The 1989 BiOp also required NOAA Fisheries to begin monitoring incidental takes more closely and reduce them as much as possible. There are two interrelated challenges to this issue which are discussed below. The first is how to measure the number of birds actually caught in the fisheries and the second is to develop effective fishing techniques that avoid catching seabirds. Working in collaboration with NOAA Fisheries, NPFMC has addressed both aspects of this issue with amendments to the BSAI and GOA FMPs, specifically BSAI Amendments 13, 27, 37 and GOA Amendments 18 and 30 (see Appendix C and D). NOAA Fisheries continued to consult with the USFWS on both a formal Section 7 basis and informal basis during TAC-setting deliberations and amendments to the FMPs. The history of these consultations and NOAA Fisheries regulatory responses as of June 2003 are summarized in Table 3.7-8.

The mandatory and recommended measures established in the 1998 BiOp (USFWS 1998c) are listed in Tables 3.7-9 and 3.7-10. In the 1998 BiOp, the USFWS required NOAA Fisheries to actively monitor the numbers of seabirds taken incidentally in the groundfish fisheries, which it does through the Observer Program, educate fishers on the identification of short-tailed albatross and the applicable laws, report any takings of short-tailed albatross immediately, institute mandatory protective measures on the longline fleet, and research the effectiveness of those protective measures. The incidental take threshold for the groundfish fisheries was set at four birds taken in a two year period (USFWS 1999b).

After the Draft Programmatic SEIS was published (August 2003), the USFWS issued two new BiOps (September 2003) as part of their ESA Section 7 consultations on the federal groundfish fisheries. These documents are available on NOAA Fisheries' website: http://www.fakr.noaa.gov/protectedresources/seabirds.html. One BiOp takes a programmatic look at the impacts of the BSAI/GOA groundfish FMPs and associated fisheries on the endangered short-tailed albatross and the threatened Steller's eider (NPFMC 2003) while the other BiOp concerns the TAC-setting process for these fisheries (NPFMC 2003). These documents conclude that the fisheries would not likely jeopardize the continued existence or recovery of either the short-tailed albatross or Steller's eider and would not adversely modify Steller's eider critical habitat (no critical habitat has been designated for short-tailed albatross in U.S. waters). The TAC-setting BiOp included updated Incidental Take Statements for these species. For short-tailed albatross, incidental take on longline gear is anticipated to be the same as previous years, with up to four birds taken every two years. In addition, for the first time the USFWS included an anticipated take for short-tailed albatross through collisions with trawl gear. Unlike the situation with the longline fleet where there are over ten years of Observer Program data on take of albatross, the USFWS and NOAA Fisheries have only recently begun investigating how frequently albatross may be colliding with trawl gear. Because of this uncertainty, the Incidental Take Statement anticipates that up to two birds could be taken by the trawl fleet but the time period was left open until the BiOp is superceded by a new one. This open-ended period allows USFWS and NOAA Fisheries to continue gathering data on the potential risk of trawl gear before a new Section 7 consultation is initiated.

The TAC-setting BiOp also includes mandatory terms and conditions that NOAA Fisheries must follow in order to be in compliance with the ESA. The first of these is the implementation of seabird deterrent measures for the longline fisheries as proposed by NOAA Fisheries in February 2003 (68 FR 6386) and adopted as final regulations on January 13, 2004 (69 FR 1930). These regulations are in effect as of February 2004 and vary by length of vessel, area fished, type of gear, and other factors. They are available at NOAA Fisheries website: http://www.fakr.noaa.gov/protectedresources/seabirds.html. Other provisions include continued outreach and training of fishing crews as to proper deterrence techniques, continued training of observers in seabird identification, retention of all seabird carcasses until observers can identify and record takes, continued analysis and publication of estimated incidental take in the fisheries, collection of information regarding the efficacy of seabird protection measures, cooperation in reporting sightings of short-tailed albatross, and continued research and reporting on the incidental take of short-tailed albatross in trawl gear.

Past and Present Effects and Management Actions

Direct Mortality: Natural Events

Toroshima Island in Japan, the main breeding site of short-tailed albatross, is an active volcano and has erupted as recently as August 2002. While a volcanic eruption is a natural event, it could have a devastating impact on the population if it occurred while the birds were nesting. Monsoon rains have also caused mud slides and erosion that have destroyed nesting sites. Japanese biologists and technicians have worked very hard in the past thirty years to reclaim and protect nest sites on Torishima from these natural threats. Although diseases and parasitic infestations do not appear to be significant at present, the fact that the species is so restricted in its nesting locations makes it more susceptible to these natural mortality factors.

Because of the critically small population size of this endangered species, fishery-related mortality is a conservation concern. In consideration of this, USFWS recently noted that in the event of a major population decline resulting from a natural environmental catastrophe (such as a volcanic eruption on Torishima Island) or an oil spill, the effects of longline fisheries on short-tailed albatrosses could be significant under ESA (USFWS 2000c). If such a catastrophic event were to occur, it would constitute new information requiring the reinitiation of a Section 7 consultation under the ESA (USFWS 1999b).

Direct Mortality: Harvest and Other Intentional Take

Early Aleut and Eskimo hunters apparently preferred albatross for their meals because archeologists find hundreds of albatross bones in the remains of old houses and villages along the Bering Sea coast (Smithsonian's Arctic Studies Center 2002). Although these remains have not been identified to species, some of these birds may have been short-tailed albatross given the fact that the species was once much more abundant and widespread in the Bering Sea. No albatross were identified in recent Alaska Native subsistence hunts (Denlinger and Wohl 2001).

The most important factor affecting the short-tailed albatross population was their near extermination by commercial harvesting almost 100 years ago. From the late 1800s to the 1930s, hunters killed millions of short-tailed albatross in their breeding colonies for feathers, meat, and eggs (Hasegawa and DeGange 1982). Between 1885 and 1903, an estimated 5 million birds were killed on Torishima Island alone. As stated above, even though they are now protected from harvest, they are still extremely rare and this magnifies the importance of other potential impacts.

Direct Mortality from Incidental Take in External Fisheries

In general, seabirds are vulnerable to becoming entangled in derelict fishing gear. The magnitude of the impact on short-tailed albatross is unknown. Hasegawa (personal communication 1997) reports that three to four birds per year on Torishima come ashore entangled in derelict fishing gear, some of which die as a result. He also stated that some take by Japanese fishermen (handliners) may occur near the nesting colonies, although no such take has been reported. There is no additional information on the potential effects of fisheries near Torishima on the species. Lost or abandoned fishing gear could be a threat to the species throughout its range and is not restricted to the breeding colony around Torishima.

The issue that has received the most attention is the incidental take of short-tailed albatross on the baited hooks of longline fisheries throughout their range. Although short-tailed albatross are likely taken in several international fisheries, there is no quantitative information available on the numbers of birds taken. This situation is the result of several factors; relatively few fishermen can identify rare species of seabirds (especially subadult plumages), there is no international reporting center, and very few fishing vessels have trained observers on board to monitor seabird incidental take. The lack of reliable data is problematic for effective mitigation management.

The Pacific halibut fishery, managed by the IPHC and regulated by NOAA Fisheries, sets millions of hooks each year but does not have an observer program. Under the authority of the ESA, USFWS has required NOAA Fisheries to investigate all options for monitoring the incidental take of short-tailed albatross in the Pacific halibut fishery in waters off Alaska and to institute appropriate changes to the fishery as a result of its investigation. NOAA Fisheries has contracted with the IPHC to carry out this research and make recommendations for management actions. IPHC is evaluating the use of video as a monitoring tool, with cost comparison to deploying observers.

Direct Mortality from Incidental Take on Groundfish Longlines

Seven short-tailed albatross have been reported to be taken incidentally in Alaska fisheries since 1983 (Table 3.7-11), six from vessels using hook-and-line gear. For most seabird species, NOAA Fisheries uses sampling statistics to extrapolate the numbers of seabirds incidentally caught in the entire fishery from the portion of the fleet covered by the Observer Program. However, since they are so scarce, the situation for short-tailed albatross is more difficult and uncertain. Until 1995, no short-tailed albatross had even been taken within an observer sample. At the February 1999 NPFMC meeting, the SSC stated in its minutes that ". . . Because incidental catch is so small, estimation of the total take of short-tailed albatross is problematic. Uncertainty exists on how the known take of albatross should be expanded to the unobserved portion of the fishery."

In the NOAA Fisheries analysis of the 1993-2001 observer data, only three of the albatross taken were identified as short-tailed albatross and all were from the BSAI region (Tables 3.7-2 and 3.7-3). Of the albatross taken, not all were identified. This analysis of 1993-2001 data resulted in an estimated average of one short-tailed albatross being taken annually in the BSAI groundfish longline fishery and zero short-tailed albatross taken annually in the GOA longline fishery. The incidental take threshold, as established by USFWS, is based on the actual reported takes of short-tailed albatross and not on extrapolated takes.

The uncertainty in estimating actual numbers of short-tailed albatross taken, combined with their endangered species status, places a great deal of importance on the issue of avoiding seabird bycatch in general, especially for longliners. Fishermen have a natural interest in reducing or eliminating the ability of seabirds to get at their bait since any hook that has caught a seabird or had its bait stolen is not available to catch fish. However, no one technique can be applied to all fishing vessels and gear types and whatever technique is used has to meet basic safety standards and not hinder the deployment or retrieval of fishing gear. In conjunction with USFWS, NOAA Fisheries recommended a series of seabird protection measures to NPFMC In 1997, NPFMC reviewed these measures and requested NOAA Fisheries to enact regulations that required longliners to use at least one of several different options to avoid incidental seabird takes. Within a range of criteria, fishermen were allowed to experiment with different techniques to see what worked best for their fishing style (see Section 3.7.1). NOAA Fisheries then began to measure the effectiveness of various seabird avoidance measures through changes in the Observer Program which required observers to gather data on the techniques used and their effectiveness in avoiding seabird take. Data collection was expanded in 1999 and 2000 to incorporate more detailed information about the frequency of measures used during a fishing trip and specific characteristics of different avoidance measures.

The seabird avoidance measures implemented in 1997 did not prevent additional takes of the short-tailed albatross. Two short-tailed albatross were taken in late September 1998 in the BSAI Pacific cod fishery and both vessels that hooked these birds were using the required seabird avoidance devices. However, the regulations do not include performance standards and, even though they were technically in compliance, reports from observers on these vessels indicated that the avoidance gear was set in a very ineffective configuration. There was a great deal of concern within the fishing industry at that point because they were close to reaching the incidental take threshold of four birds within a two year period established by USFWS. Under the regulations and authority of the ESA, exceeding this threshold would have required an immediate Section 7 consultation with USFWS to review the seabird protection measures. One possible, yet remote, outcome was that the fishery would have to close until new measures were in place, regardless of the economic impact. This concern prompted the longline industry to petition NPFMC to revise the existing seabird protection measures for the longline fisheries in the BSAI and GOA. At its April 1999 meeting, NPFMC recommended revising the existing regulations to make the most effective techniques mandatory. They also recommended that NOAA Fisheries undertake a comprehensive scientific study to test the effectiveness of these different techniques. This study was conducted by the Washington Sea Grant Program in 1999 and 2000 in the IFQ halibut and sablefish fishery and in the BSAI Pacific cod freezer-longliner fishery, with funding by NOAA Fisheries and USFWS and substantial support from the Observer Program and the longline industry. This research was carried out with the active cooperation and participation of the fishing industry to make sure that the techniques developed would meet with safety and "fishability" requirements.

The final report from the Washington Sea Grant study (Melvin *et.al.* 2001) indicates that use of paired streamer lines (with specified parameters) effectively eliminated all bycatch of Laysan albatross and northern fulmar without impacting catch rates of target species. While the study participants took special precautions when short-tailed albatross were sighted and none of these birds were caught during the study, the dramatic reduction of incidental take of similar-feeding species with the use of paired streamer lines indicates that the risk of incidental take to the endangered species would be greatly reduced if this avoidance measure was widely adopted. The use of single streamer lines was almost as effective as the paired streamer lines for overall seabird bycatch avoidance but Laysan albatross were caught five times as frequently with single versus paired streamer lines. The study concluded that the risk of hooking albatrosses, including short-tailed albatross, remains when only single streamer lines are used. Based on the results of their research (Melvin *et al.* 2001), the Washington Sea Grant Program, USFWS, and NOAA Fisheries jointly developed recommended changes to the existing seabird avoidance regulations required in the groundfish and halibut hook-and-line fisheries off Alaska. At its October and December 2001 meetings, NPFMC reviewed these recommendations, made some changes, and requested NOAA Fisheries to implement the necessary regulations. (See Section 3.7.1) The longline fleet has been very proactive in adopting these techniques and most vessels may already be in compliance in advance of the new regulations becoming legalized.

<u>Direct Mortality from Vessel Strikes</u>

Many trawl vessels deploy a cable ("third wire") from the vessel to the trawl net monitoring device (sonar transducers). There are 16 records of birds striking the "third wire" in the Observer Notes Database. These incidents involved 79 birds, mainly fulmars and Laysan albatross, with approximately 90 percent mortality (NPFMC 2002c). However, these cables are not typically monitored by groundfish observers and any birds killed by such collisions would not be likely to make their way into the trawl net and would therefore not be recorded in observers' haul samples. The distribution and extent of seabird mortalities or injuries by species is therefore unknown. NOAA Fisheries' AFSC is currently pursuing the possibility of using video technology to evaluate this issue. NOAA Fisheries and USFWS are presently trying to determine if this impact poses a threat to short-tailed albatross (USFWS 2000c). Solutions may be as simple as hanging streamers from the third wire (G. Balogh, USFWS, Anchorage, personal communication).

Other Past and Present Effects

In addition to potentially catastrophic natural events, the USFWS has identified several other human-induced impacts as potential threats to the species conservation and recovery (USFWS 2000c). Not enough information is available to assess the extent of these impacts quantitatively. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Direct mortality from incidental take in groundfish trawls.** No short-tailed albatross have been recorded as being taken in the groundfish trawl fishery but the similar Laysan albatross have been taken in trawls. The first recorded short-tailed albatross taken in Alaska fisheries was caught in a brown crab net (Table 3.7-11).

- **Indirect effects through changes in prey availability.** The impacts of groundfish and other fisheries on the availability of prey to short-tailed albatross are unknown. The ability of albatross to forage over huge areas is presumed to lessen the potential impact of localized depletion of prey. The fact that the short-tailed albatross population is growing at or near its theoretical maximum rate and that the environment used to support millions of them, it is thought that food availability is not limited at present (USFWS 2000c).

- **Indirect effects through consumption of fishery discards.** Short-tailed albatross are attracted to fishing vessels and processors to eat discards and offal. Benefits of the food source are countered by an increased risk of incidental take on longlines.

- **Indirect effects through plastics ingestion.** Species feeding primarily by surface-seizing, including short-tailed albatross, have the highest frequencies of plastic ingestion (Sievert and Sileo 1993). Dr. Hiroshi Hasegawa (personal communication 1997) reports that short-tailed albatross on Torishima commonly regurgitate large amounts of plastic debris. Hasegawa has observed a large increase in the occurrence of plastics in birds on Torishima over the last 10 years. His impression is that the vast majority of regurgitated plastics have been washed out to sea from land-based activities (USFWS 1998b). Plastic ingestion may cause physiological stress as a result of satiation and mechanical blockages (Auman *et al.* 1997) and may affect chick survival when the volume of plastic ingested is high (Sievert and Sileo 1993).

- **Indirect effects through contamination by oil spills.** Surface-feeding pelagic seabirds, including short-tailed albatross, are moderately sensitive to oil effects given their extreme reliance on open-water marine habitats for feeding and roosting, making them susceptible to incidents in these settings (King and Sanger 1979). Dr. Hiroshi Hasegawa (personal communication 1997) has observed some birds on Torishima with oil spots on their plumage. An oil spill in an area where a large number of individuals were rafting, such as near breeding colonies, could affect the population significantly.

Comparative Baseline

Short-tailed albatross were nearly exterminated by commercial hunting about 100 years ago but are making a comeback. The population appears to be increasing at a near-maximum rate. They are still one of the rarest species on earth with an estimated population of only 1600 to 1700 birds and are listed as "endangered" under the ESA. The need to protect this species from all sources of human-induced mortality has driven a great deal of research and regulation of seabird/fisheries interactions in the BSAI and GOA area. The institution of mandatory seabird protection measures for longliners in 1997 did not eliminate incidental take of this species but no incidental takes have been reported since September 1998. Recent scientific research indicates that new seabird avoidance techniques can greatly reduce the incidental take of species with similar feeding behavior as short-tailed albatross. NPFMC has recommended that these techniques be made mandatory for the groundfish longline fleet. NOAA Fisheries is currently in the process of implementing new seabird avoidance regulations for the longline fleet. The past and present effects on short-tailed albatross are summarized in Table 3.7-12.

Status for Cumulative Effects Analysis

Incidental take of short-tailed albatross remains a concern under all alternatives. The species' endangered status under the ESA requires that it receive consideration in the cumulative effects analysis. Because of its special status, it will not be grouped with any other species in the analysis of FMP Alternatives.

3.7.5 Northern Fulmar (*Fulmarus glacialis*)

Life History and Distribution

The northern fulmar has a wide range of color variations and looks similar to gulls but is actually related to the albatross. Fulmars are one of the few species in the tubenose family that breeds in Alaska. Nesting on remote, steep-sided island cliffs, both sexes share parental duties. The single egg is incubated for about eight weeks and the young fledge about seven weeks after they hatch.

The foraging range during nesting season is potentially large: the parents alternately depart from the colony every four to five days on foraging trips and are known to forage out to 100 km or more (Hatch and Nettleship 1998). They disperse throughout ice-free Alaskan waters and in the North Pacific Ocean in winter (Gould *et al.* 1982, Shuntov 1993). Fulmars do not reach breeding age until at least six years old and can live up to 50 years or longer.

Northern fulmars inhabit the northern oceans of the world, with separate populations in the Pacific and Atlantic (Harrison 1983). The estimated worldwide population of this species is 10 to 12 million individuals with an estimated population of 4 to 5 million individuals in the North Pacific (Hatch and Nettleship 1998). Ninety-nine percent of the Alaskan population nests in four colonies: Semidi Islands (GOA), Chagulak Island (Aleutian Islands), the Pribilof Islands (Bering Sea), and St. Matthew/Hall Islands (Bering Sea) (Hatch and Nettleship 1998). The estimated population is 1,500,000 fulmars in the BSAI area and 600,000 in the GOA area (Table 3.5-62).

Population trend data has been collected from permanent sample plots in several areas. The population of fulmars on the Pribilof Islands (St. George and St. Paul) was estimated at about 70,000 individuals in the 1970s (S. Hatch, personal communication, USGS, Alaska Biological Science Center). Permanent study plots for fulmars were established on St. George Island in 1976. The census for these plots was relatively consistent for the next twelve years but then rose dramatically from about 970 birds in 1988 to a high count of 1979 birds in 1992. The census for these plots then declined even more dramatically to 475 birds in 1999 (Dragoo *et al.* 2001). On nearby St. Paul Island, a much smaller colony, census plots showed a similar pattern of stability and then major increase to a high in 1992 and then a decline in subsequent years.

On Chowiet Island, the main fulmar colony in the Semidi Islands in the GOA, census numbers for permanent study plots show a similar pattern to that in the Pribilofs. After relatively stable counts from 1976 to 1991, numbers increased substantially to a maximum in 1993 and then declined by more than half that number in 1998 (Dragoo *et al.* 2001). There are no regularly censussed sample plots on the St. Matthew/Hall or Chagulak Island colonies.

Trophic Interactions

Northern fulmars forage on a variety of surface species including squid, jellyfish, crustaceans, other invertebrates, and small fish (including juvenile pollock in the Pribilof Islands) (Ainley and Sanger 1979, Hunt *et al.* 1981a, DeGange and Sanger 1986, Sanger 1987, Schneider *et al.* 1986, Baird 1990, Hatch 1993, Gould *et al.* 1997). Food is taken from the water surface or just beneath it, including at night when pelagic prey migrate close to the surface (Schneider *et al.* 1986, Hatch 1993). Fulmars probably do much of their foraging at night, and may use olfactory cues in locating food because their sense of smell is highly developed (Hatch and Nettleship 1998). Fulmars obtain food by dipping, surface-seizing, surface-plunging, pursuit-diving, and scavenging. They are apparently unable to pick up prey while on the wing.

Ranging over large areas of ocean, fulmars forage from the continental shelf to beyond the continental shelf break (Hunt *et al.* 1981c, Gould *et al.* 1982, Schneider and Hunt 1984, DeGange and Sanger 1986, Schneider *et al.* 1986, Hatch 1993). The outer front and shelf edge, where water from the continental slope is upwelled, is important to several surface-feeding seabird species, including fulmars. Availability of prey to these seabirds may vary with strength of the upwelling (Schneider *et al.* 1987).

Although the location of breeding sites influences seabird feeding distribution, fisheries also have a strong influence on the distribution of seabirds at sea (Garthe and Huppop 1994). Fulmars are common scavengers of discarded fish thrown overboard by commercial fishing boats, sometimes forming vast chattering groups of thousands of birds.

Management Overview

Wildlife management responsibility for the northern fulmar is under the jurisdiction of the USFWS. The species is protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*).

Past and Present Effects and Management Actions

Direct Mortality from Incidental Take in External Fisheries

Past fisheries in the North Pacific, both foreign and domestic, have taken fulmars in the course of their operations. For most of these fisheries, the numbers of individual species taken were not recorded. One exception is the Japanese salmon mothership fishery where an average of 2,352 fulmars were taken every year between 1981-1984 (Jones and DeGange 1988). In 1977, the land-based Japanese salmon gillnet fishery killed an estimated 1,536 fulmars. In 1987, after substantial reductions in the fishing effort, an estimated 694 fulmars were taken (DeGange and Day 1991). The incidental take of fulmars in other current foreign gillnet fisheries is unknown. Since they usually forage at-sea, they are unlikely to be taken in coastal gillnet fisheries.

State-managed longline fisheries (cod, sablefish, rockfish) and halibut fisheries may contribute only a small amount to the overall incidental take of fulmars. The larger hooks used in the halibut fisheries presumably result in lower incidental catch rates than in the groundfish fisheries. In 1998, incidental takes of 57 fulmars were documented in the halibut fishery through interviews with fishermen (Trumble and Geernaert 1999). However, since the halibut and state-managed fisheries are not subject to the NOAA Fisheries Observer Program, there is no way to independently verify or quantify the numbers of particular species taken by these vessels.

Direct Mortality from Incidental Take on Groundfish Longlines

The numbers of fulmars that were caught in the BSAI and GOA groundfish longline fisheries between 1993-2001 were estimated from Observer Program data (Tables 3.7-2 and 3.7-3). Fulmars are taken incidentally on longlines far more frequently than any other species. In the BSAI, fulmars constitute an average of 60 percent of all birds taken and in the GOA, 46 percent are fulmars. Between 1993 and 2001, the estimated number of fulmars killed by longlines in the BSAI varied between 4,251 and 15,533 birds per year with an estimated average of 8,644 fulmars per every year (95 percent confidence interval is 8,252 - 9,036 birds). In the GOA, an estimated average of 479 fulmars were taken every year (95 percent confidence interval is 388 - 569 birds).

In an effort to reduce the incidental take of seabirds on longlines, NOAA Fisheries instituted mandatory seabird avoidance measures for the groundfish fleet in 1997 (62 FR 23176). These measures included some flexibility for captains to decide which options to use in order to accommodate their particular fishing vessels and techniques. Based on the observation that most seabirds fed during daylight hours, one of these options was to fish at night. Unfortunately, fulmars are an exception to that general rule and often feed at night. Prior to 1997, the average estimated numbers of fulmars taken in the BSAI were 6,087 birds per year. Between 1997and 2001, the estimated annual average take in the BSAI increased to 10,689 fulmars per year, with the two largest takes in 1997 and 1998. In contrast, the GOA 1993-1996 average was 569 fulmars per year and the 1997-2001 average decreased to 406 birds per year. It is not known what proportion of fishing effort was conducted at night as a seabird avoidance measure and whether the different responses in the BSAI and GOA were the result of different fishing strategies or other factors. During the Washington Sea Grant Program experimental tests of the efficacy of the various seabird avoidance measures, night sets of longline fishing gear showed significant increases of fulmar incidental catch over daytime sets (Melvin *et al.* 2001). This study also indicated that use of paired streamer lines (with specified parameters) effectively eliminated all bycatch of northern fulmars without impacting catch rates of target species. In response to the Washington Sea Grant results, NOAA Fisheries' pending new regulations eliminate night fishing as an optional seabird deterrent technique and require that paired or single streamer lines be used on all groundfish longline vessels longer than 26 ft LOA.

Several factors are likely to affect the risk of seabird incidental catch, including fishing effort (number of hooks per year), the distribution of effort by sub-area and season, the abundance and distribution of seabirds in the vicinity of fishing vessels, the nutritional condition of the birds (i.e. starving or not), and the use of seabird deterrents. The relative importance of these factors has not been fully studied. NOAA Fisheries analyzed the relationship between fishing effort and numbers of birds hooked in the BSAI and GOA longline fisheries and found that the relationship varies for different species groups (Figures 3.7-5 and 3.7-6, respectively). The data suggest that fishing effort in longline fisheries (number of hooks set) does play a strong role in determining how many fulmars are caught. This was not the case for the other major groups of seabirds that are taken.

Direct Mortality from Incidental Take in Groundfish Trawls

The combined BSAI and GOA trawl fishery took an estimated average of between 274 fulmars (low estimate) and 5,891 fulmars per year (high estimate) from 1997-2001 (Table 3.7-4).

Direct Mortality from Incidental Take in Groundfish Pot Gear

Fulmars are one of the few species that are caught in the pot fisheries and actually make up a large majority of birds caught (Table 3.7-5). Still, pot fisheries account for relatively few incidental takes. Between 1993 and 2001, an average of 33 fulmars were taken in the combined BSAI and GOA pot fisheries. Many of these birds may actually have been killed by collisions with the pot gear while it was on deck, rather than as it was fishing, with dead birds being caught in the gear before it was deployed.

Direct Mortality from Vessel Strikes

According to the Observer Program records of bird-strikes from 1993-2000, fulmars are the species most frequently observed to strike the vessel, rigging, or trawl “third wires”. Of the 120 recorded collisions, 564 fulmars were involved in 38 incidents. Monitoring these types of collisions is not part of the observer’s normal duties so the true extent of this impact is not known. NOAA Fisheries is currently investigating the issue, especially as it relates to “third wires” (NPFMC 2002c).

Assessment of Population-Level Effects

One major question for resource managers is whether a given level of incidental take is significant at the population-level. The Observer Program data has been combined from many different areas to give a broad, regional average for incidental take. Taken as a percentage of a regional population estimate, a given average level of incidental take may not appear to be a significant impact. However, if a majority of the fulmars taken annually in the groundfish fishery originate from one colony (such as St. George), and if a substantial proportion of the catch consists of adult birds, then it is possible that fishery incidental take could be contributing to population declines at specific colonies. As noted above, fulmar sample plots on St. George, St. Paul, and Chowiet islands all showed a similar pattern of stability in the 1970s and 1980s followed by a major increase in the early 1990s and an even larger decline thereafter (Dragoo *et al.* 2001). This pattern was especially dramatic on St. George. There is some question regarding the accuracy of the sample plots in reflecting actual population-level fluctuations. For instance, due to their conservative life history strategy, fulmars would not be expected to double their population over 4 years as did the sample plot numbers between 1988 and 1992 at St. George. If the count on St. George in 1992 was anomalously high (for some unexplained reason), the apparent subsequent ‘decline’ may be less meaningful in terms of actual population impacts. In order to address this uncertainty, the USGS/Biological Resource Division has recently begun to collect data on the at-sea foraging distribution of northern fulmars as well as identifying the colony of provenance of a sample of incidentally taken fulmars. Results will be used in the development of population models that may elucidate the potential for incidental take in groundfish fisheries to have colony-level population impacts. There are, of course, other factors besides fishing impacts that may cause population-levels to fluctuate, including variable environmental conditions, and these will be investigated as well.

Other Past and Present Effects

The following issues have been identified as having potential impacts on northern fulmars but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** The impacts of groundfish and other fisheries on the availability of prey to fulmars are unknown. The ability of fulmars to forage over huge areas is presumed to lessen the potential impact of localized depletion of prey.

- **Indirect effects through consumption of fishery discards.** Fulmars are attracted to fishing vessels and processors to eat discards and offal. Benefits of the food source are countered by increased risk of incidental take on longlines.

- **Indirect effects through plastics ingestion.** Species feeding primarily by surface-seizing, including northern fulmar, have the highest frequencies of plastic ingestion (Sievert and Sileo 1993).

- **Indirect effects through contamination by oil spills.** Surface-feeding pelagic seabirds, including fulmars, are moderately sensitive to oil effects given their extreme reliance on open-water marine habitats for feeding and roosting, making them susceptible to incidents in these settings (King and Sanger 1979).

Comparative Baseline

Northern fulmars are abundant breeders and residents in the BSAI and GOA area with an estimated population of 2 million birds in the BSAI and GOA. They are strongly attracted to fishing vessels where they scavenge for fish processing waste and bait. Their numbers and behavior have contributed to their status as the bird species most frequently taken incidental to the groundfish fisheries. The institution of mandatory seabird protection measures for longliners in 1997 actually led to an increase of fulmars taken in the BSAI even though incidental take in the GOA decreased. Fulmars make up the majority of birds taken in the trawl fisheries with annual take in the thousands. Investigations into possible colony-level population impacts are currently underway. The past and present effects on northern fulmar are summarized in Table 3.7-13.

Status for Cumulative Effects Analysis

Incidental take of northern fulmars is expected to continue under all alternatives and warrants consideration in the cumulative effects analysis. Because of their status as the most frequently taken seabird species in all sectors of the groundfish fisheries, they will be discussed as a separate species in the analysis of FMP Alternatives.

3.7.6 Shearwaters

- Short-tailed shearwater (*Puffinus tenuirostris*)
- Sooty shearwater (*Puffinus griseus*)

Life History and Distribution

Shearwaters belong to the order Procellariiformes, the tubenoses, along with albatross, fulmars, and storm-petrels. Both species common to the BSAI and GOA, the short-tailed and sooty shearwaters, are dark gray with long, narrow wings and are difficult to distinguish from each other. Shearwaters breed in the Southern Hemisphere: short-tailed shearwaters in southeastern Australia and Tasmania, sooty shearwaters in New Zealand and in Chile along the South American coast. Both short-tailed and sooty shearwaters visit Alaskan waters from May through September. Short-tailed shearwaters are found in the Bering and Chukchi Seas as well as the GOA while sooty shearwaters range primarily south of the Aleutian Islands and in the GOA (Hunt *et al.* 1981b, Gould *et al.* 1982).

The total world population of short-tailed shearwaters, almost all of which spend the austral winter in the North Pacific, has been estimated at 23 million (Everett and Pitman 1993). The population of sooty shearwaters may exceed 30 million (Springer *et al.* 1999). The populations of these two species account for over 50 percent of all seabirds in Alaskan waters in summer (Sanger and Ainley 1988).

Three different time-series of pelagic bird abundance collected in disparate portions of the California Current revealed a 90 percent decline in sooty shearwater abundance between 1987 and 1994. The decline was negatively correlated with a concurrent rise in sea-surface temperatures (Veit *et al.* 1996 and 1997). The widely separated surveys suggest that this abundance change may be more than just a local change in distribution. An overall decreasing trend in sooty and short-tailed shearwater abundance at breeding colonies has occurred over the past 20 to 30 years. (Baduini, University of California, Irvine, personal communication 2000). The extent and mechanism(s) for these potential declines have not yet been established.

Trophic Interactions

Both short-tailed and sooty shearwaters forage on the surface or can dive to at least 60 m (Weimerskirch and Sagar 1996, Weimerskirch and Cherel 1998). Shearwaters depend on areas where prey are concentrated by upwellings, convergences, or bottom terrain features, especially along the inner front (boundary between wind-mixed and stratified water on the Bering Sea shelf) (Hunt *et al.* 1981b, Schneider *et al.* 1986, Hunt *et al.*1996c). The short-tailed shearwater eats primarily large euphausiids and some jellyfish and small schooling fish (Marchant and Higgins 1990). Diets of short-tailed shearwaters in spring varied by region in the western subarctic (Springer *et al.* 1999). This apparently reflects the availability of prey species rather than dietary preferences since elsewhere (e.g., Sea of Okhotsk and Bering Sea) other prey predominate (Ogi *et al.* 1980). Sooty shearwaters eat primarily small schooling fish, such as Pacific saury and myctophids, and their movements are believed to coincide with the movements of the sauries (Ogi 1984). Sooty shearwaters forage on squid on the outer shelf and shelf break (DeGange and Sanger 1986) and with increasing prominence at higher latitudes (Ogi 1984).

Shearwaters in the southeastern Bering Sea have, in the past, consumed a large biomass of euphausiids. Recent evidence (Baduini *et al.* 2000) suggests that, since 1997, short-tailed shearwaters over the southeastern Bering Sea shelf have been taking increasing amounts of fish. Inshore of the inner front, Pacific sand lance is taken, whereas most foraging flocks offshore of the inner front were focused on age-0 gadids, most likely pollock. This apparent dependence on age-0 pollock may occur when euphasiids are scarce over the middle domain (Hunt *et al.* 1998).

Short-tailed shearwaters occasionally die-off in large numbers during late summer, apparently due to widespread scarcity of prey during anomalous oceanographic conditions. Major die-offs were recorded in Alaska in 1983, 1986, and 1997 (Nysewander and Trapp 1984, Irons *et al.* 1986, Hatch 1987, Baduini *et al.* 1998, Mendenhall *et al.* 1998). In 1997, a die-off of short-tailed shearwaters, apparently from starvation, was estimated at 11 percent of the population surveyed (Baduini *et al.* 2000). This estimate was based on a count of floating carcasses in the southeast Bering Sea as a percent of the population surveyed. In 1998, anomalous climate conditions were repeated for a second consecutive year, with elevated water temperature, cross-shelf advection of zooplankton and larval fish, major changes in the structure of the zooplankton community, and an unprecedented second observation of a large-scale coccolithophorid phytoplankton bloom (Hunt *et al.* 1999a). Although no unusual mortality of short-tailed shearwaters was seen, birds were underweight. In both years, shearwater diets were broader than in previous years, with fish becoming a dominant prey in 1998.

The recent large-scale die-off of short-tailed shearwaters suggests that these birds are vulnerable to changes in the abundance or availability of their preferred foods in the southeastern Bering Sea (Vance *et al.* 1998). Changes in water temperature or productivity may influence the abundance of euphausiids either directly, through bottom-up effects, or indirectly through changes in the distribution of predators that compete with shearwaters for euphausiids. When euphausiids are scarce, shearwaters can use age 0 pollock, if they are present in high concentrations. Shearwater use of age 0 pollock may need to be considered in future management decisions (G.L. Hunt, Jr., University of California, Irvine, personal communication). Major changes in the zooplankton community will be likely to affect other higher trophic level species, including fish and whales (Hunt *et al.* 1999a).

Management Overview

Wildlife management responsibility for shearwaters is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*).

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Shearwater chicks, called "muttonbirds" because of their high fat content, have been heavily harvested by subsistence and commercial hunters in the South Pacific for many years. In Australia alone, an estimated 700,000 short-tailed shearwater chicks are harvested every year (Everett and Pitman 1993).

Direct Mortality from Incidental Take in External Fisheries

Short-tailed and sooty shearwaters are attracted to fishing vessels throughout their range and have been taken incidentally in many different fisheries. The fact that they migrate between subarctic and subantarctic waters exposes them to a great variety of fisheries. High-seas driftnet fisheries for tuna, squid, and salmon have been identified as a major source of mortality for shearwaters in the past. The Japanese large-mesh driftnet fishery for tuna and swordfish dates back to 1905. This fishery peaked in 1982 with over 700 vessels but declined to only 70 vessels by 1991. There is no data on the incidental take of seabirds for most of this period except for the 1990-1991 season when over 3500 seabirds were estimated to be taken, including a large number of sooty shearwaters (DeGange *et al.* 1993). Between 1981 and 1984, the Japanese salmon mothership fishery took an average of 95,500 shearwaters each year, mostly short-tailed (Jones and DeGange 1988). In the Japanese land-based drift gillnet fishery, an estimated 80,000 shearwaters (again, mostly short-tailed) were killed in 1977. By 1987, fishing effort had been reduced and an estimated 27,500 shearwaters were killed (DeGange and Day 1991). These estimates do not include birds that fell out of the nets before being retrieved or birds that were released alive. Driftnet fisheries targeting flying squid were started in the late 1970s by Japan, Korea, and Taiwan. At their peak in the late 1980s, these fisheries deployed millions of kilometers of driftnet. Rough estimates of the total number of seabirds killed by the squid driftnet fisheries ranged between 875,000 and 1,660,000 seabirds annually. Up to 70 percent of these birds consisted of sooty shearwaters and over 100,000 birds were identified as short-tailed shearwaters (DeGange *et al.* 1993). Due to the tremendous amount of waste and ecosystem damage associated with the high-seas driftnet fisheries, they were outlawed by international agreement through United Nations Resolution (46/215) in December of 1992 (Paul 1994). Because shearwaters are such long-lived and slowly maturing species, high rates of mortality from the driftnet fisheries may have a lingering impact on the populations at present.

State-managed longline fisheries and halibut fisheries may contribute only a relatively small amount to the overall incidental take of shearwaters. In 1998, incidental take of 3 unidentified shearwaters were documented in the halibut fishery through interviews with fishermen (Trumble and Geernaert 1999).

Direct Mortality from Incidental Take on Groundfish Longlines

The estimated numbers of seabirds caught in the BSAI and GOA groundfish longline fisheries are listed in Tables 3.7-2 and 3.7-3. The two species are combined into one "shearwater" category and are probably also included to some extent in the "unidentified tubenoses" category. The combination of these categories averaged 674 birds per year between 1993 and 2001 in the BSAI and about 30 birds per year in the GOA.

In an effort to reduce the incidental take of seabirds on longlines, NOAA Fisheries instituted mandatory seabird avoidance measures for the groundfish fleet in 1997 (62 FR 23176). Prior to 1997, the average estimated number of identifiable shearwaters taken in the BSAI was 389 birds per year (not including "unidentified tubenoses"). Between 1997 and 2001, the estimated average take in the BSAI increased to 578 shearwaters per year. Much of this increased average take was due to an unusually high number of birds taken in 1998 (1,131 shearwaters). The reason this one year was so different than the others is not known but may be related to nutritional stress of the birds. In the GOA, the average take before and after the seabird avoidance measures were enacted declined from 35 shearwaters per year in 1993-1996 to 18 shearwaters per year in 1997-2001. Although the Washington Sea Grant Program results indicate that new seabird avoidance techniques could reduce overall incidental take of seabirds by 70-95 percent, incidental take of species such as shearwaters that can dive deep in pursuit of baited hooks were not reduced when single or paired streamer lines were employed (Melvin *et al.* 2001).

Direct Mortality from Incidental Take in Groundfish Trawls

The estimated number of shearwaters caught in the combined BSAI and GOA groundfish trawl fisheries varied considerably between years (Table 3.7-4). The average estimated number of shearwaters taken was between 271 birds per year (low estimate) and 1,327 birds per year (high estimate) in 1997-2001.

Direct Mortality from Vessel Strikes

According to preliminary analysis of the Observer Program records of bird-strikes from 1993-2000, sooty shearwaters were observed to strike the vessel or rigging on 6 occasions but these involved 526 birds. Collisions of large numbers of birds typically occur during the night or during storms or foggy conditions when bright deck lights are on, which can cause the birds to be disoriented (NPFMC 2002c).

Other Past and Present Effects

The following issues have been identified as having potential impacts on short-tailed and sooty shearwaters but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** The impacts of groundfish and other fisheries on the availability of prey to short-tailed and sooty shearwaters are unknown. The ability of short-tailed and sooty shearwaters to forage over huge areas is presumed to lessen the potential impact of localized depletion of prey.

- **Indirect effects through consumption of fishery discards.** Shearwaters are attracted to fishing vessels and processors to eat discards and offal. Benefits of the food source are countered by increased risk of incidental take on longlines and trawls.

- **Indirect effects through plastics ingestion.** Species feeding primarily by surface-seizing or pursuit-diving, including shearwaters, have the highest frequencies of plastic ingestion (Sievert and Sileo 1993).

- **Indirect effects through contamination by oil spills.** Diving pelagic seabirds, including shearwaters, are moderately sensitive to oil effects given their extreme reliance on open-water marine habitats for feeding and roosting, making them susceptible to incidents in these settings (King and Sanger 1979).

Comparative Baseline

Short-tailed and sooty shearwaters are by far the most abundant seabirds in Alaska, even though they do not breed here. They have been hunted in huge numbers on their breeding grounds and taken incidentally in various fisheries throughout their range. Increasing ocean water temperatures and changing ocean currents have apparently altered their prey availability and caused periodic massive die-offs due to starvation. Both species may have experienced population declines in the past twenty years but they continue to be very abundant. The numbers of shearwaters taken in the BSAI and GOA groundfish fisheries is relatively small. The past and present effects on shearwaters are summarized in Table 3.7-14.

Status for Cumulative Effects Analysis

Incidental take of shearwaters is expected to continue under all alternatives and warrants consideration in the cumulative effects analysis. Because of the similarity of their fishery interactions and responses to management measures, sooty and short-tailed shearwaters will be discussed together in the "shearwater" group in Chapter 4.

3.7.7 Storm-Petrels

- Leach's storm-petrel (*Oceanodroma leucorhoa*)
- Fork-tailed storm-petrel (*Oceanodroma. furcata*)

Life History and Distribution

Storm-petrels are tubenoses and are thus related to albatross, fulmars, and shearwaters. Two species breed in Alaska: Leach's storm-petrel and fork-tailed storm-petrel. Both are robin-sized birds with forked tails. Leach's is dark gray with a white rump and the fork-tailed is mostly whitish-gray with darker wings. Both species nest on islands in burrows that they dig or in crevices in the rocks. They lay one egg in June, incubate it for about 40 days, and fledge chicks about 70 days later. These species are active at the colony only at night, and often stay at sea during the day or on moonlit nights (Boersma and Groom 1993).

Both the Leach's and fork-tailed storm-petrels breed on islands from the western Aleutians through the GOA, but not farther north (USFWS 1998a). These species winter over the deep ocean, including the Bering Sea Basin (Shuntov 1993). Populations of most seabirds that nest in burrows and crevices, including these two storm-petrels, have not been adequately counted at any season. Population estimates are extremely crude and may only indicate their numbers within an order of magnitude (Boersma and Groom 1993). Although difficult to count, these species appear to be quite abundant in the BSAI and GOA. USFWS (1998a) estimates that there are 4.5 million Leach's storm-petrels in the BSAI and 1.5 million in the GOA. Fork-tailed storm-petrels are thought to number 4.5 million in the BSAI and 1.2 million in the GOA (Table 3.5-62).

USFWS conducts annual surveys of the populations of storm-petrels on three islands in Alaska: St. Lazaria (southeast), Aiktak (eastern Aleutians), and Buldir (western Aleutian Islands) (Figure 3.7-1). Breeding populations are indexed by counting burrow holes on permanent plots. Since they cannot be distinguished reliably, burrows made by Leach's and fork-tailed storm-petrels are combined for a total storm-petrel population index. On all three islands, the density of burrow holes has generally increased since counts were begun in the early 1990s (Dragoo *et al.* 2001).

Trophic Interactions

Storm-petrels seize prey from the water's surface and forage at night. They have well-developed olfactory senses and find their food and perhaps nest sites by scent (Boersma and Groom 1993). Storm-petrels feed on small fishes, particularly juvenile lantern fish, squid, and euphausiids (Springer *et al.* 1999), but in some areas, fork-tailed storm-petrels may depend on capelin (Ainley and Sanger 1979, Baird and Gould 1986, DeGange and Sanger 1986).

Storm-petrels forage at distances of more than 100 km from breeding colonies and typically forage over the shelf edge and deep water (Springer *et al.* 1999). Leach's storm-petrels forage from the shelf-break seaward (Ainley and Sanger 1979, Hunt *et al.* 1981b, Gould *et al.* 1982, Schneider *et al.* 1986). Fork-tailed storm-petrels most typically forage over the outer shelf and adjacent ocean. This species has also been observed feeding on the southeast Bering Sea shelf near the Slime Bank area and in large groups in Resurrection Bay coming out of Seward (C. Baduini, University of California, Irvine, personal communication).

Management Overview

Wildlife management responsibility for storm-petrels is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*).

Past and Present Effects and Management Actions

Direct Mortality from Incidental Take in External Fisheries

Storm-petrels are attracted to fishing vessels throughout their range and have been taken incidentally in many different fisheries. Between 1981 and 1984, the Japanese salmon mothership fishery took an estimated annual average of 94 Leach's storm-petrels and 954 fork-tailed storm-petrels (Jones and DeGange 1988). In the Japanese land-based drift gillnet fishery, an estimated 1,843 fork-tails were killed in 1977 and 578 were killed in 1987 (DeGange and Day 1991). No estimates of incidental take are available for the high seas squid gillnet fisheries of Japan, Korea, and Taiwan.

Direct Mortality from Incidental Take in the Groundfish Fisheries

Storm-petrels are not identified by species in the Observer Program data (Tables 3.7-2 through 3.7-5) but are presumably included in the "unidentified tubenoses", "other", and "unidentified seabird" categories. Storm-petrels account for an unknown fraction of these totals.

Direct Mortality from Vessel Strikes

According to the Observer Program records of bird-strikes from 1993-2000, storm-petrels strike the vessel or rigging on a regular basis. Of the 120 recorded collisions, 631 storm-petrels were involved in 19 incidents. It is not known what proportion of these birds were killed or injured (NPFMC 2002c).

Other Past and Present Effects

The following issues have been identified as having potential impacts on storm-petrels but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** The impacts of groundfish and other fisheries on the availability of prey to storm-petrels are unknown. The ability of storm-petrels to forage over large areas is presumed to lessen the potential impact of localized depletion of prey.

- **Indirect effects through contamination by oil spills.** Storm-petrels are moderately sensitive to oil effects given their extreme reliance on open-water marine habitats for feeding and roosting, making them susceptible to incidents in these settings (King and Sanger 1979).

- **Indirect effects by introducing mammalian predators to nesting islands.** Burrowing seabirds, including storm-petrels, were decimated or seriously reduced on many islands in the Aleutian chain and GOA after the introduction of arctic and red foxes by fox farmers. Storm-petrels have begun to re-colonize some of those islands after the removal of the foxes but populations are probably still depressed from pre-fox levels. (Bailey and Kaiser 1993). At present, rats pose the greatest predator threat to seabirds breeding in Alaska, especially for burrow and crevice nesters such as storm-petrels. It is not known what proportion of fishing vessels carry rats. The USFWS in Alaska has an extensive program to reduce the threat of new rat invasions.

Comparative Baseline

Leach's and fork-tailed storm-petrels are abundant in the BSAI and GOA area. Reliable population estimates and trends are not available for these species. These species are probably taken occasionally by groundfish vessels, at least through vessel strikes. They are not gregarious at sea and can forage long distances from their breeding colonies and are thus not likely to be impacted by potential local depletion of forage species. The past and present effects on storm-petrels are summarized in Table 3.7-15.

Status for Cumulative Effects Analysis

The frequency of interaction between storm-petrels and the groundfish fleet warrants further consideration in the cumulative effects analysis. Due to the lack of quantitative information on fishing impacts on these species, they will be included in the "other planktivorous species" group in the following analysis of FMP Alternatives.

3.7.8 Cormorants

- Pelagic cormorant (*Phalacrocorax pelagicus*)
- Red-faced cormorant (*Phalacrocorax urile*)
- Double-crested cormorant (*Phalacrocorax auritus*)

Life History and Distribution

Cormorants are large, dark, heavy-bodied birds with long necks and tails. There are four species that breed in Alaska. The pelagic cormorant breeds throughout the BSAI and GOA, the red-faced cormorant breeds in the BSAI north to the Pribilofs and the GOA west of PWS, and the double-crested cormorant breeds in the Aleutian Islands and GOA. Brandt's cormorant (*P. penicillatus*) primarily breeds south of Alaska but has two small colonies in southeastern Alaska and one near the entrance to PWS (USFWS 1998a). It does not regularly interact with the groundfish fisheries and is not described further here. The other three species nest on rocky island ledges in relatively small colonies and lay 3-5 eggs. Both sexes share parental duties. Eggs hatch in 20-25 days and young fledge in 45-60 days.

Cormorants usually range within 20 km of shore (Schneider and Hunt 1984). Winter distributions are similar to their breeding distribution except that birds will move to ice-free coasts and protected waters. Rough estimates of cormorant numbers indicate that they are not nearly as numerous as many other seabird species. In the BSAI, there are an estimated 80,000 pelagics, 90,000 red-faced, and 9,000 double-crested. In the GOA, there are an estimated 70,000 pelagics, 40,000 red-faced, and 8,000 double-crested (Table 3.5-62). Population trends are difficult to ascertain for cormorants because they are known to shift nesting locations between years. Variation in nest counts on survey plots may reflect this tendency to nest in different places rather than indicate changes in population-level. Given this caveat about interpreting the limited sample plot data, pelagic cormorant colonies in the BSAI appear to be relatively stable or decreasing over the past 20 years, decreasing in the GOA, and increasing in southeast Alaska. Red-faced cormorants are surveyed separately in only one location, Chiniak Bay (GOA), and appear to be decreasing. No trend data are available for double-crested cormorants (Dragoo *et al.* 2001).

Trophic Interactions

Cormorants are basically small fish eaters that will also take some crustaceans and other invertebrates. Cormorant species in Alaska are known to take capelin, herring, sandlance, pollock, and other small fish (Siegel-Causey and Litvinenko 1993). Cormorants forage by diving as deep as 40 m (DeGange and Sanger 1986).

Management Overview

Wildlife management responsibility for cormorants is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*).

Past and Present Effects and Management Actions

Direct Mortality from Incidental Take in Fisheries

The incidental take of cormorants in worldwide fisheries is unknown. Given their preference for nearshore waters, cormorants are more likely to be taken in coastal gillnet fisheries than offshore groundfish fisheries. Cormorants are not distinguished by species in the Observer Program data of incidental take in the groundfish fisheries. It is not known how many cormorants might be included in the "unknown" or "other" categories in the various sectors (Tables 3.7-2 through 3.7-5).

Direct and Indirect Effects through Contamination by Oil Spills

A great deal of research has been conducted on the impacts of *Exxon Valdez* oil spill in 1989 on affected species, including cormorants. Carcasses of 838 cormorants were recovered following the oil spill, including 418 pelagic, 161 red-faced, 38 double-crested, and 221 unidentified cormorants. Many more cormorants probably died as a result of the spill, but their carcasses were not found. Counts on the outer Kenai Peninsula coast suggested that the direct mortality of cormorants due to oil resulted in fewer birds in this area in 1989 compared to 1986. In addition, there were statistically-significant declines in the estimated numbers of cormorants (all three species combined) in the oiled portion of PWS based on pre- and post-spill boat surveys in July 1972-1973 compared to 1989-1991. More recent surveys (through 1998) have not shown an increasing population trend since the oil spill, and for that reason these species are considered to be not recovered in the spill area. (EVOS Trustee Council 2002).

Comparative Baseline

Cormorants are widely distributed in the BSAI and GOA but are not abundant anywhere. These species have not been studied in great detail so there are many unknowns regarding their ecosystem and anthropogenic interactions. No quantitative data is available on their interaction with the groundfish fisheries. The past and present effects on cormorants are summarized in Table 3.7-16.

Status for Cumulative Effects Analysis

Since these species do not interact very often with the groundfish fisheries and there is no quantitative data on either their population trends or impacts of the fisheries, these species will not be carried forward for cumulative effects analysis except in the general category of fish-eating (piscivorous) birds.

3.7.9 Spectacled Eider (*Somateria fischeri*)

Life History and Distribution

Spectacled eiders are large diving sea ducks that spend most of the year in marine waters and nest in coastal tundra. Like the other eider species, spectacled eiders are dimorphic; males are mostly white and black while females are mottled brown, making them very difficult to see as they tend the nest. In contrast to the conservative reproductive strategy of alcids and other seabird species, spectacled eiders can lay up to 8 eggs per year and reach sexual maturity in their second year, but may live for only 10 years (Terres 1980). After breeding, the adults travel to protected marine waters where they undergo a complete molt of their flight feathers. Two principal molting and staging areas have been identified off coastal Alaska (Ledyard Bay and eastern Norton Sound) and two off coastal Russia (Petersen *et al.* 1999).

Spectacled eiders congregate during the winter in exceedingly large and dense flocks in polynyas in the pack ice in the central Bering Sea between St. Lawrence and St. Matthew Islands. Spectacled eiders from all three known breeding areas (in Alaska, Canada, and Russia) use this wintering area. Because nearly all individuals of this species may spend each winter occupying an area of ocean less than 50 km (31 miles) in diameter, they may be particularly vulnerable to chance events during this time (USFWS 2000a).

The North American Waterfowl Breeding Pairs Survey indicates that the numbers of spectacled eiders breeding on the Yukon-Kuskokwim Delta dropped from about 48,000 pairs in the 1970s to less than 2,500 pairs by 1992, a 95 percent decline (Ely *et al.* 1994, Stehn *et al.* 1993). Recent surveys suggest the Yukon-Kuskokwim Delta population has stabilized or increased and now stands at about 4,000 pairs (Bowman *et al.* 1999, Eldridge and Dau 1999, USFWS 2000a). Biologists estimate that about 9,000 pairs currently nest on Alaska's arctic coastal plain and at least 40,000 pairs nest in arctic Russia. The current worldwide population estimate is 360,000 birds, which is derived from winter surveys in the Bering Sea and includes non-breeding birds (USFWS 1999c).

Trophic Interactions

While at sea, spectacled eiders appear to be primarily bottom feeders, eating mollusks and crustaceans at depths of up to 70 m in the wintering area (Dau and Kitchinski 1977, USFWS 1999a). They may also forage on pelagic amphipods that are concentrated along the seawater-pack ice interface (Kessel 1989). On their nesting grounds, insect larva and aquatic vegetation dominates the diet (Kistchinski and Flint 1974). Spectacled eiders nest in arctic tundra areas where they are susceptible to predation by arctic fox and several predatory birds. Predation at sea is unknown.

Management Overview

Spectacled eiders, similar to other sea ducks, are co-managed by the USFWS and the ADF&G under the Migratory Bird Treaty Act. Bag limits for sport hunting are set by the USFWS. The ADF&G, Division of Subsistence, monitors subsistence harvest of eiders along with other species of sea ducks.

Spectacled eiders have also been listed as "threatened" under the ESA (May 10, 1993, 58 FR 27474), primarily due to a rapid decline in their breeding population on the Yukon-Kuskokwim Delta. Under the requirements of the ESA Section 7, the USFWS is responsible for determining whether proposed federal actions are likely to jeopardize the recovery of the species. In 1992, while it was a candidate species for the ESA, NOAA Fisheries had its first consultation with the USFWS concerning the effects of the BSAI and GOA groundfish fisheries on spectacled eiders (USFWS 1992). The resulting BiOp concluded that the groundfish fishery would not adversely affect spectacled eiders, based primarily on the lack of spatial/temporal overlap between the marine ranges of the eiders and the groundfish harvest. The USFWS made the same determination (not likely to adversely affect) for the 1993 and 1994 groundfish TAC specifications (USFWS 1993b, USFWS 1994) and decided that it would restrict further consultations on the fishery to the endangered short-tailed albatross.

At the time the species was listed under the ESA, the USFWS determined that it would not be prudent to designate critical habitat for spectacled eiders (USFWS 1993a). After a series of legal challenges, the USFWS reversed its decision and designated critical habitat for spectacled eiders on Feb. 6, 2001, including parts of the Yukon-Kuskokwim Delta and nearby marine waters, Norton Sound, Ledyard Bay, and an area of marine water between St. Lawrence Island and St. Matthew Island (66 FR 9146) (Figure 3.7-8).

Past and Present Effects and Management Actions

Direct Mortality from Harvest and Other Intentional Take

Spectacled eiders have been used for subsistence hunting and egging purposes by local Native residents for centuries. The USFWS estimated that at least 3.75 percent of the breeding adult spectacled eiders on the Yukon-Kuskokwim Delta are taken by subsistence hunters each year, but it is not known what effect this level of harvest has on the population. Take of spectacled eiders on the North Slope are not currently known (Larned *et al.* 2001).

Direct Mortality from Incidental Take in Fisheries

The Observer Program does not distinguish sea ducks by group or by species so there is no data on incidental take of spectacled eiders. However, spectacled eiders are not likely to be directly affected by the BSAI groundfish fisheries because the winter distribution of spectacled eiders occurs within the ice pack in the northern Bering Sea and at other times they are either in nearshore waters for molting or inland to nest.

Indirect Effects through Changes in Prey Availability

Disturbance of marine benthic feeding areas by commercial bottom-trawl fisheries as well as bottom-feeding walruses and gray whales have been identified as possible reasons for the decline of spectacled eider populations (USFWS 1993a, USFWS 1999c). Although there is no direct evidence for adverse impacts of bottom-trawling, the USFWS has recommended that the fisheries avoid disturbing or harvesting benthic communities in eider molting and wintering areas during any time of year (USFWS 1999c).

Indirect Effects through Contamination by Oil Spills and Other Toxic Compounds

Consumption of lead shot in the Yukon-Kuskokwim Delta breeding grounds was identified as a likely contributing factor in the decline of this species (Flint *et al.* 1997). The use of lead shot for hunting was made illegal but lead shot already present on the breeding grounds remains available to birds and poses a continuing risk of toxic contamination.

The tendency of spectacled eiders to congregate in dense flocks on the water makes them particularly susceptible to localized oil spills. The USFWS has recommended several measures to minimize the chances of such spills occurring in eider critical habitat (USFWS 1999c).

Comparative Baseline

Spectacled eiders were listed as threatened under the ESA in 1993 due to major declines in their Alaska breeding populations. Although there appears to be almost no spatial/temporal overlap with the groundfish fisheries and marine waters used by spectacled eiders, the potential effects of BSAI groundfish bottom-trawling on the benthic habitat of eider prey has been cited as one of several possible reasons for the declining population. Specific evidence of adverse impacts from the fishery have not been demonstrated. The breeding population of spectacled eiders on the Yukon-Kuskokwim Delta appears to be increasing in recent years. The current worldwide population estimate is 360,000 birds, including non-breeding birds. The past and present effects on spectacled eiders are summarized in Table 3.7-17.

Status for Cumulative Effects Analysis

The impact of the groundfish fisheries on the feeding ecology and survival of spectacled eiders at sea is largely unknown but remains a concern under all FMP Alternatives. The status of spectacled eiders as threatened under the ESA warrants further consideration in the cumulative effects analysis. Because of the similarities in their conservation concerns and status under the ESA, spectacled eiders will be considered in conjunction with Steller's eiders in the analysis of FMP Alternatives.

3.7.10 Steller's Eider (*Polysticta stelleri*)

Life History and Distribution

Steller's eiders are the smallest species of eider. Like the other eider species, Steller's eiders are dimorphic; males are mostly white and black while females are mottled brown. Females can lay up to 10 eggs per year (Terres 1980). After the nesting season, Steller's eiders return to protected marine waters where they undergo a complete molt of their flight feathers. Concentrations of molting Steller's eiders have been noted in Russia, near St. Lawrence Island in the Bering Sea, and along the northern shore of the Alaska Peninsula.

There are two geographical populations of Steller's eiders, one that winters in the North Atlantic Ocean and one in the Pacific. Most of the Pacific population inhabits the maritime tundra of northeast Siberia (Solovieva 1997), and a smaller population nests in Alaska on the Yukon-Kuskokwim Delta (Flint and Herzog 1999) and the arctic coastal plain (USFWS 1999a). The Pacific population winters primarily along the Alaska Peninsula, from the eastern Aleutian Islands to southern Cook Inlet, in shallow nearshore waters (Palmer 1976). In spring, large numbers concentrate in Bristol Bay before migration. Along open coastline, Steller's eiders usually remain within about 400 m of shore in water less than 10 m deep but they can also be found in waters well offshore in shallow bays and lagoons or near reefs (USFWS 1997, USFWS 2000b).

Population data for Steller's eiders is sketchy due to several reasons; they nest predominately in remote areas of Russia, they do not appear to have many consistent concentration areas, and they have never received much wildlife management attention because they are not an important duck hunting species. Historical accounts of "enormous flocks" of Steller's eiders in the early 1900s were noticeably reduced by the 1950s (USFWS 1997). While recent aerial surveys indicate that the Russian-nesting Pacific population still contains 100,000 to 150,000 birds (USFWS 1999a), the Alaska-nesting population has decreased substantially since the1920s. On the Yukon-Kuskokwim Delta, where they were once described as being widespread and "common" nesters, they currently number only in the tens or hundreds (USFWS 1997, Flint and Herzog 1999). On the arctic coastal plain, Steller's once nested all the way from Wainwright east to the Canadian border but their nesting range has been greatly reduced (Kertell 1991). Aerial surveys of the arctic coastal plain during breeding season averaged 4,800 pairs from 1990 to 1998 (USFWS 1999a). There is evidence that molting and wintering populations of Steller's eiders along the Alaska Peninsula have declined since the 1960s, indicating that the Russian-nesting population is also in decline (Jones 1965, Kertell 1991, USFWS 1999a).

Trophic Interactions

Steller's eiders spend the majority of the year in shallow, near-shore marine waters where they feed by diving and dabbling for clams, polychaete worms, snails and amphipods (Petersen 1980, USFWS 1997). They are opportunistic feeders and will modify their diet according to what is available. A diet study of Steller's eiders conducted in Nelson Lagoon from April to October in 1977 and 1979 indicated that bivalves and amphipods were the primary food items, specifically blue mussels (*Mytilus edulis*), clams (*Macoma balthica*), and gammarid amphipods (Petersen 1981). In freshwater, they commonly feed on insect larvae (Cottom 1939).

Management Overview

Steller's eiders, like other sea ducks, are co-managed by the USFWS and the ADF&G under the Migratory Bird Treaty Act. Bag limits for sport hunting are set by the USFWS. The ADF&G, Division of Subsistence, monitors subsistence harvest of eiders along with other species of sea ducks.

Steller's eiders were listed as "threatened" under the ESA on June 11, 1997 (62 FR 31748) due to a substantial decrease in its nesting range in Alaska. Under the requirements of the ESA Section 7, the USFWS is responsible for determining whether proposed federal actions are likely to jeopardize the recovery of the species. In 1992, while it was a candidate species for the ESA, NOAA Fisheries had its first consultation with the USFWS concerning the effects of the BSAI and GOA groundfish fisheries on Steller's eiders (USFWS 1992). The resulting BiOp concluded that the groundfish fishery would not adversely affect Steller's eiders, based primarily on the lack of spatial/temporal overlap between the marine habitats of the eiders and the groundfish harvest. The USFWS made the same determination (not likely to adversely affect) for the 1993 and 1994 groundfish TAC specifications (USFWS 1993b, USFWS 1994). In the most recent BiOps (USFWS 2003), the USFWS concluded that the fisheries would not likely jeoparidze the continued existence or recovery of Steller's eider and would not adversely modify Steller's eider critical habitat.

At the time the species was listed under the ESA, the USFWS determined that it would not be prudent to designate critical habitat for Steller's eiders (USFWS 1993a). After a series of legal challenges, the USFWS reversed its decision and designated critical habitat for Steller's eiders on Feb. 2, 2001 (66 FR 8849), including breeding habitat on the Yukon-Kuskokwim Delta , and marine waters in northern Kuskokwim Bay, Seal Islands, Nelson Lagoon, and Izembek Lagoon on the north side of the Alaska Peninsula (Figure 3.7-9).

Past and Present Effects and Management Actions

Direct Mortality from Harvest and Other Intentional Take

Steller's eiders have probably been taken in small numbers for subsistence and sport hunting for many years. An average of 31 Steller's eiders were taken every year for subsistence purposes between 1987 and 1997 (Paige and Wolfe 1999).

Direct Mortality from Incidental Take in Groundfish Fisheries

The Observer Program does have a species code for Steller's eiders but none have been recorded to be taken in the groundfish fisheries. Steller's eiders are not likely to be taken by the BSAI and GOA groundfish fisheries because they are not attracted to fishing vessels and prefer to forage in nearshore waters. The one area where there is regular overlap of the fishery and the eiders involves the yellowfin sole bottom trawl fishery in the northern portion of Kuskokwim Bay and this fishery only involved two vessels in 2001.

Indirect Effects through Changes in Prey Availability

There is no direct competition by eiders for species targeted by the groundfish fisheries so any potential impact would have to be through ecosystem-level mechanisms. Non-specific changes in the marine ecosystem have been cited as a possible cause of the population decline but whether those changes were brought about by natural or anthropogenic factors is not known (USFWS 1997). No studies have been made to determine if the yellowfin sole fishery in Kuskokwim Bay or any other area directly affects prey availability or habitat used by the eiders.

Indirect Effects through Contamination by Oil Spills and Other Toxic Compounds

Consumption of lead shot in the Yukon-Kuskokwim Delta breeding grounds is a potential contributing factor in the decline of this species (USFWS 1997). The use of lead shot for hunting is now illegal but lead shot already present on the breeding grounds remains available to birds and poses a continuing risk of toxic contamination.

The concentration of Steller's eiders during molting and migration makes them particularly susceptible to localized oil spills in those situations. The USFWS has recommended several measures to minimize the chances of such spills occurring in eider critical habitat (USFWS 1999a).

Comparative Baseline

No reliable overall population estimates are available but there appear to be over 100,000 Steller's eiders nesting in Russia. Steller's eiders were listed as threatened under the ESA in 1997 due to major declines in their Alaska breeding populations. Although there appears to be no direct competition for prey and very little spatial/temporal overlap with the groundfish fisheries and marine waters used by Steller's eiders, the contribution of the fishery to changes in the marine environment has been cited as one of several possible reasons for the declining population. Specific evidence of adverse impacts from the fishery has not been demonstrated. The past and present effects on Steller's eider are summarized in Table 3.7-18.

Status for Cumulative Effects Analysis

The impact of the groundfish fisheries on the feeding ecology and survival of Steller's eiders at sea is largely unknown but remains a concern under all FMP Alternatives. The status of Steller's eiders as threatened under the ESA warrants further consideration in the cumulative effects analysis. Because of the similarities in their conservation concerns and status under the ESA, Steller's eiders will be considered in conjunction with spectacled eiders in the analysis of FMP Alternatives.

3.7.11 Jaegers

- Long-tailed jaeger (*Stercorarius longicaudus*)
- Parasitic jaeger (*Stercorarius parasiticus*)
- Pomarine jaeger (*Stercorarius pomarinus*)

Life History and Distribution

Jaegers are dark, gull-like birds that spend most of the year at sea, coming ashore only to nest on arctic islands, coasts, and tundra areas throughout the northern hemisphere. They spend their winters on the oceans of the southern hemisphere. They traverse the waters of the BSAI and GOA during their spring and fall migrations. All three species of jaegers have similar life-history strategies. All three species nest on tundra or wet grasslands, lay 2 to 3 eggs, and share parental duties. Jaegers are very fast and agile fliers and often chase gulls and terns until they drop food items.

Population trends for jaegers are unknown. All three species are considered "uncommon" or "rare" during migration in the BSAI and GOA area, with estimated relative abundance in the 10,000 to less than 1000 range (Table 3.5-62).

Trophic Interactions

The principal marine foods for jaegers are small schooling fish such as capelin and Pacific sand lance, either caught by themselves or taken from other seabirds (Gabrielson and Lincoln 1959, DeGange and Sanger

1986). While nesting they usually forage over land and are efficient predators on small birds, mammals, and insects.

Management Overview

Wildlife management responsibility for jaegers is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*).

Past and Present Effects and Management Actions

Direct Mortality from Incidental Take in Fisheries

The incidental take of jaegers in worldwide fisheries is unknown. Jaegers are not distinguished by species or as a group in the Observer Program data on incidental take by the groundfish fisheries. It is not known how many jaegers might be included in the "unknown seabird" categories in the various sectors (Tables 3.7-2 through 3.7-5).

Other Past and Present Effects

The following issues have been identified as having potential impacts on jaegers but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** The impacts of groundfish and other fisheries on the availability of prey to jaegers are unknown. The ability of jaegers to forage over huge areas, as well as their ability to force other seabirds to disgorge their food, is presumed to lessen the potential impact of localized depletion of prey.

Comparative Baseline

Jaegers migrate through the BSAI and GOA area in relatively small numbers. There is essentially no data on the interactions of these species with the groundfish fleet or their ecology in Alaska waters. The past and present effects on jaegers are summarized in Table 3.7-19.

Status for Cumulative Effects Analysis

Since these species do not interact very often with the groundfish fisheries and there is no quantitative data on either their population trends or impacts of the fisheries, these species will not be carried forward for cumulative effects analysis except in the general category of fish-eating (piscivorous) birds.

3.7.12 Gulls

- Glaucous-winged gull (*Larus glaucescens*)
- Glaucous gull (*Larus hyperboreus*)
- Herring gull (*Larus argentatus*)
- Mew gull (*Larus canus*)
- Bonaparte's gull (*Larus philadelphia*)
- Sabine's gull (*Xema sabini*)

Life History and Distribution

These six species, plus the two kittiwake species considered separately, are the commonly encountered gulls in the BSAI and GOA area. Adults are mostly gray and white while immatures are various shades of brown. The three largest species, glaucous-winged, glaucous, and herring gulls, all take four years to reach adult plumage. Mew gulls take three years and the two smallest species, Bonaparte's and Sabine's, are two-year gulls (Harrison 1983). The large number of immature plumages plus the fact that many of these species regularly hybridize with other gulls means that there is a great deal of plumage variability in these birds. It requires extensive training and practice to distinguish the different species in the field, especially for non-adult plumages. For this reason, observations and data on the interactions of these species with fisheries are usually lumped together under a common "gull" category.

Glaucous-winged gulls breed from the central Bering Sea southeastward through the GOA. Glaucous gulls breed from Bristol Bay northward. Herring gulls are widespread in North America and breed along the Alaska coast as well as inland. Mew gulls also breed along the Alaska coast and inland. Bonaparte's and Sabine's gulls breed from the Alaska Peninsula northward (Sibley 2000). At sea, gulls forage both near shore and at the shelf edge during the summer. In winter, most gulls disperse across the shelf from the ice edge to the deep ocean (Gould *et al.* 1982, DeGange and Sanger 1986, Schneider *et al.* 1986, Shuntov 1993). The edge of the ice pack and polynyas within it provide important winter and spring habitat for large gulls that forage on zooplankton and fish of the ice-edge system (Hunt 1991, Hunt *et al.* 1996b).

The USFWS has made no effort to systematically census gull populations in Alaska. In the BSAI and GOA area, very rough abundance estimates have been made at seabird colonies for some gull species (USFWS 1998a). These data only provide an "order of magnitude" approximation of breeding numbers and should not be used to assess population-level effects. These estimates do not include birds that nest and reside over the mainland rather than in marine areas of the BSAI and GOA (Table 3.5-62). The number of glaucous-winged gulls is estimated to be 150,000 in the BSAI and 300,000 in the GOA. Glaucous gulls are less numerous with an estimated 30,000 in the BSAI and 2,000 in the GOA. Herring gulls rarely nest on the islands and coasts of the BSAI and GOA area and are barely represented in the population estimates. Mew gulls are rare in the BSAI colonies, with only an estimated 700 birds, but have 40,000 in the GOA. Bonaparte's are listed as "rare" (less than 1000 birds) in the BSAI and "uncommon" (1,000 to 10,000 birds) in the GOA. Sabine's are listed as "uncommon" in both the BSAI and GOA.

Population trend data are available for only one species, glaucous-winged gulls, which are censussed on permanent USFWS sample plots on an annual or semi-annual basis. On Buldir Island (western Aleutians), the numbers have declined steadily since the plot was established in 1992. At Middleton Island (GOA), nesting glaucous-winged gulls have increased dramatically since counts were begun in 1974. On four other islands in the BSAI and GOA, numbers have fluctuated but show no consistent pattern of increase or decrease. (Dragoo *et al.* 2001).

Trophic Interactions

Most gulls are highly opportunistic and omnivorous feeders, taking a wide variety of prey from near the surface of the water, including small schooling fish such as capelin, Pacific sand lance, and herring. They will also eat invertebrates and carrion wherever they find them, often while scavenging among floating debris and on beaches. Large gulls also prey on the eggs and young of waterfowl and seabirds (Swartz 1966, Baird and Gould 1986, Bowman *et al.* 1997). They are strongly attracted to bait and discards behind fishing vessels, which exposes them to the risk of incidental take. Gulls can switch to invertebrate prey or scavenging when schooling fish decline during the breeding season, but reproductive success suffers (Murphy *et al.* 1984).

Management Overview

Wildlife management responsibility for gulls is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*).

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Breeding colonies of gulls have been used for subsistence purposes by Native peoples of the BSAI and GOA for thousands of years. Harvest of adult birds from breeding colonies continues to the present time in some coastal communities, most commonly by means of shotguns and motorized boats (Denlinger and Wohl 2001). Egg collection is a widespread activity that provides a significant source of high quality food in early summer and is an important cultural tradition for many coastal communities (Lowenstein 1986). Historical catch data were not recorded but recent community surveys by the ADF&G, USFWS, and tribal governments have provided some indication of the scope of seabird harvests (Denlinger and Wohl 2001). In 1996, communities in the BSAI and GOA area reported takes of 1,571 unspecified gulls, mostly from the St. Lawrence Island/Diomede Islands, Yukon-Kuskokwim Delta, and Bristol Bay areas. In 1995, about 115,000 seabird eggs were collected in the BSAI and GOA area, including a large proportion of unspecified gull eggs. Gull eggs were the most commonly collected eggs in Bristol Bay and the northern Alaska Peninsula regions (Paige and Wolfe 1997). These estimates are considered to be minimal given the nature of post-harvest user surveys. They do not include any estimates of the numbers of eggs that may have been lost during collection activities, either by falling off the cliffs when adults were disturbed or to predatory gulls and ravens when left unprotected.

Direct Mortality from Incidental Take in External Fisheries

Gulls are attracted to fishing and processing vessels to scavenge on fishery wastes. Data on incidental take of gulls has not been recorded for most fisheries or has been included in “unidentified” categories. Although they are likely taken in many types of longline and net gear, in both nearshore and offshore fisheries, the frequency of take appears to be relatively infrequent or rare.

Direct Mortality from Incidental Take on Groundfish Longlines

The numbers of gulls taken in the BSAI and GOA groundfish longline fisheries in 1993- 2001 are estimated in Tables 3.7-2 and 3.7-3. Observers have individual species codes for the large gulls and kittiwakes plus an "unidentified gull" category but for analysis and reporting purposes, all species are combined in one "gull" category. An unknown number of them are also included in the "unidentified seabird" category. For just the gull category, the estimated average take was 2,707 birds per year in the BSAI and 114 birds per year in the GOA between 1993-2001.

In an effort to reduce the incidental take of seabirds on longlines, NOAA Fisheries instituted mandatory seabird avoidance measures for the groundfish longline fleet in 1997 (62 FR 23176). Prior to 1997, the average estimated take of gulls (not including "unidentified seabirds") in the BSAI was 2,007 birds per year. Between 1997 and 2001, the estimated average take in the BSAI increased to 3,268 gulls per year. Much of that increase was derived from high takes in 1998 and 2000 which may have been related to a general shortage of natural food in those years. In the GOA, the number of gulls taken from 1993-1996 was 74 birds per year but that average increased to 147 gulls per year from 1997-2001. It is not clear whether the increase in average takes after 1997 was due to ineffective deployment of seabird deterrent techniques, at least on some vessels, or whether the nutritional state of the birds (i.e., starvation) may have changed the behavior of the birds so that the deterrence was less effective.

Direct Mortality from Incidental Take in Groundfish Trawls

The estimated number of gulls caught in the combined BSAI and GOA groundfish trawl fisheries varied considerably between years, with two years showing zero take (Table 3.7-4). The average estimated number of gulls taken was between 150 birds per year (low estimate) and 398 birds per year (high estimate) in 1997-2001.

Indirect Effects through Consumption of Fishery Discards

Scavenging of fishing discards and processing wastes can have population-level effects for gulls. Scavenged processing wastes and other artificial foods may not be adequate foods for rearing chicks successfully (Murphy *et al.* 1984, Baird and Gould 1986, Irons *et al.* 1986, DeGange and Sanger 1986). On the other hand, abundant scavenging during winter may increase gull populations because survival of immature birds is enhanced (Patten and Patten 1982). Larger gull numbers can reduce local populations of other birds through increased competition for nest sites and predation pressure on their young, although scientists disagree about the magnitude of this problem (Spaans and Blokpoel 1991). Hunt (1972) found that herring gulls on the coast of Maine that used discarded waste had increased breeding success. Studies on two gull species in Spain indicate that a dependence on discards from commercial fishing activities may be a limiting factor in the breeding success of these species (Oro *et al.*1995, Oro 1996). Fishery wastes may have lower caloric density than the best of the forage fishes, but when good-quality forage fish are scarce, food from discards, offal, and garbage may be important for successful reproduction (G. L. Hunt, Jr., University of California, Irvine, personal communication). In the Atlantic Ocean, about 30 percent of total food consumed by seabirds in the North Sea is estimated to be discards (including offal) (Tasker and Furness 1996). Numerous instances are cited showing potential relationships between discards in diets and changes in breeding populations (Garthe *et al.* 1999) but no data are available on these effects in Alaska.

In many areas of the world, fishery discards appear to have benefitted large, aggressive, and predatory seabird species. For example, in the North Sea, populations of great skuas (*Catharacta skua*) and black-backed gulls (*Larus marinus*) have increased due to use of fishery discards, and these birds prey on other seabird species. Sudden withdrawal of discards might cause the predatory species to increase pressure on kittiwakes, puffins, sea ducks, and guillemots long before the skuas and gulls decline to previous levels (Furness 1999).

Other Past and Present Effects

The following issues have been identified as having potential impacts on gulls but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** The impact of groundfish fisheries on the availability of prey to gulls is likely to only be a factor if it leads to localized depletion of prey around breeding colonies. The extent of this potential impact on gulls is unknown. NPFMC has prohibited directed fisheries on forage fish to minimize any indirect impact on seabirds (BSAI FMP Amendment 36 and GOA Amendment 39).

Comparative Baseline

The Alaska populations of the different species of gulls are not surveyed on a regular basis so it is essentially impossible to assess population-level impacts of natural or anthropogenic phenomena. Highly variable plumages makes identification of the different gull species difficult so they are often lumped together in Observer Program data. Average incidental take of gulls on longlines has increased in the BSAI and GOA since seabird avoidance regulations were enacted in 1997. The past and present effects on gulls are summarized in Table 3.7-20.

Status for Cumulative Effects Analysis

Incidental take of gulls is expected to continue under all alternatives and warrants consideration in the cumulative effects analysis. Because there is no species specific quantitative data on either their population trends or impacts of the fisheries, these species will be discussed in conjunction with the fish-eating (piscivorous) birds in Chapter 4.

3.7.13 Kittiwakes

- Black-legged kittiwake (*Rissa tridactyla*)
- Red-legged kittiwake (*Rissa brevirostris*)

Life History and Distribution

Kittiwakes are small gray and white gulls with black wing tips. Their names tip off their leg color. Kittiwakes are gregarious at all times and nest in dense colonies on steep-sided cliffs. They build nests of mud and vegetation and typically lay 1-2 eggs. Both sexes look alike and share parental duties. Eggs incubate for about a month and chicks fledge in about 45 days. Black-legged kittiwakes take three years to reach adult plumage while red-leggeds take only two years (National Geographic 1999).

The black-legged kittiwake is a holarctic species that breeds in coastal waters throughout Alaska except for southeast. The red-legged kittiwake is restricted to the Bering Sea and North Pacific and breeds only in four colonies in the BSAI (USFWS 1998a). Black-legged kittiwakes forage over the entire continental shelf and shelf break. Red-legged kittiwakes forage from the shelf break seaward. The foraging range during the breeding season is 100 km or more (Schneider and Hunt 1984, Schneider *et al.* 1986, Hatch 1993). Both also forage locally near the coast if schooling prey are available (Schneider *et al.*1990, Suryan *et al.* 1998b, Suryan *et al.* 2000). Black-legged kittiwakes require a shelf several tens of kilometers wide, where prey items are concentrated by upwellings, and are few or absent in colonies with a very narrow shelf (Springer *et al.* 1996, Byrd *et al.* 1997). Black-legged kittiwakes winter over the shelf and deep ocean (Gould 1983, Shuntov 1993). The wintering area of the red-legged kittiwake includes the waters south of the Aleutians and the western GOA (Harrison 1983, Sibley 2000).

The total number of black-legged kittiwakes from hundreds of colonies are estimated to be around 800,000 in the BSAI and 1 million in the GOA. Red-legged kittiwakes are easier to survey since they are limited to only a few colonies in the BSAI. They are estimated to number around 150,000, almost 80 percent of which nest on St. George Island in the Pribilofs (Table 3.5-62).

Kittiwake population trends, as opposed to population totals, are measured by censussing permanent sample -plots on an annual or semi-annual basis. Trends differ among regions of the state (Table 3.7-21, Hunt and Byrd 1999, Dragoo *et al.* 2001). Populations of both species declined steeply on the Pribilof Islands after 1976 (the year when monitoring began). Red-legged kittiwakes on the sample plots have declined to approximately half their original numbers. Black-leggeds declined by almost 75 percent on St. Paul and 65 percent on St. George. Although it appeared that black-legged kittiwake populations on St. George Island had stabilized by 1996 (Hunt and Byrd 1999), later counts continued the overall pattern of decline (Dragoo *et al.* 2001). It is not clear if the population of red-legged kittiwakes on St. Paul Island has stabilized (Hunt and Byrd 1999, Dragoo *et al.* 2001). In contrast, both species have increased in the smaller colonies of the western Aleutian Islands (Agattu and Buldir) from the mid-1970s until the present. Black-legged kittiwakes are stable or increasing in the northern Bering Sea (Bluff colony), Aleutian Islands, and parts of the northern GOA. However, populations are declining in Cook Inlet, Kodiak Island, and parts of Bristol Bay. At their largest colony in the GOA, Middleton Island, black-leggeds have declined on sample plots by almost 85 percent from their high in 1981. (Table 3.7-21; Dragoo *et al.* 2001).

Trophic Interactions

Prey are taken at the surface or by dives within a meter of the surface. Both species consume small schooling fish and zooplankton, relying primarily on fish when feeding their young. These species appear to depend on fatty species of forage fish as well as age-0 and age-1 pollock for successful reproduction (Hunt *et al.* 1996a).

The principal fish prey of black-legged kittiwakes are capelin and Pacific sand lance, herring or small cods in some locations, and myctophids (lanternfish) as well as juvenile pollock in the central Bering Sea. Black-legged kittiwakes also consume processing wastes in the North Sea when larger seabirds are not numerous near vessels (Furness and Ainley 1984). Little is known about the extent of scavenging by this species in Alaska. Red-legged kittiwakes consume the same fish but with more emphasis on myctophids and zooplankton (Hunt *et al.*1981a, Springer *et al.* 1984, Springer *et al.* 1986, Springer *et al.* 1987, Sanger 1987, Hatch 1993). Myctophids and probably zooplankton are taken primarily at night (Hatch 1993).

Capelin and Pacific sand lance vary greatly in availability among years, and breeding success in most areas is correlated with abundance of one or the other species in the diet (Troy and Baker 1985, Baird and Gould 1986, Springer *et al.* 1987, Baird 1990). Similarly, the availability of juvenile herring affects kittiwake foraging efforts and breeding success in PWS (Suryan *et al.* 2000). For kittiwake colonies in low productivity areas, the availability of all three forage species (capelin, Pacific sand lance, and herring) may be important to maintaining productivity (Suryan *et al.* 2000). Consumption of juvenile pollock, although prominent in kittiwake diets in the Pribilof Islands in some years, results in slower chick growth than other principal forage fish, which have a higher energy content (Romano *et al.* 1998). Winter diets are poorly known; both species probably rely more on invertebrates in winter than when feeding young (Hatch 1993).

Factors that limit the food availability to seabirds have been investigated primarily during the past ten years, and directed research is recent. Intensive work on the diets of kittiwakes, along with other species, has taken place in the southeastern Bering Sea (Springer *et al.* 1986, Schneider *et al.* 1990, Hunt *et al.* 1981a, Hunt *et al.* 1981b, Decker *et al.* 1995); northern Bering and Chukchi Seas (Springer *et al.* 1987, Elphick and Hunt 1993, Kinder *et al.* 1983); and Cook Inlet and PWS (Piatt *et al.* 1998, Suryan *et al.* 1998a, Suryan *et al.* 1998b, Suryan *et al.* 2000). In each place, only part of the factors affecting bird forage availability have been explored. All studies were restricted to summer. Limiting factors in areas that have not yet been studied are likely to differ in type and importance, and they may be completely different in winter when forage species and locations are different. Most critical is the lack of information on how events beyond a seabird's foraging range may influence prey availability. Such factors may include environmental changes, fluctuations in regionwide stocks of forage and non-forage species, and commercial fishery harvests.

Management Overview

Wildlife management responsibility for kittiwakes is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*).

The red-legged kittiwake is a USFWS "species of management concern" because 80 percent of its worldwide population nests in only one colony, St. George Island, and because its recent severe population decline has not been explained (USFWS 1995b). For these reasons, the species was recently assigned "vulnerable" status on the World Conservation Union's *Red List of Threatened Species* (IUCN 2000).

Past and Present Effects and Management Actions

<u>Direct Mortality: Harvest and Other Intentional Take</u>

Breeding colonies of seabirds have been used as a source of meat, eggs, and skins for clothing by Native peoples of the BSAI and GOA for thousands of years. Kittiwakes are not usually distinguished from other gull species in accounts of these traditional harvests but they probably never accounted for a large percentage of the take because of their small size and relatively inaccessible nests. Recent community harvest surveys estimate that in 1996, 476 black-legged kittiwakes and 688 red-legged kittiwakes were taken in the BSAI and GOA area, almost all of which were from the Aleutian and Pribilof Islands (Denlinger and Wohl 2001). Those same survey results indicate that over 100,000 seabird eggs were taken in the BSAI and GOA area in 1995 but there is no estimate what fraction of these, if any, were kittiwake eggs.

Direct Mortality from Incidental Take in External Fisheries

Past fisheries in the North Pacific, both foreign and domestic, have taken kittiwakes in the course of their operations. For most of these fisheries, the numbers of individual species taken were not recorded. One exception is the Japanese salmon mothership fishery where an estimated average of 95 black-legged kittiwakes (out of a total average of 165,000 birds) were taken every year between 1981-1984 (Jones and DeGange 1988). Although the land-based Japanese salmon gillnet fishery was responsible for millions of seabird deaths from 1952-1992, no kittiwakes were identified in those totals (DeGange and Day 1991). The incidental take of kittiwakes in the current foreign gillnet and longline fisheries is unknown.

Direct Mortality from Incidental Take on Groundfish Longlines

The numbers of seabirds caught in the BSAI and GOA groundfish longline fisheries are estimated from Observer Program data in Tables 3.7-2 and 3.7-3. Observers have individual species codes for the two kittiwakes but they are included in the "gull" category for analysis and reporting purposes. An unknown number of kittiwakes are also probably included in the "unidentified seabird" category. For just the gull category, the estimated average take was 2,707 birds per year in the BSAI and 114 birds per year in the GOA between 1993-2001.

Direct Mortality from Incidental Take in Groundfish Trawls

The numbers of seabirds caught in the combined BSAI and GOA groundfish trawl fisheries are estimated from Observer Program data in Table 3.7-4. Kittiwakes "other" are included in the "gull" category for analysis and reporting purposes. An unknown number of kittiwakes are also probably included in the "unidentified seabird" category. For just the gull category, the estimated average take was between 150 birds per year (low estimate) and 398 birds per year (high estimate) between 1997 and 2001.

Indirect Effects through Changes in Prey Availability.

Birds that breed in Alaska and prey on forage fish, including kittiwakes, may be impacted by indirect fishery effects on prey abundance and availability. Given the wide variety of foods used by kittiwakes and the extensive areas over which they forage, it seems unlikely that they are very susceptible to localized depletion of prey during the non-breeding season. However, while nesting, kittiwakes are more limited in their options and are more susceptible to localized depletions of prey around their colonies. Variability in food supplies around the colonies is likely to impact reproductive success rather than survival of adult birds but may effect survival if the depletion is severe.

The energy content of prey has recently been found to influence the growth of seabird chicks and reproductive success at the colony level (Hunt *et al.* 1996a, Kitaysky 1999, Kitaysky *et al.* 1999, Golet *et al.* 2000). Fish with high lipid and low water content provide the most efficient food "package" for growing seabird chicks; such fish include myctophid, capelin, Pacific sand lance, and larger age groups of herring. Energy-poor forage species include pollock and benthic fish. Slow-growing young birds in colonies may ultimately starve in the nest or be more vulnerable to post-fledgling stresses than well-fed young. For instance, kittiwakes are able to raise chicks on age-0 and age-1 pollock in the Pribilof Islands, where capelin and Pacific sand lance has declined dramatically since the mid-1970s (Hunt *et al.*1996c, Hunt *et al.* 1981a, Schneider and Hunt 1984). However, kittiwake breeding success is relatively low in these colonies compared with other parts of Alaska (Hatch *et al.* 1993), and the kittiwake populations have recently declined on the Pribilof Islands.

Black-legged kittiwakes occasionally die-off in large numbers during late summer, apparently due to widespread scarcity of prey at the surface during anomalous oceanographic conditions. Major die-offs were recorded in Alaska in 1983 and 1997 (Nysewander and Trapp 1984, Hatch 1987, Mendenhall *et al.* 1998). It has been hypothesized that the failure of the seabird populations on the Pribilof Islands to show enhanced reproductive performance subsequent to the reduction of breeding populations suggests that the carrying capacity of the southeastern Bering Sea declined for seabirds in the early 1980s and was reset at a new, lower level than had existed in the mid-1970s. Because kittiwake populations were apparently only affected at the Pribilof Islands, the mortality must have occurred when birds would have been near their colonies (Hunt and Byrd 1999). The cause(s) for this decrease in carrying capacity, whether due to climatic conditions and/or ecosystem effects related to commercial fishing, are being investigated. NPFMC has addressed fishery impacts on forage fish by prohibiting directed fisheries on this size class and group of species that are important to seabirds and some marine mammals (BSAI FMP Amendment 36 and GOA Amendment 39).

Other Past and Present Effects

The following issues have been identified as having potential impacts on kittiwakes but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through consumption of fishery discards.** Kittiwakes are attracted to fishing vessels and processors to eat discards and offal. Benefits of the food source are countered by increased risk of incidental take on longlines and trawls.

- **Indirect effects by introducing mammalian predators to nesting islands.** Cliff nesting species like kittiwakes are susceptible to predation by introduced rats. The USFWS has an extensive program to reduce the threat of new rat invasions. Efforts include maintaining networks of poison-bait boxes at ports on rat-free islands; training local communities to monitor and counteract rats aboard ships and on land; conducting public outreach programs to encourage operation of rat-free vessels in Alaskan waters; and training emergency-response teams to attack rats when they are found at remote shipwrecks. Some of the most intensive efforts in this regard have been carried out on the Pribilof Islands (A. Sowls, USFWS, personal communication).

Comparative Baseline

Black-legged kittiwakes are widespread and abundant in the BSAI and GOA. Red-legged kittiwakes are much less numerous and far more restricted in their breeding locations with the great majority nesting on St.

George Island. Substantial declines in their population have led to their classification as a USFWS species of management concern and "vulnerable" status under international conservation standards. Commercial fishing does not appear to have much direct impact on these species (i.e., through incidental take) but substantial population declines at some colonies in recent years, coupled with documented declines in forage fish, have instigated research on whether the fisheries are impacting fish-eating seabird species indirectly or whether the observed declines are attributable to natural environmental fluctuations. The past and present effects on kittiwakes are summarized in Table 3.7-22.

Status for Cumulative Effects Analysis

The frequency with which both species interact with the groundfish fisheries warrants further consideration in the cumulative effects analysis. Since some alternative FMPs call for special management goals for species of management concern, red-legged kittiwakes will be considered along with other species of management concern (marbled and Kittlitz's murrelets) in Chapter 4. Black-legged kittiwakes will be discussed in conjunction with the fish-eating (piscivorous) birds in Chapter 4.

3.7.14 Terns

- Arctic tern (*Sterna paradisaea*)
- Aleutian tern (*Sterna aleutica*)

Life History and Distribution

Terns are fork-tailed and sharp-winged relatives of the gulls that have a distinctive "floating" flight pattern. Arctic terns range all over the globe, migrating between the arctic and antarctic twice a year, and are common inland as well as in marine waters. Aleutian terns are more marine in nature and appear to be restricted to the North Pacific although their winter range is not known. Both species breed in coastal areas throughout the BSAI and GOA area.

The arctic tern population is roughly estimated to include 7,000 breeding birds in the BSAI and 20,000 in the GOA. Aleutian terns are estimated to number 9,000 breeding birds in the BSAI and 25,000 in the GOA (Table 3.5-62). Populations trends are not monitored in Alaska.

Trophic Interactions

Terns forage in coastal waters within a few miles of their colonies. They feed on the surface, or just beneath it, on small schooling fish (capelin, Pacific sand lance) and zooplankton. Fish are essential diet components when terns are feeding their young (Hunt *et al.* 1981c, Baird and Gould 1986, DeGange and Sanger 1986, Baird 1990).

Stratification of the water column can be disadvantageous to species that depend on complete mixing of the water column. In summer, lack of wind and strong solar heating can result in higher surface temperatures, which may in turn cause certain prey species to seek deeper water and be unavailable to such surface-feeding birds as terns (Baird 1990). The influence of stratification on tern foraging in most specific areas is unknown. Breeding success and population trends of kittiwakes, which have similar feeding habits as terns, are correlated with years when schools of Pacific sand lance are available (Springer *et al.* 1987, Hayes and Kuletz 1997). Schools must be at or near the surface in order for kittiwakes and terns to reach them. These birds are usually observed feeding on shoals of Pacific sand lance in years when reproductive success is high (Baird 1990).

Management Overview

Wildlife management responsibility for terns is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*).

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Terns are taken in small numbers by Alaska Native subsistence hunters in the Bristol Bay area. An unknown number of tern eggs are also taken in this area and around Kodiak (Denlinger and Wohl 2001).

Direct Mortality from Incidental Take in Fisheries

There are no specific records of terns being taken in any fisheries of the North Pacific, including the groundfish fisheries of the BSAI and GOA. There may be some terns included in "unidentified" seabird incidental take records from these fisheries but the extent of that take is unknown. Given the predominantly off-shore distribution of the groundfish fleet and the in-shore foraging habits of breeding terns, potential direct impacts of the fisheries appear to be minimal.

Other Past and Present Effects

The following issues have been identified as having potential impacts on terns but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** The impact of groundfish fisheries on the availability of prey to terns is likely to only be a factor if it leads to localized depletion of prey around breeding colonies. The extent of this potential impact on terns is unknown. NPFMC has prohibited directed fisheries on forage fish to minimize any indirect impact on seabirds (BSAI FMP Amendment 36 and GOA Amendment 39).

Comparative Baseline

Arctic and Aleutian terns are uncommon breeders in the BSAI and GOA that appear to have very little interaction with the groundfish fisheries. No population trend information is available in the project area. The past and present effects on terns are summarized in Table 3.7-23.

Status for Cumulative Effects Analysis

Since these species do not interact very often with the groundfish fisheries and there is no quantitative data on either their population trends or impacts of the fisheries, these species will not be carried forward for cumulative effects analysis except in the general category of fish-eating (piscivorous) birds.

3.7.15 Murres

- Common murre (*Uria aalge*)
- Thick-billed murre (*Uria lomvia*)

Life History and Distribution

Murres are the largest species in the Alcidae family, which also includes guillemots, murrelets, auklets, and puffins. Like the other alcids, murres use their wings to "fly" underwater and can dive to great depths. They are also fast fliers in the air, beating their relatively small, narrow wings very quickly. They are gregarious throughout the year and will come together on the water in very dense "rafts" prior to crowding onto their rocky nesting cliffs. They do not actually build a nest but lay their single egg directly on the rock. If an egg is lost early in the season, it will often be replaced, but only once. Both sexes look alike and share parental duties. Eggs are laid in late June, hatch about a month later, and chicks jump off the cliffs into the water, still unable to fly, by the end of August or early September. The parents continue to care for their chick at sea for some time, bringing fish to the surface until the chick is big enough to dive and catch fish on its own.

Both murre species are widespread in the North Pacific and Atlantic oceans. In Alaska, common murres breed on rocky coasts and islands throughout the BSAI and GOA. Thick-billed murres breed mostly in the BSAI and north of the Bering Strait but have some smaller colonies in the GOA (USFWS 1998a). Birds from colonies north of the Bering Strait winter in the central Bering Sea (Shuntov 1993, Hatch *et al.* 1996). The edge of the ice pack and polynyas within it provide important winter and spring habitat for murres and other seabirds that forage on zooplankton and fish of the ice-edge system (Hunt 1991, Hunt *et al.* 1996b).

The USFWS has compiled population estimates of seabirds, including both species of murres, from many researchers at many colonies throughout Alaska in the Beringian Seabird Colony Catalog (USFWS 1998a). Many of these estimates are rated as "poor" or "fair" in quality and the resultant population totals cannot be considered reliable for anything but the most generalized discussions. They are certainly not sufficient for documenting anything but the most extreme changes in population-levels. With that caveat, the total numbers of common murres from hundreds of colonies are estimated to be around 3 million in the BSAI and 2 million in the GOA. Thick-billed murres are estimated to number 5 million in the BSAI and 200,000 in the GOA (Table 3.5-62).

Murre population trends are determined by an index method using permanent sample plots in different colonies (Figure 3.7-1, Dragoo *et al.* 2001). Both species are monitored together in some areas because they are too difficult to distinguish reliably under common survey conditions. Trends differ between regions and sometimes between nearby colonies. In the northern Bering Sea (Bluff and Hall Island), common murre numbers have remained relatively stable since the early 1980s. Common murre trends have varied in the southeastern Bering, with steady declines at St. Paul Island, Cape Newenham, and Cape Pierce, and an increasing trend on St. George Island (Dragoo *et al.* 2001). No counts are made of just common murres in the Aleutians (combined counts with thick-bills are described below). In the GOA where separate common murre counts are made, numbers have either increased (E. Amatuli and Gull Islands) or remained stable (Nord Island). Thick-billed murres show a similarly mixed set of trends. In the northern Bering Sea (Hall Island), thick-billed murres have decreased since the early 1980s. At the Pribilofs, thick-bills decreased in the 1970s but have remained relatively stable since the early 1980s. Thick-bills have increased substantially on Buldir Island (western Aleutians) since the mid 1970s. No separate counts of thick-bills are made in the GOA. Among the colonies where common and thick-billed murres are counted together, Agattu Island (western Aleutians) had increasing numbers in the 1970s and 1980s and remained stable in recent years (Hunt and Byrd 1999). In the GOA, combined counts of murres have remained stable at Aiktak Island, increased at Chowiet Island, and decreased at Puale Bay, Middleton Island, and St. Lazaria Island (Dragoo *et al.* 2001).Table 3.7-21 summarize this trend data.

Trophic Interactions

Murres use their wings to propel themselves underwater and can dive as deep as 210 m to catch fish and other prey (Croll *et al.* 1992). Common murres consume small fish, especially energy-rich species such as capelin and Pacific sand lance, and will take juvenile pollock and cod as well as various kinds of zooplankton. Thick-billed murres eat the same fish and also myctophids (lanternfish). They will take larger numbers of zooplankton and other invertebrates than do common murres (Hunt *et al.* 1981a, Vermeer *et al.* 1987, Sanger 1987, Elliott *et al.* 1990, Schneider *et al.* 1990). Thick-billed murres nesting in the western Aleutian Islands feed primarily on squid (Springer *et al.* 1996). Both species are highly dependent on densely schooling prey (Cairns and Schneider 1990, Piatt 1990, Mehlum *et al.* 1996). During the breeding season, common murres have a foraging range of approximately 50 to 80 km while thick-bills range up to 100 km from the colonies (Schneider and Hunt 1984, Bradstreet and Brown 1985, Piatt and Nettleship 1985, Hatch *et al.* 1996).

Murres forage over the continental shelf, particularly in small areas where benthic terrain, currents, or upwellings create local prey concentrations. The inner front (boundary between wind-mixed and stratified water on the Bering Sea shelf) is associated with an upwelling 5 to 15 km in width, which tends to concentrate some zooplankton and their predators and is heavily used by murres (Schneider *et al.* 1987, Brodeur *et al.* 1997, Decker and Hunt 1996). Unusually high concentrations of both species of murres are known to regularly forage on euphausiids over a submarine ridge on the east side of St. George Island (Coyle *et al.* 1992). Thick-billed murres also forage over the outer shelf and shelf edge (Hunt *et al.* 1981b, Kinder *et al.* 1983, Schneider and Hunt 1984, Schneider *et al.* 1986, Schneider *et al.* 1990, Shuntov 1993, Decker and Hunt 1996). Common murres require a shelf at least several tens of kilometers wide and are few or absent in colonies with a very narrow shelf. In contrast, thick-billed murres tend to occupy areas near a shelf edge, although they also breed in a few northern colonies on broad shelves (Springer *et al.* 1996, Byrd *et al.* 1997, USFWS 1998a).

Upwellings also occur where tides or currents move water from the deep ocean onto the shelf, such as tidal upwellings onto the shelf between islands in the Pribilof Islands (Coyle *et al.* 1992) and the Aleutian Islands (Hunt *et al.* 1998), or the Anadyr Current west of St. Lawrence Island (Hunt *et al.* 1990). Upwelling of deep water onto the shelf north of the Barren Islands and in the western GOA supports large colonies of murres (Piatt and Anderson 1996). At the Pribilofs Islands, the currents that influence prey availability are mostly tidal, though zooplankton are advected from offshore (Hunt *et al.* 1996b, Stabeno *et al.* 1999). Currents that run parallel to the shelf break along the 100-m and 200-m isobaths, which spawn eddies that cross onto the shelf, are likely to be most important (Stabeno and van Meurs 1999). These currents may also be important for the transport of age-0 pollock to the Pribilofs, suggesting that pollock spawning events near Unimak Pass may influence prey availability at the Pribilofs (G. L. Hunt, Jr., University of California, Irvine, personal communication).

Murres can forage deeper than any other seabird species, which buffers them against changes in vertical distribution of their prey. However, their need for dense aggregations of prey may make them vulnerable to occasional die-offs when prey are scattered or otherwise unavailable (Piatt and van Pelt 1997). During the breeding season, murres can increase their daily foraging time away from the colony in order to obtain scarce or distant prey, and they sometimes are able to maintain breeding success under poor conditions.

Common murres occasionally die-off in large numbers during winter and early spring, apparently due to widespread scarcity of prey. Major die-offs of up to an estimated 120,000 birds were recorded in Alaska in 1970, 1993, and 1998 (Bailey and Davenport 1972, Piatt and van Pelt 1997, Mendenhall *et al.* 1998). Major shifts in seabird food habits occurred at the Pribilof Islands between the mid-1970s and the late 1980s. These diet shifts coincided with the decline of murre and kittiwake populations there, and with the decline of forage fishes and age 1 pollock in the bottom trawl surveys around the Pribilof Islands (Decker *et al.* 1995, Hunt *et al.* 1996a, 1996b). It has recently been hypothesized that declines in thick-billed murres at the Pribilof Islands were caused by large die-offs of adults from this population (Hunt and Byrd 1999).

Management Overview

Wildlife management responsibility for murres is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*). In 1999, protocol amendments to the Migratory Bird Treaty Act were ratified that mandated participation of subsistence users and their traditional knowledge in a co-management relationship between Native, Federal, and State of Alaska representatives. This co-management group is charged with developing conservation, research, and management plans for all species taken in subsistence harvests, including murres (Denlinger and Wohl 2001).

Past and Present Effects and Management Actions

<u>Direct Mortality: Harvest and Other Intentional Take</u>

Breeding colonies of murres have been used as a source of meat, eggs, and skins for clothing by Native peoples of the BSAI and GOA for thousands of years. An account from the mid-1800s describes the widespread use of baleen nooses to capture birds on the steep cliffs of the Aleutian Islands. These methods were efficient enough to cause noticeable declines in breeding populations, at least at colonies that were accessible from settlements (Veniaminov 1840). Harvest of adult birds from breeding colonies continues to the present time in some coastal communities, most commonly by means of shotguns and motorized boats (Denlinger and Wohl 2001). Egg collection is also a traditional early summer activity, usually conducted in family groups. Egging is limited to a short period of time when eggs are freshly laid but it provides a significant source of high quality food and is an important cultural tradition for many coastal communities (Lowenstein 1986). Historical catch data were not recorded but recent community surveys by the Alaska

Dept. of Fish and Game, USFWS, and tribal governments have provided some indication of the species-specific scope of seabird harvests (Denlinger and Wohl 2001). In 1996, communities in the BSAI and GOA area reported takes of 9,743 common murres, 433 thick-billed murres, and 150 unidentified murres. The great majority of these birds were taken in the St. Lawrence Island/Diomede Islands area. In 1995, about 100,000 seabird eggs were collected in the BSAI and GOA area, including an unknown number of murre eggs. Murre eggs were the most commonly collected eggs in the Seward Peninsula area but these totals also include large numbers of tern and gull eggs. These estimates are considered to be minimal given the nature of post-harvest user surveys. They do not include any estimates of the numbers of eggs that may have been lost during collection activities, either by falling off the cliffs when adults were disturbed or to predatory gulls and ravens when left unprotected.

Direct Mortality from Incidental Take in External Fisheries

Murres are not attracted to fishing vessels like many of the surface-feeding seabirds and are rarely caught by longline fisheries. They are more susceptible to being caught in trawl and drift nets which hang down into the water column where murres dive for fish. Past fisheries in the North Pacific, both foreign and domestic, have taken murres in the course of their operations. For most of these fisheries, the numbers of individual species taken were not recorded. One exception is the Japanese salmon mothership fishery where an average of 14,175 thick-billed murres and 1,850 common murres were taken every year between 1981-1984 (Jones and DeGange 1988). The land-based Japanese salmon gillnet fishery was responsible for an estimated 8 million seabird deaths from 1952-1987 (DeGange and Day 1991). In 1977 alone, this fishery killed an estimated 17,245 thick-billed and 2,150 common murres. In 1987, after substantial reductions in fishing effort, an estimated 4,625 thick-bills were taken along with 580 commons (DeGange and Day 1991). On the Russian side of the Bering Sea, Japanese salmon gillnet fisheries took an estimated 1.1 million seabirds between 1993 and 1998, 62 percent of which were alcids, and may have had population-level impacts on thick-billed murre colonies (Artukhin *et al.* 2000). The incidental take of murres in other current foreign gillnet fisheries is unknown.

State-managed salmon and herring gillnet fisheries in Alaska take murres incidentally on a regular but infrequent basis. Based on the perceptions of one bird-observant fisherman, the total number of murres taken in these coastal fisheries are probably less than 1000 birds per year in the entire BSAI and GOA (DeGange *et al.* 1993).

Direct Mortality from Incidental Take on Groundfish Longlines

The numbers of seabirds caught in the BSAI and GOA groundfish longline fisheries are estimated from Observer Program data in Tables 3.7-2 and 3.7-3. Observers have individual species codes for the two murres but they are included in the "alcid" category for analysis and reporting purposes. An unknown number of murres may also be included in the "unidentified seabird" category. The alcids accounted for an average of 15 birds per year taken in the BSAI between 1993 and 2001 and one bird per year in the GOA.

Direct Mortality from Incidental Take in Groundfish Trawls

The BSAI and GOA trawl fishery took between 178 alcids per year (low estimate) and 340 alcids per year (high estimate) between 1997 and 2001 (Table 3.7-4). The numbers of murres in these totals is unknown.

Indirect Effects through Contamination by Oil Spills

All types of oil and fuel are dangerous, and only a few drops of oil are enough, under some situations, to kill a seabird. The species at most risk are diving seabirds, which spend more time resting on the water than do surface-feeders (King and Sanger 1979). More specifically, alcids are considered to be the most vulnerable to oil of all bird groups. The EVOS Trustee Council (EVOS Trustee Council 2002e) reports that about 22,000 carcasses of oiled murres (mostly common murres) were picked up in the first four months following the oil spill in 1989. Piatt and Ford (1996) used drift recovery data to estimate that only 15 percent of seabirds that died as a result of EVOS were actually recovered as carcasses. By this estimate, about 146,000 murres were killed. Based on surveys of breeding colonies in the spill area, murre populations may have declined by about 40 percent following the spill. In addition to direct losses of murres, there is evidence that the timing of reproduction was disrupted and productivity reduced. Post-spill monitoring at the breeding colonies in the Barren Islands indicated that reproductive success was again within normal bounds by 1993, and it has stayed within these bounds each breeding season since then (EVOS Trustee Council 2002e).

Other Past and Present Effects

The following issues have been identified as having potential impacts on murres but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** The impact of groundfish fisheries on the availability of prey to murres is likely to only be a factor if it leads to localized depletion of prey around breeding colonies. The density and distribution of fish schools may change with the overall abundance of many forage fish species. The issue is whether particular fluctuations in forage fish populations are the result of natural environmental cycles or whether they are caused or compounded either directly or indirectly by fishing pressure. The complexity of the system is such that there will always be a great deal of scientific uncertainty regarding causality of such fluctuations. In the face of this uncertainty, NPFMC prohibited directed fisheries on forage fish to minimize any indirect impact on seabirds (BSAI FMP Amendment 36 and GOA Amendment 39, 1997).

- **Indirect effects by introducing mammalian predators to nesting islands.** Cliff nesting species like murres were decimated or seriously reduced on many islands in the Aleutian chain and GOA after the introduction of arctic and red foxes by fox farmers from the 1700s to the 1930s (Bailey and Kaiser 1993). The USFWS has exterminated foxes from many of these islands and murres have begun to recolonize them. At present, murres are susceptible to predation by introduced rats. The USFWS has an extensive program to reduce the threat of new rat invasions. Some of the most intensive efforts in this regard have been carried out on the Pribilof Islands which host large murre colonies (A. Sowls, USFWS, personal communication).

Comparative Baseline

Common and thick-billed murres are abundant in the BSAI and GOA. Population trends at breeding colonies are varied throughout the area with some colonies expanding while others are stable or decreasing. Food abundance and availability appear to be major factors in population fluctuations. Murres are hunted for meat and eggs by Alaska Natives and have been taken incidentally in various fisheries. The specific numbers of murres taken in the groundfish fisheries are not reported but the numbers appear to be rather small relative to their overall population-levels. The past and present effects on murres are summarized in Table 3.7-24.

Status for Cumulative Effects Analysis

The frequency with which common and thick-billed murres interact with the groundfish fisheries warrants further consideration in the cumulative effects analysis. Because there is no species specific quantitative data on the impacts of the fisheries, these species will be discussed in conjunction with the fish-eating (piscivorous) birds in Chapter 4.

3.7.16 Guillemots

- Black guillemot (*Cepphus grylle*)
- Pigeon guillemot (*Cepphus columba*)

Life History and Distribution

Guillemots are medium-sized alcids with black and white bodies and bright orange-red feet. They are much less gregarious than other alcids and generally nest in the vicinity of only a few other pairs of birds. Nest sites are in crevices, burrows, or among the rocks of seaside cliffs. These two species (along with *Synthliboramphus* murrelets) are unique among the alcids in that they can lay up to two eggs in a clutch. This may be an adaptation to compensate for high rates of predation on both young and adults (Piatt and Naslund 1995). Eggs are laid on the bare ground and tended by both parents in turn. Incubation and fledging each takes about one month (Terres 1980).

Black guillemots are circumpolar in distribution, breeding north of the Bering Strait and ranging into the Bering Sea in winter. Pigeon guillemots are restricted to Pacific waters, breeding in the entire BSAI and GOA area, and ranging into the central Pacific waters in winter. Black guillemots winter at sea in and near the pack ice while most pigeon guillemots prefer ice-free coastal waters (Ewins *et al.* 1993, Carter *et al.* 1995, Shuntov 1993).

The Beringian Seabird Colony Catalog (USFWS 1998a) includes an estimate of 100,000 pigeon guillemots in the BSAI and 100,000 in the GOA (Table 3.5-62). Since guillemots are highly dispersed, rather than concentrated in dense breeding colonies like most alcids, totals of their populations should be considered very rough estimates. Another estimate places their numbers in all Alaska waters (BSAI and GOA combined) at only 40,000 birds (Ewins *et al.* 1993). Black guillemots do not nest in the project area and are considered rare visitors in winter. Pigeon guillemot population trends are monitored only in PWS, where the population has declined over the past two decades, possibly due to reductions in prey availability (Hayes and Kuletz 1997).

Trophic Interactions

The foraging ecology of pigeon guillemots has been studied in detail in PWS. The diet is diverse and includes small schooling fish such as capelin, sand lance, and herring, as well as bottom-dwelling fish and invertebrates (DeGange and Sanger 1986, Kuletz 1983, Golet *et al.* 2000). Benthic fish are a reliable food source but support only modest reproductive success. Schooling fish allow higher reproductive success (because their abundance and energy content are higher), but their availability fluctuates in time and space (Kuletz 1983, Golet *et al.* 2000). Pigeon guillemot chick growth and reproductive success are correlated with the availability of schooling species (Golet *et al.* 2000).

Guillemots forage in coastal waters during the breeding season, within 10 km of the colony (Ewins *et al.* 1993, G. Golet, USFWS, unpublished data). Black guillemots dive to approximately 50 m (Piatt and Nettleship 1985) and pigeon guillemots up to 45 m (Ewins *et al.* 1993).

Management Overview

Wildlife management responsibility for guillemots is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*).

Past and Present Effects and Management Actions

<u>Direct Mortality from Incidental Take in External Fisheries</u>

Almost no species-specific data exists on the direct impact of past and present fisheries on guillemot populations. Since these are diving birds, they are more likely to be caught in drift and trawl nets than on longlines. In the Japanese land-based drift gillnet fishery, pigeon guillemots made up a small fraction of the seabirds caught, including an estimated 307 in 1977 and decreasing to 116 in 1987 (DeGange and Day 1991). Offshore fisheries have probably taken many fewer guillemots since they prefer nearshore waters. The Japanese high-seas salmon driftnet fishery only took an estimated annual average of 13 pigeon guillemots between 1981-1984 (Jones and DeGange 1988). Inshore gillnet fisheries probably take guillemots incidentally but there is no data on how many birds are caught in Alaska (Ewins *et al.* 1993).

<u>Direct Mortality from Incidental Take in Groundfish Fisheries</u>

The numbers of seabirds caught in the BSAI and GOA groundfish fisheries are estimated from Observer Program data (Tables 3.7-2 through 3.7-5). Guillemots are included in the "alcid" and perhaps the"unidentified seabird" categories. Although alcids are taken more frequently in trawls than in either longline or pot fisheries, the numbers of guillemots taken is unknown. Given their nearshore preferences and less gregarious behavior, it is unlikely that guillemots are taken regularly in any of the MSA groundfish fisheries.

<u>Indirect Effects through Contamination by Oil Spills</u>

The nearshore, benthic foraging behavior of pigeon guillemots and their tendency to socialize on intertidal rocks makes them susceptible to being killed in disproportionate numbers by oil spills (Oakley and Kuletz 1996). An estimated 10-15 percent of the population in the EVOS area died immediately following the spill. Pigeon guillemot populations still had not recovered from the EVOS disaster nine years later, probably because foraging conditions were inadequate to support an increase in the population (Hayes and Kuletz 1997).

Other Past and Present Effects

The following issues have been identified as having potential impacts on guillemots but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** The impact of groundfish fisheries on the availability of prey to guillemots is unknown. The density and distribution of fish schools may change with the overall abundance of many forage fish species. The issue is whether particular fluctuations in forage fish populations are the result of natural environmental cycles or whether they are caused or compounded either directly or indirectly by fishing pressure. The complexity of the system is such that there will always be a great deal of scientific uncertainty regarding causality of such fluctuations. In the face of this uncertainty, NPFMC prohibited directed fisheries on forage fish to minimize any indirect impact on seabirds (BSAI FMP Amendment 36 and GOA Amendment 39, 1997).

Comparative Baseline

Guillemots are distributed widely in the BSAI and GOA, especially in nearshore waters, but are not found in large concentrations anywhere. Overall population estimates are uncertain and population trends are monitored only for pigeon guillemots in PWS, where they have been decreasing. Guillemots are susceptible to changes in the local distribution and abundance of forage fish and have been impacted by past oil spills. Their direct interactions with the groundfish fleet are probably minimal. The past and present effects on guillemots are summarized in Table 3.7-25.

Status for Cumulative Effects Analysis

Because there is no species specific quantitative data on either their population trends (outside PWS) or impacts of the fisheries, these species will be discussed in conjunction with the fish-eating (piscivorous) birds in Chapter 4.

3.7.17 Murrelets

- Marbled murrelet (*Brachyramphus marmoratus*)
- Kittlitz's murrelet (*Brachyramphus brevirostris*)
- Ancient murrelet (*Synthliboramphus antiquus*)

Life History and Distribution

Murrelets are medium-sized alcids that share the ability to "fly" underwater with other members of the family. These three species have very different nesting sites and reproductive strategies that impact conservation efforts. Marbled and Kittlitz's murrelets are unique among the alcids in having a mottled brown, cryptic coloration in their breeding plumage. This is an indication that predation on adults (by raptors and possibly corvids) plays a major role in their life history strategy (Piatt and Naslund 1995). Other clues to the importance of predation include the fact that nest sites are dispersed, rather than colonial, and that parent birds travel to and from their nests only under low light conditions, a habit which has made it very difficult to locate nests. Marbled murrelets nest predominately on moss-covered limbs of huge trees, sometimes up to 70 km from the sea, and are thus associated with old-growth forests (Piatt and Ford 1993). Kittlitz's murrelets also nest away from the water but choose nest sites on rocky slopes of high alpine areas, especially in areas close to glaciers (Piatt *et al.* 1999). The remote, hidden, and dispersed nesting habits of these two species has greatly restricted research on their reproductive biology. Ancient murrelets are colonial, dig burrows under boulders, tree roots, or dense vegetation, and nest on islands free of mammalian predators. They are unusual among the alcids (along with guillemots) in having the capacity to lay up to two eggs in a clutch. This may have evolved as a way to compensate for high rates of predation and helps stabilize the population from other adult mortality factors (Piatt and Naslund 1995).

Marbled murrelets breed from the Aleutian Islands east along the coast of Alaska and south to the coast of California. Kittlitz's murrelets breed in selected areas throughout the BSAI and GOA. Ancient murrelets breed from the southern Bering Sea south and east to British Columbia. Ancients, more than the other two species, are more likely to winter offshore in deep waters.

Population estimates for seabird species with dispersed, well-hidden nests are best made from at-sea survey data. However, the reliability of these census techniques for population trend analysis is still under investigation (Ralph *et al.* 1995). For marbled murrelets, the total North American population is estimated to be about 300,000 birds, 85 percent of which breed along the coast of the GOA and in PWS (Ralph *et al.* 1995). An estimated 2,400 marbled murrelets breed in the BSAI (Piatt and Naslund 1995). The worldwide estimate for Kittlitz's murrelet was about 20,000 birds in 1993, 90 percent of which were in the GOA area (van Vliet 1993). Another estimate in 1993 put the figure in the 25,000-100,000 range (Ewins *et al.* 1993), although the upper limit has been challenged (Day *et al.* 1999). Ancient murrelet populations have been estimated at breeding colonies. Rough estimates of these underground nesters include 200,000 birds in the BSAI and 600,000 in the GOA (USFWS 1998a) (Table 3.5-62). No population trend data are available for ancient murrelets.

As stated above, population trend data are somewhat tenuous for marbled and Kittlitz's murrelets and are best documented in PWS due to the amount of research in that area following the EVOS in 1989. Based on Christmas Bird Count data from northern GOA communities, marbled murrelets are estimated to have declined by at least 50 percent between 1972 and 1992 (Piatt and Naslund 1995). Boat surveys in PWS, conducted in many areas and in both winter and summer, indicate that combined counts of the two *Brachyramphus* species declined by 67-73 percent between the early 1970s and late 1980s (Piatt and Naslund 1995). Numbers appeared to stabilize between 1989 and 1993 but then declined further in 1996 and 1998 (Agler and Kendall 1997 and 1998, Lance *et al.* 1999).

One early estimate for the Kittlitz's murrelet population in PWS concluded that there were about 60,000 birds in 1972 (Isleib and Kessel 1973). This estimate is much higher than recent estimates and its methodology has been challenged (Day and Nigro 1999). However, standardized surveys since the Exxon Valdez oil spill have also shown major and continuing declines in two major concentrations of Kittlitz's murrelets. In PWS, Kittlitz's numbers declined an average of over 14 percent per year from 1989-1998 (Lance *et al.* 1999). In Glacier Bay, the population of Kittlitz'z murrelets has declined by almost 80 percent between 1991 and 1999 and they have disappeared from areas where they were once common (USGS 2001).

These studies have been cited in a recent petition to the USFWS to list the species as "endangered" under the ESA (Center for Biological Diversity *et al.* 2001).

The typical alcid life history strategy is to compensate for low reproductive potential (one-egg clutches) with high adult survivorship and long life. Marbled and Kittlitz's murrelets have taken this to an extreme. Although there are no data on adult survival rates, there is evidence that reproduction rates are very low and impacted to a large extent by predation. This means that these populations may be especially sensitive to changes in natural mortality rates and additional anthropogenic sources of mortality (Piatt and Naslund 1995).

Trophic Interactions

Diets of murrelets are dominated by small schooling fish such as capelin and Pacific sand lance. Some zooplankton and other invertebrates are also consumed by Kittlitz's murrelet and especially by ancient murrelets (Sanger 1987, Ewins *et al.* 1993, Springer *et al.* 1993, Gaston 1994). All three murrelets forage by diving. Marbled murrelets dive in water primarily less than 20 m deep (Nelson 1997).

Marbled murrelets forage in shallow waters within 5 km of shore and are associated with sites of upwellings or small fronts that might make prey available (Nelson 1997, Kuletz *et al.* 1995). Kittlitz's murrelets prefer inlets and forage near glaciers where available (Sanger 1987, Ostrand *et al.* 1998, Day *et al.* 1999a, Day and Nigro 2000). Ancient murrelets forage over the shelf and shelf break, but also occur near land at sites of tidal upwellings (Gaston 1994). Some murrelets winter in ice-free bays throughout the state; others apparently move south or offshore to unknown areas (Ewins *et al.* 1993, Carter *et al.* 1995).

Management Overview

Wildlife management responsibility for murrelets is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*). In 1999, protocol amendments to the Migratory Bird Treaty Act were ratified that mandated participation of subsistence users and their traditional knowledge in a co-management relationship between Native, Federal, and State of Alaska representatives. This co-management group is charged with developing conservation, research, and management plans for all species taken in subsistence harvests, including murrelets (Denlinger and Wohl 2001).

In 1990, marbled murrelets were listed as "threatened" in British Columbia by the Canadian government because of significant population declines and loss of nesting habitat. For similar reasons, the species was listed as "threatened" under the ESA for California, Oregon, and Washington in 1993. Marbled murrelets are not listed under the ESA in Alaska. However, in 1995, the USFWS designated marbled and Kittlitz's murrelets as "species of management concern" (USFWS 1995b). These species are of concern because of 1) documented or apparent population declines, 2) small or restricted populations, or 3) dependence on restricted or vulnerable habitats. The Fish and Wildlife Conservation Act of 1980, as amended in 1988, requires the designation of concern for species that, without additional conservation action, are likely to become candidates for listing under the ESA. On May 9, 2001, a group of non-governmental organizations petitioned the Secretary of the Interior to list Kittlitz's murrelet as "endangered" under the ESA, citing evidence of major and consistent population declines in their core breeding areas in southeast Alaska (Center for Biological Diversity *et al.* 2001).

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Seabirds have been hunted by the Native peoples of Alaska for thousands of years. There are no historical records of the numbers of murrelets taken but the impact was probably small and limited to birds hunted on the water. In recent community surveys by the ADF&G, USFWS, and tribal governments, 30 ancient murrelets were taken in 1996, all from the Aleutian/Pribilof Islands District (Denlinger and Wohl 2001). No marbled or Kittlitz's murrelets were identified in the surveys but there were a reported 1,246 "unidentified seabirds" taken in 1996 from southeast Alaska, the area most likely to be harvesting murrelets.

Direct Mortality from Incidental Take in External Fisheries

Murrelets are not attracted to fishing vessels like many of the surface-feeding seabirds and are not likely to be caught by longline fisheries. They are more susceptible to being caught in trawl and drift nets which hang down into the water column where they dive for fish and other prey. Past fisheries in the North Pacific, both foreign and domestic, have taken murrelets in the course of their operations. For most of these fisheries, the numbers of individual species taken were not recorded. Some data is available from the Japanese salmon mothership fishery where an average of 1,533 ancient murrelets were taken every year between 1981-1984 (Jones and DeGange 1988). The land-based Japanese salmon gillnet fishery, active from 1953-1992, was responsible for killing an estimated 307 ancient murrelets in 1977. In 1987, after substantial reductions in the fishing effort, an estimated 116 ancient murrelets were taken (DeGange and Day 1991). On the Russian side of the Bering Sea, Japanese salmon gillnet fisheries took an estimated 1.1 million seabirds between 1993 and 1998, 62 percent of which were unspecified alcids (Artukhin *et al.* 2000). The incidental take of murrelets in other current foreign gillnet fisheries is unknown.

Because murrelets spend most of their time in nearshore waters, especially during the breeding season, they are susceptible to being caught in nearshore gillnet fisheries (i.e., state-managed fisheries). Largely anecdotal evidence suggested that perhaps thousands of murrelets were killed annually in coastal Alaska gillnet fisheries in the 1970s (Carter and Sealy 1984, DeGange *et al.* 1993). Based on quantitative seabird bycatch data from salmon fisheries in PWS, an estimated annual average of 690 marbled and 130 Kittlitz's murrelets were killed in 1990 and 1991 (Piatt and Naslund 1995). Extrapolating from the number of 1989 drift net permits and PWS bycatch rates, Piatt and Naslund (1995) estimate that 3,300 *Brachyramphus* murrelets are killed annually in Alaskan gillnet fisheries. Kittlitz's murrelets appear to be particularly susceptible to being caught. Kittlitz's represent only 7 percent of all murrelets in PWS but represent 30 percent of all murrelets caught (Day and Nigro 1999). Since most of these birds are adults and population dynamics of seabirds are typically driven by adult survival rates, this amount of mortality is a significant conservation concern. These estimates also do not include suspected mortality in set nets, pound nets, or seine nets (Piatt and Naslund 1995). Gillnet fisheries have also been shown to cause significant amounts of mortality in ancient murrelets in British Columbia (Bertram 1995) but no data exists for Alaska fisheries.

Direct Mortality from Incidental Take in Groundfish Fisheries

The numbers of seabirds caught in the BSAI and GOA groundfish fisheries are estimated from Observer Program data (Tables 3.7-2 through 3.7-5). Marbled and Kittlitz's murrelets have individual species codes under the observer protocol but are included in the "alcid" category for analysis and reporting purposes. An unknown number may also be included in the and "unidentified seabird" category. Alcids are taken more frequently in trawls than in either longline or pot fisheries but the numbers of murrelets taken is unknown. Given their nearshore preferences and less gregarious behavior, it is unlikely that murrelets are taken regularly in any of the MSA groundfish fisheries.

Indirect Effects through Contamination by Oil Spills

The threat of both catastrophic and chronic oil spills to seabirds is well-known (Piatt *et al.* 1990, Burger and Fry 1993, Piatt and Ford 1996, Huguenin *et al.* 1996). All types of oil and fuel are dangerous, and only a few drops of oil are enough, under some situations, to kill a seabird. The species at most risk are diving seabirds, which spend more time resting on the water than do surface-feeders, and marbled and Kittlitz's murrelets are rated as two of the most susceptible species in the state (King and Sanger 1979). More specifically, alcids are considered to be the most vulnerable to oil of all bird groups. Based on the actual numbers of birds recovered on beaches after the Exxon Valdez oil spill and estimates of carcass recovery rates, the spill killed an estimated 8,400 marbled murrelets and perhaps as many as 1000-2000 Kittlitz's, representing about 3 percent and 5 to 10 percent of their respective estimated Alaska populations (Piatt and Naslund 1995, van Vliet and McAllister1994).

Indirect Effects through Disturbance by Fishing Vessels

Although many surface-feeding birds are attracted to fishing vessels (Furness 1999), murrelets are disturbed by nearby boats (of all types) and may be displaced from forage areas by vessel activity (Kuletz 1996). Dramatic declines in Kittlitz's murrelets in Blackstone Bay in PWS may be attributable in part to the high numbers of recreational boaters in the area (Day and Nigro 1999). The popularity of tidewater glacier tours from cruise ships is also growing and since these areas are also preferred by Kittlitz's, there is growing concern about this disturbance impact.

Other Past and Present Effects

The following issues have been identified as having potential impacts on murrelets but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** Highly dispersed, non-colonial birds such as marbled and Kittlitz's murrelets may be particularly well adapted to patchy, highly dispersed prey in low-density schools (Ostrand *et al.* 1998, Kuletz 1999). However, in PWS, reproductive success of marbled murrelets correlated with years and sites of relative abundance of forage fish species (Kuletz unpublished data). The big unanswered question for murrelets, as with all piscivores, is whether variations in their food supplies are caused by human activities or are predominately natural cycles. Despite intensive and ongoing research into the factors that determine the composition, abundance, and availability of forage fish, it is still not clear how much impact various fisheries have in relation to climate and oceanography-driven changes in primary productivity and food web dynamics (Piatt and Anderson 1996, Agler *et al.* 1999, Anderson and Piatt 1999). In the face of this uncertainty, NPFMC prohibited directed fisheries on forage fish to minimize any indirect impact on seabirds (BSAI FMP Amendment 36 and GOA Amendment 39 1997).

- **Indirect effects by introducing mammalian predators to nesting islands.** Burrowing seabirds, including ancient murrelets, were decimated or seriously reduced on many islands in the Aleutian chain and GOA after the introduction of arctic and red foxes by fox farmers from the 1700s to the 1930s (Bailey and Kaiser 1993). The USFWS has exterminated foxes from many of these islands and ancient murrelets have begun to recolonize them. At present, ancient murrelets are susceptible to predation by introduced rats. The USFWS has an extensive program to reduce the threat of new rat invasions.

- **Indirect effects from logging.** Due to their nesting ecology, marbled murrelets also face the threat of habitat loss from logging operations, a rather unique threat for seabirds. This issue is addressed in great detail in the U.S. Forest Service's Tongass National Forest Land and Resource Management Plan (USDA 1997).

Comparative Baseline

Population data for all three murrelet species are imprecise. Marbled and Kittlitz's murrelets are species of management concern in Alaska due to recent dramatic declines in their numbers in core habitats in southeast Alaska. The numbers of murrelets taken in the groundfish fisheries is unknown due to lack of differentiation among alcids in the Observer Program. Several factors external to the groundfish fisheries have been identified as conservation concerns for marbled and Kittlitz's murrelets. Ancient murrelets are taken in small numbers by pelagic fisheries but there are no population trend data for this species which might be used to monitor or model impacts. The past and present effects on murrelets are summarized in Table 3.7-26.

Status for Cumulative Effects Analysis

Even though they do not appear to interact with the groundfish fisheries very regularly, the status of marbled and Kittlitz's murrelets as species of management concern warrants further consideration in the cumulative effects analysis. Since some Alternative FMPs call for special management goals for seabird species of management concern, marbled and Kittlitz's murrelets will be considered with the other species of management concern (red-legged kittiwakes) in Chapter 4. Because population trend data for ancient murrelets are not available and there is no species specific quantitative data on the impacts of the fisheries, ancient murrelets will be discussed in conjunction with the fish-eating (piscivorous) birds in Chapter 4.

3.7.18 Auklets

- Cassin's auklet (*Ptychoramphus aleutica*)
- Parakeet auklet (*Aethia psittacula*)
- Least auklet (*Aethia pusilla*)
- Whiskered auklet (*Aethia pygmaea*)
- Crested auklet (*Aethia cristatella*)

Life History and Distribution

Auklets are small (6 to 10 inches long) members of the Alcidae family, which also includes the murres and puffins. Like the other alcids, these birds are highly adapted to life at sea and come to land only to nest. They use their short, narrow wings to "fly" underwater in pursuit of prey. All of these auklets, except parakeet, are usually found in flocks at sea. Sometimes those flocks are huge and dense with thousands of birds. There are differences in their preferred nest sites but they all basically nest in crevices, burrows, or within rock piles. Parakeet auklets are the exception again in that they do not nest in dense aggregations like the others. All species lay just one egg on the bare ground and the sexes take turns incubating and brooding the young.

These auklets are all North Pacific birds and, with the exception of Cassin's auklet, breed only in the BSAI and GOA area. Cassin's nest from the Aleutians south to California. Whiskered auklets only breed in the central and western Aleutians. The other three species nest from the GOA north and west to the Bering Strait. Cassin's and parakeets are concentrated in northern waters but range south to California in winter. The other three species are restricted to waters around the Aleutians and Alaska Peninsula in winter.

Population estimates for these five auklet species are not very reliable because of their underground or hidden nesting habits. Numbers listed in the Beringian Seabird Colony Catalog (USFWS 1998a) should be used for only the most generalized discussions and are not sufficient for documenting anything but the most extreme changes in population-levels. Still, this is one of the most abundant groups of birds in the Bering Sea (Table 3.5-62). Cassin's auklets are estimated to number 250,000 in the BSAI and 750,000 in the GOA. Parakeets have an estimated 800,000 in the BSAI and 150,000 in the GOA. Least auklets are the most abundant species with an estimated 9 million birds, essentially all in the BSAI. There are only about 30,000 whiskered auklets, all in the BSAI. Crested auklets are abundant with an estimated 3 million in the BSAI and 50,000 in the GOA.

Population trends of auklets are poorly known at present because monitoring of their underground nests is extremely difficult. Least auklets have been monitored on Kasatochi Island (central Aleutians) since 1991 and have fluctuated but do not exhibit any consistent trend (Dragoo *et al.* 2001). Least auklets may be increasing in the central and northern Bering Sea (Springer *et al.* 1993). Crested auklets have been monitored at the same sites and appear to be stable or increasing (Table 3.7-21, Springer *et al.* 1993, Dragoo *et al.* 2001).

Trophic Interactions

The abundance and diversity of small auklets is much higher in the Bering Sea than elsewhere in the world, owing to the large-scale advection of oceanic zooplankton onto the shelf in areas such as the Aleutian passes and Bering Strait (Springer and Roseneau 1985). They seek water structures that concentrate small prey at depths of 5 to 30 m, such as pycnoclines, fronts, or tide rips over shallow sills (Hunt 1990, Hunt *et al.* 1990, Hunt *et al.* 1993). All forage by pursuit diving (Ashmole and Ashmole 1967). Cassin's auklets take a variety of zooplankton along with squid and some small fish. Parakeet auklets eat a diverse diet of small schooling fish such as Pacific sand lance and juvenile pollock, jellyfish, squid, other invertebrates, and zooplankton (Hunt *et al.* 1993, Springer *et al.* 1993, Hunt *et al.* 1998). Least auklets depend exclusively on zooplankton, especially *Neocalanus plumchrus*, a type of copepod (Hunt 1997). Whiskered auklets also depend exclusively on zooplankton. Crested auklets eat zooplankton and other invertebrates, especially the euphausid, *Thysanoessa raschii* (Hunt *et al.* 1998).

A recent study conducted in the shallow passes of the Aleutian Islands demonstrated that least, crested, and parakeet auklets timed their foraging in a pass to correspond with the presence of strong tidal currents. The diets of these three auklet species differed in composition despite the proximity of the areas in which they foraged. The researchers concluded that the three auklet species exhibited strong preferences for particular prey types, and that these prey preferences resulted in small-scale differentiation of preferred foraging sites. The strong tidal currents provided the energy for enhancing the availability of different prey (Hunt *et al.* 1998).

Numerous studies highlight the foraging ecology of auklets and relationships to physical oceanographic processes (Hunt and Harrison 1990, Russell and Hunt 1992, Hunt 1997, Hunt *et al.* 1998, Russell *et al.* 1999). Upwellings occur where tides or currents move water from the deep ocean onto the shelf, such as between the islands in the Pribilofs (Coyle *et al.* 1992), the Aleutian Islands (Hunt *et al.* 1998), or the Anadyr Current west of St. Lawrence Island (Hunt *et al.* 1990). Auklets nest abundantly in these areas because upwellings bring oceanic zooplankton to shallow waters nearby (Springer and Roseneau 1985, Hunt *et al.* 1993).

It has been suggested that auklet population trends are due in part to food-web changes following reductions in plankton-eating whales or other predators (Springer 1991b, Springer 1992, Springer *et al.* 1993). Other studies, however, indicate that decadal changes in primary productivity of northern versus southern Pacific waters have altered zooplankton abundance, which has not always resulted in population increases of seabirds (Francis *et al.* 1998, McGowan *et al.* 1998).

Management Overview

Wildlife management responsibility for auklets is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*). In 1999, protocol amendments to the Migratory Bird Treaty Act were ratified that mandated participation of subsistence users and their traditional knowledge in a co-management relationship between Native, Federal, and State of Alaska representatives. This co-management group is charged with developing conservation, research, and management plans for all species taken in subsistence harvests, including auklets (Denlinger and Wohl 2001).

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Auklets have been hunted for their meat, skins, and decorative beaks by Native peoples in the BSAI and GOA area for thousands of years. These hunts are usually done in family groups and are significant subsistence and cultural traditions. Harvest of adult birds from breeding colonies continues to the present time in some coastal communities, most commonly by means of shotguns and motorized boats. Recent community surveys by the ADF&G, USFWS, and tribal governments indicate that crested auklets are the most frequently taken seabird in subsistence hunts (Denlinger and Wohl 2001). In 1996 alone, an estimated 12,300 crested auklets were taken, all from the St. Lawrence/Diomede Islands area. A few hundred parakeet and least auklets were also taken in that year as well as about 4,700 unidentified auklets. Most of these birds are taken in the northern Bering Sea but they are also hunted in the Aleutians and Kodiak Island area (Denlinger and Wohl 2001).

Direct Mortality from Incidental Take in External Fisheries

Auklets are not attracted to fishing vessels because of fish scraps like many of the surface-feeding seabirds and are rarely caught by longline fisheries. They are more susceptible to being caught in trawl and drift nets which hang down into the water column where auklets dive for zooplankton and fish. Past fisheries in the North Pacific, both foreign and domestic, have taken auklets in the course of their operations. For most of these fisheries, the numbers of individual species taken were not recorded. Some data is available for the Japanese salmon high-seas driftnet (mothership) fishery where an average of 304 Cassin's, 583 parakeet, 219 least, and 5,565 crested auklets were taken every year between 1981-1984 (Jones and DeGange 1988). The land-based Japanese salmon gillnet fishery was responsible for millions of seabird deaths between 1952-1987, including an estimated 7,079 parakeet and 307 crested auklets in 1977. By 1987, fishing effort had been reduced and catch rates declined to an estimated 1,966 parakeet and 116 crested auklets (DeGange and Day 1991). On the Russian side of the Bering Sea, Japanese salmon gillnet fisheries took an estimated 1.1 million seabirds between 1993 and 1998, 62 percent of which were unidentified alcids (Artukhin *et al.* 2000). The incidental take of auklets in other current foreign gillnet fisheries is unknown.

Direct Mortality from Incidental Take on Groundfish Longlines

The numbers of seabirds caught in the BSAI and GOA groundfish longline fisheries are estimated from Observer Program data in Tables 3.7-2 and 3.7-3. Auklets are included in the "alcid" and "unidentified seabird" categories. The alcids accounted for an average of 15 birds per year taken in the BSAI between 1993 and 2001 and one bird per year in the GOA.

Direct Mortality from Incidental Take in Groundfish Trawls

The BSAI and GOA trawl fishery took between 178 alcids per year (low estimate) and 340 alcids per year (high estimate) between 1997 and 2001 (Table 3.7-4). The numbers of auklets in these totals is unknown.

Direct Mortality from Vessel Strikes

Crested auklets do not seem to strike fishing vessels very frequently but when they do, the incidents often involve large numbers of birds. According to preliminary analysis of the observer records of bird-strikes from 1993-2000, 1,305 crested auklets were involved in 7 recorded collisions. In one historical account, approximately 6,000 crested auklets were attracted to lights and collided with a fishing vessel near Kodiak Island during the winter of 1977 (Dick and Donaldson 1978). Monitoring these types of collisions is not part of the observer's normal duties so the true extent of this impact is not known (NPFMC 2002c).

Other Past and Present Effects

The following issues have been identified as having potential impacts on auklets but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** Although parakeet auklets take some fish, auklets are primarily plankton feeders and are much more likely to be affected by changes in the primary productivity of the ecosystem (due to climactic or ocean current shifts) rather than top-down effects. However, the relationship between the abundance and distribution of commercial fish stocks, most of which are also plankton feeders at some point in their life cycle, and food web dynamics is poorly understood.

- **Indirect effects through contamination by oil spills.** Alcids are considered to be the most vulnerable of all bird groups to the risk of chronic and acute oil contamination from all sources (King and Sanger 1979).

- **Indirect effects through plastics ingestion.** Parakeet auklets are among the species with the highest recorded frequencies of plastic ingestion even though most alcids ingest little or no plastic (Sievert and Sileo 1993).

- **Indirect effects by introducing mammalian predators to nesting islands.** Burrowing and cliff-nesting seabirds, including auklets, were decimated or seriously reduced on many islands in the Aleutian chain and GOA after the introduction of arctic and red foxes by fox farmers from the 1700s to the 1930s (Bailey and Kaiser 1993). The USFWS has exterminated foxes from many of these islands and auklets have begun to recolonize them. At present, auklets are susceptible to predation by introduced rats. The USFWS has an extensive program to reduce the threat of new rat invasions.

Comparative Baseline

The five species of auklets common to the BSAI and GOA area are generally abundant and widely distributed in the project area. Their population numbers and trends are poorly known. Direct auklet interactions with the groundfish fisheries appear to be infrequent and minor in scale except for the occasional mass collision of crested auklets with fishing vessels in poor weather. The specific numbers of auklets taken in the groundfish fisheries are not recorded by the Observer Program but the numbers appear to be rather small relative to their overall population-levels. The past and present effects on auklets are summarized in Table 3.7-27.

Status for Cumulative Effects Analysis

Because population trend data for these species are very limited and there is no species specific quantitative data on the impacts of the fisheries, these species will be discussed in conjunction with the “other planktivorous species” group in Chapter 4.

3.7.19 Puffins

- Rhinoceros auklet (*Cerorhinca monocerata)*
- Horned puffin (*Fratercula corniculata*)
- Tufted puffin (*Fratercula cirrhata*)

Life History and Distribution

Puffins are familiar to many people as the birds with the large, colorful bills that are frequently depicted on Alaska tee shirts and advertisements. The rhinoceros auklet is included in this account because it is much closer in size, behavior, and anatomy to the two puffins than to the other auklets. These three alcid species are all about the same size, 15 inches in length, and are more brightly colored in the summer than winter. They dig burrows for their nest sites on the tops of islands or less frequently nest within rock crevices. Following the conservative seabird pattern, they lay only one egg and take turns with parental care. They are usually seen singly or in small numbers at sea but can be abundant on waters around their colonies.

Rhinoceros auklets breed and winter along the coast from the Aleutian Islands to California. Horned puffins breed along the Alaska coast in the entire BSAI and GOA area and winter in the North Pacific. Tufted puffins have a similar range but will also breed in coastal waters south to California.

Population estimates for the puffin species are not very reliable because of their underground or hidden nesting habits. Numbers listed in the Beringian Seabird Colony Catalog (USFWS 1998a) are not sufficient for documenting anything but the most extreme changes in population-levels. There are an estimated 200,000 rhinoceros auklets in Alaska, essentially all of which nest in the GOA. Horned puffins have an estimated 500,000 in the BSAI and 1.5 million in the GOA. Tufted puffins are the most abundant species with an estimated 2.5 million birds in the BSAI and 1.5 million in the GOA (Table 3.5-62).

Population trends for burrow nesting species are very difficult to determine with any accuracy. Rhinoceros auklets are monitored on permanent sample plots in only one location, St. Lazaria Island (southeast Alaska). Since 1994, the density of burrow holes has fluctuated but shows no clear trend. Plots have been set up to monitor horned puffins on Buldir Island but no acceptable sampling method has been developed to date. The density of tufted puffin burrows have increased slightly on Bogoslof and Aiktak Islands (central and eastern Aleutians) and shows no obvious trend on E. Amatuli in the GOA or St. Lazaria. (Table 3.7-21, Dragoo *et al.* 2001).

Trophic Interactions

Rhinoceros auklets and the puffins forage both near shore and over the shelf, although rhinoceros auklets primarily feed near shore and the puffins primarily feed on the shelf (DeGange and Sanger 1986, Schneider *et al.* 1986, Sanger 1987). All three species dive for small schooling fish such as capelin, Pacific sand lance, and herring. Horned and tufted puffins also consume pollock, squid, and zooplankton. The rhinoceros auklet may forage more often at twilight than other puffins. The tufted puffin has the most diverse diet of the three and consumes the largest proportion of invertebrates (DeGange and Sanger 1986, Vermeer *et al.* 1987, Hatch and Sanger 1992, Byrd *et al.* 1997). Tufted puffin populations in PWS may be partly limited by low prey densities (Piatt *et al.* 1997).

Management Overview

Wildlife management responsibility for puffins is under the jurisdiction of the USFWS. These species are protected under the U.S. Migratory Bird Treaty Act (16 USC 703 *et.seq.*). In 1999, protocol amendments were ratified that mandated participation of subsistence users and their traditional knowledge in a co-management relationship between Native, Federal, and State of Alaska representatives. This co-management group is charged with developing conservation, research, and management plans for all species taken in subsistence harvests, including puffins (Denlinger and Wohl 2001).

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Puffins have been hunted for their meat, skins, and decorative beaks by Native peoples in the BSAI and GOA area for thousands of years. An account from the mid-1800s describes the widespread use of baleen nooses to capture birds on the steep cliffs of the Aleutian Islands. These methods were efficient enough to cause noticeable declines in breeding populations of puffins, at least at colonies that were accessible from settlements (Veniaminov 1840). These hunts are usually done in family groups and are significant subsistence and cultural traditions. Harvest of adult birds from breeding colonies continues to the present time in some coastal communities, most commonly by means of shotguns and motorized boats. Recent community surveys by the ADF&G, USFWS, and tribal governments indicate that puffins make up a small part of the harvest (Denlinger and Wohl 2001). In 1996, an estimated 48 horned puffins, 65 tufted puffins, and 115 unidentified puffins were taken in the BSAI area. It is not known whether any puffins were taken in the GOA that year (Denlinger and Wohl 2001).

Direct Mortality from Incidental Take in External Fisheries

Puffins are not attracted to fishing vessels like many of the surface-feeding seabirds and are not likely to be caught by longline fisheries. They are more susceptible to being caught in trawl and drift nets which hang down into the water column where they dive for fish. Past fisheries in the North Pacific, both foreign and domestic, have taken puffins in the course of their operations. For most of these fisheries, the numbers of individual species taken were not recorded. Some data is available for the Japanese salmon high-seas (mothership) fishery where an average of 19 rhinoceros auklets, 8,249 horned puffins, and 38,600 tufted puffins were taken every year between 1981-1984 (Jones and DeGange 1988). The land-based Japanese salmon gillnet fishery, operating from 1952-1992, was responsible for killing an estimated 4,929 rhinoceros auklets, 1,229 horned puffins, and 31,403 tufted puffins in 1977. In 1987, after substantial reductions in the fishing effort, an estimated 1,387 rhinoceros auklets were taken along with 462 horned puffins and 9,481 tufted puffins (DeGange and Day 1991). Driftnet fisheries targeting flying squid were started in the late 1970s by Japan, Korea, and Taiwan. At their peak in the late 1980s, these fisheries deployed millions of kilometers of driftnet. Rough estimates of the total number of seabirds killed by the squid driftnet fisheries were between 875,000 and 1,660,000 seabirds annually, including up to 250,000 tufted puffins and 100,000 horned puffins per year (DeGange *et al.* 1993). Due to the tremendous amount of waste and ecosystem damage associated with the high-seas driftnet fisheries, they were outlawed by international agreement through United Nations Resolution (46/215) in December of 1992 (Paul 1994). On the Russian side of the Bering Sea, Japanese salmon gillnet fisheries took an estimated 1.1 million seabirds between 1993 and 1998, 62 percent of which were unidentified alcids (Artukhin *et al.* 2000). The incidental take of puffins in other current foreign gillnet fisheries is unknown.

<u>Direct Mortality from Incidental Take on Groundfish Longlines</u>

The numbers of seabirds caught in the BSAI and GOA groundfish longline fisheries are estimated from Observer Program data in Tables 3.7-2 and 3.7-3. Rhinoceros auklet and both puffins have individual species codes in the observer protocols but are included in the "alcid" category for analytical and reporting purposes. An unknown number of these species may also be included in the "unidentified seabird" category. The alcids accounted for an average of 15 birds per year taken in the BSAI between 1993 and 2001 and one bird per year in the GOA.

<u>Direct Mortality from Incidental Take in Groundfish Trawls</u>

The BSAI and GOA trawl fishery took between 178 alcids per year (low estimate) and 340 alcids per year (high estimate) between 1997 and 2001 (Table 3.7-4). The numbers of puffins in these totals is unknown.

Other Past and Present Effects

The following issues have been identified as having potential impacts on puffins but not enough information is available to assess the extent of these impacts quantitatively or at a population-level. The nature of these effects are outlined in the introduction to seabirds (see Section 3.7.1).

- **Indirect effects through changes in prey availability.** The impact of groundfish fisheries on the availability of prey to puffins is unknown. The big unanswered question for puffins, as with all piscivores, is whether variations in their food supplies are caused by human activities or are predominately natural cycles. In the face of this uncertainty, NPFMC prohibited directed fisheries on forage fish to minimize any indirect impact on seabirds (BSAI FMP Amendment 36 and GOA Amendment 39, 1997).

- **Indirect effects through contamination by oil spills.** Alcids are considered to be the most vulnerable of all bird groups to the risk of chronic and acute oil contamination from all sources (King and Sanger 1979).

- **Indirect effects by introducing mammalian predators to nesting islands.** Burrowing and crevice-nesting seabirds, including puffins, were decimated or seriously reduced on many islands in the Aleutian chain and GOA after the introduction of arctic and red foxes by fox farmers from the 1700s to the 1930s (Bailey and Kaiser 1993). The USFWS has exterminated foxes from many of these islands and auklets have begun to recolonize them. At present, puffins are susceptible to predation by introduced rats. The USFWS has an extensive program to reduce the threat of new rat invasions.

Comparative Baseline

All three puffin species are common or abundant in the BSAI and GOA area. Population trend data for these species are either unavailable or very limited. These species were impacted heavily by the now illegal high-seas drift fisheries. The numbers of puffins taken in the groundfish fisheries is unknown due to lack of differentiation among alcids in the Observer Program but the numbers appear to be rather small relative to their overall population-levels. The past and present effects on puffins are summarized in Table 3.7-28.

Status for Cumulative Effects Analysis

Because population trend data for these species are very limited and there is no species specific quantitative data on the impacts of the fisheries, these species will be discussed in conjunction with the fish-eating (piscivorous) birds in Chapter 4.

3.8 Marine Mammals

The purpose of this chapter is to describe the baseline condition of marine mammals as they relate to the federally managed groundfish fishery in Alaska. This baseline condition includes a description of the pertinent natural history for each species and an assessment of the various natural and anthropogenic factors that have shaped the status of each species in Alaskan waters. These accounts summarize the human and natural effects on each species, to the extent that they are known, and thus provide the historical and scientific basis for analyzing the potential effects of the alternative FMPs in Chapter 4.

The geographical and temporal scope of material presented in this chapter is not consistent between different species because of the wide variability in their distributions and the incompleteness of historical information. For some species, like many of the baleen whales, commercial whaling that took place many years ago and often in distant waters have greatly influenced their present status in Alaska. For other species, like the "ice seals" (spotted, bearded, ribbon, and ringed), there are few historical records of impacts and basic biological parameters such as population abundance are still not known. The intent is to provide as much relevant information as possible for each species. In order to minimize redundancy in the individual species accounts, general information on the types of effects that may impact marine mammal populations are described below. Information pertinent to only one species will be presented in the individual species accounts.

Marine mammals occur in diverse habitats, including deep oceanic waters, the continental slope, and the continental shelf (Lowry *et al.* 1982). In the areas fished by the federally managed groundfish fleets, twenty-six species of marine mammals are present from the orders Pinnipedia (seals, sea lion, and walrus), Carnivora (sea otter and polar bear), and Cetacea (whales, dolphins, and porpoises) (Lowry and Frost 1985). Most species are resident throughout the year, while others seasonally migrate into and out of Alaskan waters.

Marine Mammal Protection Act

The MMPA of 1972 (16 USC 1361 *et seq.*), as amended through 1996, establishes a federal responsibility to conserve marine mammals. Management responsibility for cetaceans and pinnipeds other than walrus is vested with the NOAA Fisheries Protected Resources Division. The USFWS is responsible for management of walrus and sea otters. The MMPA's primary management objective is to maintain the health and stability of the marine ecosystem, with a goal of obtaining an optimum sustainable population of marine mammals within the carrying capacity of the habitat. The MMPA is intended to work in concert with the provisions of the ESA. If a fishery affects a marine mammal population, then the potential impacts of the fishery must be analyzed in the appropriate environmental assessment document, and NPFMC or NOAA Fisheries may be requested to consider regulations to mitigate adverse impacts.

Assessment of Population-Level Effects

In order to fulfill their oversight responsibilities under the MMPA, NOAA Fisheries and USFWS have developed appropriate survey methodologies to census the various species of marine mammals. The results of these surveys, and other factors that affect the status of each species, are published in an annual "Marine Mammal Stock Assessment" report that is available on the internet at:
http://www.nmfs.noaa.gov/prot_res/PR2/Stock_Assessment_Program/sars.html.

Some species are much more difficult to census accurately than others so there is a great deal of variation in the uncertainty of various population estimates. In addition, the huge expanses over which many species traverse and the remoteness of their habitats make surveys logistically difficult and expensive. For budgetary and logistical reasons, surveys of most species are not carried out every year and survey effort is prioritized for species of management concern. As a result, population estimates for some species may be outdated and trend information may not exist. While it is the intent of this chapter to assess the past effects of various events on the various populations of marine mammals, including fishery management actions, those efforts may be limited in quantitative detail by the availability of population trend information.

Some species are divided into separate stocks for management purposes based on genetic, morphological, behavioral, or home range information. Even though some individual animals may cross over from one stock to another, the following species accounts concentrate on the stocks that regularly spend at least part of the year in the project area.

Past and Present Effects on Marine Mammals

Direct Mortality from Intentional Take

Commercial harvests of marine mammals have occurred at various times and places, sometimes with devastating impacts on the populations of particular species. In some cases, such as the northern right whale, the species have not recovered to pre-exploitation population-levels even though commercial whaling was halted decades ago.

Marine mammals have been hunted by Alaska Natives for thousands of years and continue to be an important source of food, clothing, and material for a variety of uses. They also have an overriding cultural significance that goes far beyond their value as subsistence resources. Data on the harvest of marine mammals in subsistence hunts is collected by several entities, including the ADF&G and various Alaska Native organizations. In some cases, Alaska Native groups have entered into cooperative management agreements with NMFS, USFWS, and ADF&G to regulate subsistence takes.

Direct Mortality from Incidental Take in Fisheries

Some types of fisheries are much more likely to catch marine mammals incidentally than others. High seas driftnet fishing killed thousands of mammals before it was prohibited in 1991. Longline and pot fisheries very rarely catch marine mammals directly. NMFS requires all commercial fisheries in the U.S. EEZ to report the incidental take and injury of marine mammals that occur during their operations (50 CFR 229.6). In addition to self-reported records, which NMFS considers to be negatively biased and under representing actual take levels, certified observers are required in some fisheries to provide independent monitoring of incidental take as well as other fishery data. Marine mammal incidental take data from the North Pacific Groundfish Observer Program is included in each of the following species accounts.

Section 118 of the MMPA (50 CFR 229.2) requires all commercial fisheries to be placed into one of three categories, based on the frequency of incidental take (serious injuries and mortalities) relative to the value of potential biological removal (PBR) for each stock of marine mammal. PBR is defined as the maximum number of animals, not including natural mortalities, that may be removed from a stock while allowing that stock to reach or maintain its optimum sustainable population. In order to categorize each fishery, NMFS first looks at the level of incidental take from all fisheries that interact with a given marine mammal stock. If the combined take of all fisheries is less than or equal to 10 percent of PBR, each fishery in that combined total is assigned to Category III, the minimal impact category. If the combined take is greater than 10 percent of PBR, NMFS then looks at the individual fisheries to assign them to a category. Category I designates fisheries with frequent incidental take, defined as those with takes greater than or equal to 50 percent of PBR for a particular stock; Category II designates fisheries with occasional serious injuries and mortalities, defined as those with takes between one percent and 50 percent of PBR; Category III designates fisheries with a remote likelihood or no known serious injuries or mortalities, defined as those with takes less than or equal to one percent of PBR. Owners of vessels or gear engaging in Category I or II fisheries are required to register with NMFS to obtain a marine mammal authorization in order to lawfully take a marine mammal incidentally in their fishing operation (50 CFR 229.4). In Alaska, this registration process has been integrated into other state and federal permitting programs to reduce fees and paperwork. Owners of vessels or gear engaging in Category III fisheries are not required to register with NMFS for this purpose. Every year, NMFS reviews and revises its list of Category I, II, and III fisheries based on new information and publishes the list in the FR.

Under provisions of the MMPA, NMFS is required to establish take reduction teams with the purpose of developing take reduction plans to assist in the recovery or to prevent the depletion of strategic stocks that interact with Category I and II fisheries. A “strategic” stock is one which: 1) is listed as endangered or threatened under the ESA, 2) is declining and likely to be listed as threatened under the ESA, 3) is listed as depleted under the MMPA, or 4) has direct human-caused mortality which exceeds the stock’s PBR.

The immediate goal of a take reduction plan is to reduce, within six months of its implementation, the incidental serious injury or mortality of marine mammals from commercial fishing to levels less than PBR. The long-term goal is to reduce, within five years of its implementation, the incidental serious injury and mortality of marine mammals from commercial fishing operations to insignificant levels approaching a zero serious injury and mortality rate, taking into account the economics of the fishery, the availability of existing technology, and existing state or regional FMPs. Take reduction teams are to consist of a balance of representatives from the fishing industry, fishery management councils, state and federal resource management agencies, the scientific community, and conservation organizations. Fishers participating in Category I or II fisheries must comply with any applicable take reduction plan and may be required to carry an observer onboard during fishing operations.

In 2002, all of the MSA groundfish fisheries (trawl, longline, and pot gear in the BSAI and GOA) were listed as Category III fisheries (67 FR 2410). In addition, a number of state-managed salmon drift and set gillnet fisheries are listed in Category II, including those in Bristol Bay, Aleutian Islands, Alaska Peninsula, Kodiak, Cook Inlet, PWS, and southeast Alaska. NMFS has recently proposed reclassifying the Cook Inlet drift and set gillnet fisheries from Category II to Category III (68 FR 1414).

Indirect Effects through Entanglement

The following effects are classified as indirect because the impacts are removed in time and/or space from the initial action although in the analysis, these effects are considered together with the direct effect of incidental take. In some cases, individual marine mammals may be killed outright by the effect. In other cases, individuals are affected in ways that may decrease their chances of surviving natural phenomenon or reproducing successfully. These sub-lethal impacts may reduce their overall "fitness" as individuals and may have population-level implications if enough individuals are impacted.

Although some fisheries have no recorded incidental take of marine mammals, all of them probably contribute to the effects of entanglement in lost fishing gear. Evidence of entanglement comes from observations of animals trailing ropes, buoys, or nets or bearing scars from such gear. Sometimes stranded marine mammals also have evidence of entanglement but it may not be possible to ascertain whether the entanglement caused the injury or whether the corpse picked up gear as it floated around after death. Sometimes an animal is observed to become entangled in specific fishing gear, in which case an incidental take or minor injury may be recorded for that particular fishery, but many times the contributions of individual fisheries to the overall effects of entanglement are difficult to document and quantify.

The Marine Plastic Pollution Research and Control Act of 1987 (33 USC §§ 1901 *et seq.*), implements the provisions relating to garbage and plastics of MARPOL. These regulations apply to all vessels, regardless of flag, on the navigable waters of the U.S. and in the EEZ of the U.S. It applies to U.S. flag vessels wherever they are located. The discharge of plastics into the water is prohibited, including synthetic ropes, fishing nets, plastic bags, and biodegradable plastics.

Indirect Effects through Changes in Prey Availability

The availability of prey to marine mammals depends on a large number of factors and differs among species and seasons. Among these factors are oceanographic processes such as upwellings, thermal stratification, ice edges, fronts, gyres, and tidal currents that concentrate prey at particular times and places. Prey availability also depends on the abundance of competing predators and the ecology of prey species, including their natural rates of reproduction, seasonal migration, and movements within the water column. The relative contributions of factors that influence prey availability for particular species and areas are rarely known. Most critical is the lack of information on how events outside an animal's foraging range or in a different season may influence the availability of prey to animals in a particular place and time.

Marine mammal species differ greatly from one another in their prey requirements and feeding behaviors, leading to substantial differences in their responses to changes in the environment. For some species, such as the baleen whales, diets consist largely of planktonic crustaceans or small squid and have no overlap of prey with species that are targeted or taken as bycatch in the groundfish fisheries. For other species, notably Steller sea lions, there is a high degree of overlap between their preferred size and species of prey and the groundfish catch. Many other species are in between, perhaps feeding on the same species but smaller sizes of fish than what is typically taken in the fisheries. Although they may take a wide variety of prey species during the year, many species may depend on only one or a few prey species in a given area and season. In addition, the prey requirements and foraging capabilities of nursing females and subadult animals may be much more restricted than for non-breeding adults, with implications for reproductive success and survival.

The question of whether different types of commercial fisheries have had an effect on the availability of prey to marine mammals has been addressed by examining the degree of direct competition (harvest) of prey and by looking for potential indirect or cascading effects of the fisheries on the food web of the mammals. For marine mammals whose diets overlap to some extent with the target or bycatch species of the fisheries, fishery removals could potentially decrease the density of prey fields or cause changes in the distribution of prey such that the foraging success of the marine mammals is affected. If alternate prey is not available or is of poorer nutritional quality than the preferred species, or if the animal must spend more time and energy searching for prey, reproductive success and/or survival can be compromised. In the case of marine mammals that do not feed on fish or feed on different species than are taken in the fisheries, the removal of a large number of target fish from the ecosystem may alter the predator/prey dynamics and thus the abundance of another species that is eaten by marine mammals. The mechanisms and causal pathways for many potential food web effects are poorly documented because they are very difficult to study scientifically at sea (Loughlin *et al.* 1999).

Although reductions in the availability of forage fish to marine mammals have been attributed to both climatic cycles and commercial fisheries, a NRC study on the Bering Sea ecosystem (NRC 1996) concluded that both factors probably are significant. Regime shifts are major changes in atmospheric conditions and ocean climate that take place on multi-decade time scales and trigger community-level reorganizations of the marine biota (Anderson and Piatt 1999). Two cycles of warm and cold regimes have been documented in the GOA in the past 100 years, with the latest shift being from a cold regime to a warm regime in 1977. The consequences of this shift on fish and crustacean populations have been documented, including major improvements in groundfish recruitment and the collapse of some high-value forage species such as shrimp, capelin, and Pacific sand lance (Anderson and Piatt 1999). Directed fisheries on forage fish can deepen and prolong their natural low population cycles (Duffy 1983, Steele 1991), with potential effects on marine mammal foraging success. There is some evidence that another regime shift may have begun in 1998 with colder water temperatures and increases in certain forage populations (NPFMC 2002c), but the implications for marine mammals are still unclear. Climate change may also affect the dynamics of the ice pack, with serious consequences for the marine mammals associated with the ice pack, such as bowhead whales, the ice seals, and walrus.

Direct Effects through Disturbance by Fishing Vessels

The effects of disturbance caused by vessel traffic, fishing operations, engine noise, and sonar pulses on marine mammals are largely unknown. With regard to vessel traffic, many baleen and toothed whales appear tolerant, at least as suggested by their reactions at the surface. Observed behavior ranges from attraction to the vessel to course modification or maintenance of distance from the vessel. Dall's porpoise, Pacific white-sided dolphins, and even beaked whales have been observed adjacent to vessels for extended periods of time. Conversely, harbor porpoise tend to avoid vessels. However, a small number of fatal collisions with various vessels have been recorded in California and Alaska in the past decade and others likely go unreported or undetected (Angliss *et al.* 2001).

Reactions to some fishing gear, such as pelagic trawls, are poorly documented, although the rarity of incidental takes suggests either partitioning of foraging and fishing areas or avoidance. Given their distribution throughout the fishing grounds, at least some individuals may be expected to occasionally avoid contact with vessels or fishing gear, which would constitute a reaction to a disturbance. Assuming these instances occur, the effects are likely temporary. Sonar devices are used routinely during fishing activity as well as during vessel transit. The sounds produced by these devices may be audible to marine mammals and may thus constitute disturbance sources. Wintering humpback whales have been observed reacting to sonar pulses by moving away (Maybaum 1990, 1993), although few other cases of reaction have been documented.

Indirect Effects through Contamination by Oil Spills

For species such as the pinnipeds and sea otters that spend a substantial amount of time on the surface of the water or hauled out on shore, oil spills pose a significant environmental hazzard, even in small amounts. The toxicological effects of ingested oil, ranging from potential organ damage to weakening of the immune system, are poorly known for most species, especially in regard to chronic low doses. Sea otters are particularly susceptible to oil spills because they depend on their thick fur to protect them from cold water, rather than layers of fat, and oil destroys the insulative properties of their fur. Thousands of sea otters died over a large expanse of the GOA as a result of the EVOS in 1989 (Garshelis 1997, Garrot *et al.* 1993, DeGange *et al.* 1994). There is very little data on the mortality of marine mammals from the much smaller volumes of oil that are more typical of marine vessel spills, resulting from fuel transfer accidents and bilge operations.

3.8.1 Steller Sea Lion (*Eumetopias jubatus*)

Life History and Distribution

The Steller sea lion, also found in the literature as Steller's sea lion and northern sea lion, is a member of the order Pinnipedia and is in the same family (Otariidae) as northern fur seals. Sea lions are strongly dimorphic, meaning that mature males and females look very different. Females weigh up to 600 pounds (270 kg) and reach 7 ft (2.1 m) in length while males can reach 2000 pounds (900 kg) and reach 10.5 ft (3.2 m) in length (Burt and Grossenheider 1976). Steller sea lions have a highly polygynous mating system, with males defending territories to restrict access to females.

Pupping and breeding occur in rookeries on relatively remote islands, rocks, and reefs. Females generally return to the rookeries where they were born to mate and give birth (Alaska Sea Grant 1993, Calkins and Pitcher 1982, Loughlin *et al.* 1984). Males establish territories in May in anticipation of the females' arrival in late May through June (Pitcher and Calkins 1981). Viable births begin in late May and continue through early July; the sex ratio at birth is slightly in favor of males. Steller sea lions give birth to a single pup each year; twinning is rare. Females breed again about two weeks after giving birth. Copulation may occur in the water, but mostly occurs on land (Pitcher *et al.* 1998, Gentry 1970, Gisiner 1985). The mother nurses the pup during the day. She stays with her pup for the first week, then goes to sea on feeding trips. Pups generally are weaned before the next breeding season, but it is not unusual for a female to nurse her offspring for a year or more. Females reach sexual maturity between three and eight years of age and may breed into their early twenties. Females can have a pup every year but may skip years as they get older, or when nutritionally stressed. Males also reach sexual maturity at about the same ages but do not have the physical size or skill to obtain and keep a breeding territory until they are nine years of age or older. Males may return to the same territory for up to seven years, but most return for no more than three years (Gisiner 1985). During the breeding season, males may not eat for 1 to 2 months. The rigors of fighting to obtain and hold a territory and the physiological stress of the mating season reduces their life expectancy. Males rarely live beyond their mid-teens, while females may live as long as 30 years.

Although most often found within the continental shelf region, sea lions may be found in pelagic waters as well (Bonnell *et al.* 1983, Fiscus *et al.* 1976, Kajimura and Loughlin 1988, Kenyon and Rice 1961, Merrick and Loughlin 1997). Observations of Steller sea lions at sea suggest that large groups usually consist of females of all ages and subadult males; adult males sometimes occur in those groups but are usually found individually. On land, all ages and both sexes haul out in aggregations during the non-breeding season. Steller sea lions are not known to migrate, but they do disperse widely at times of the year other than the breeding season. For example, sea lion pups marked near Kodiak, Alaska, have been sighted in British Columbia, Canada (about 1,700 km distant) (Raum-Suryan *et al.* 2002). Generally, animals up to about 4 years of age tend to disperse farther than adults. As they approach breeding age, they have a propensity to stay in the general vicinity of the breeding islands, and, as a general rule, return to their island of birth to breed as adults.

Steller sea lions range along the NPO rim from northern Japan to California (Loughlin *et al.* 1984), with centers of abundance and distribution in the GOA and Aleutian Islands, respectively (Figure 3.8-1). The northernmost rookery in the Bering Sea is on Walrus Island near the Pribilof Islands and in the GOA on Seal Rocks just outside of PWS (Kenyon and Rice 1961).

Population assessment for Steller sea lions has been achieved primarily by aerial surveys and on-land pup counts. Historically, this included surveys of limited geographical scope in various portions of the species' range, in many cases conducted using different techniques, and occasionally during different times of year. Consequently, population trends for Steller sea lions from the 1970s and earlier, and over a large geographical area, must be reconstructed from a patchwork of regional surveys conducted over many years. Prior to 1997, only one population of Steller sea lions was recognized in Alaskan waters. Based largely on differences in genetics, morphology, and population trends, this single population was split into two distinct population segments (DPSs) (Bickham *et al.* 1996, Loughlin 1997, 62 FR 30772). The term DPS is used in reference to the status under ESA (16 USC 1532). NOAA Fisheries, under the MMPA, uses the term "stock" when referring to a population or population segment, however for this discussion the term population is used when referring to Steller sea lions. The western DPS (western population) of Steller sea lions occurs from 144°W (approximately at Cape Suckling, just east of PWS) westward to Russia and Japan, including the Bering Sea. The eastern DPS (eastern population) of Steller sea lions occurs from southeast Alaska southward to California. Recent evidence suggests that the western population consists of two distinct sub-populations: the central population, from 144°W through the Aleutian Islands and the Commander Islands (Russia); and the Asian population, which includes all animals that breed on the Kamchatka Peninsula, Kuril Islands, and the Sea of Okhotsk (J. Bickham, Texas A&M University, report to the Steller sea lion recovery team).

<u>Western Distinct Population Segment of Steller Sea Lions</u>

Aerial surveys conducted from 1953 through 1960 resulted in combined counts of 170,000 to 180,000 Steller sea lions in what we now define as the western population in Alaska (Mathisen 1959, Kenyon and Rice 1961). Surveys during 1974 through 1980 suggested an equivocal increase to about 185,000, based on maximal counts at sites over the same area, as summarized by Loughlin *et al.* (1984). It was concurrent with the advent of more systematic aerial surveys that population declines were first observed. Declines of at least 50 percent were documented from 1957 to 1977 in the eastern Aleutian Islands, the center of what now is the western population (Braham *et al.*1980). Merrick *et al.* (1987) estimated a population decline of about 50 percent from the late 1950s to 1985 over a much larger geographical area, the central GOA through the central Aleutian Islands, based on a patchwork of regional counts and surveys (Figure 3.8-2). The population in the GOA and Aleutian Islands declined by an additional 50 percent from 1985 to 1989, resulting in an overall decline of about 70 percent from 1960 to 1989 (Loughlin *et al.* 1992).

The decline of the western population has been apparent in all regions, although not at the same rate. The decline was first observed in the eastern Aleutian Islands (Braham *et al.* 1980). During subsequent years the decline was noted in adjacent regions in the Aleutian Islands and GOA (Merrick *et al.* 1987). In the eastern Aleutian Islands, the rate of decline decreased and by 1989 or 1990 the population there appeared to stabilize, but at very low levels. Since 1975 throughout the entire range of the western population there has been a steady rate of decline of at least 6 percent a year, with an additional drop of about 8.7 percent per year during the late 1980s when the population from the Kenai Peninsula to Kiska Island in the central Aleutian Islands declined at about 15.6 percent per year (York *et al.* 1996). Other regions have demonstrated short periods of stability within a general declining trend. With the exception of the differentiation between the eastern and western populations, however, these regional boundaries are not based on ecological or other biological parameters, and differences in regional trends should be interpreted with caution.

Much of the population trend analyses during recent years has focused on trend sites as designated by the Steller Sea Lion Recovery Team (NMFS 1992, NMFS 1995b). Trend sites are those rookeries and haul-out sites surveyed consistently from the mid 1980s to the present, thus allowing analysis of population trends on a decadal scale. Trend sites include about 75 percent of animals observed in recent surveys (Strick *et al.* 1997, Sease *et al.* 1999, Sease and Loughlin 1999, Sease *et al.* 2001, Sease and Gudmundson 2002). During the 1990s, the average annual rate of decline was consistently around 5 percent (Strick *et al.* 1997, Sease *et al.* 1999, Sease and Loughlin 1999, Sease *et al.* 2001) (Figure 3.8-3). Recent surveys at 84 trend sites have shown the first region-wide increase in the last two decades. Between 2000 and 2002, non-pup abundance increased by 5.5 percent (Sease 2002, Sease and Gudmundson 2002). A similar trend was documented within the Kenai-to-Kiska subareas , an index count area of 70 sites between the Kenai Peninsula and Kiska Island, near the western end of the Aleutian Island which showed an increase of 4.8 percent from 2000 to 2002. However, the long-term trend was still a decline of 3.1 percent per year from 1991 to 2002 and an overall decrease of 26 percent from 1991 to 2002 (Loughlin and York 2000, Sease 2002, Sease and Gudmundson 2002).

Although numbers of non-pups increased in five of the six western population sub-regions from 2000 to 2002, these changes involve only a few hundred animals. The western Aleutian Islands region continued to decline by 24 percent from 2000 to 2002 following a 44 percent decline from 1998 to 2000. The overall decline in the western Aleutian Islands was 75 percent from 1991 to 2002 (Sease and Gudmundson 2002).

In most years, pups within the western population in Alaska have been counted only at selected rookeries and on an alternating schedule to minimize potential cumulative effects of disturbance. Range-wide survey efforts included pup counts at virtually all western population rookeries in Alaska in 1998, and all except the Near Islands in the western Aleutian Islands in 1994 (Strick *et al.* 1997, Sease and Loughlin 1999). The composite pup count for 2001 and 2002 for the western population, which includes counts from 24 rookeries in 2002 and seven in 2001, showed continuing decline in pup production. The area with the longest series of region-wide pup counts is the Kenai-to Kiska index area. In this area, 2002 numbers were down 7.8 percent from 1998, 24 percent from 1994, and 42.4 percent from 1990 to 1991. Pup counts increased in only one region (5.5 percent in the western GOA) from 1998 to 2002, but declined in the five other regions. The western Aleutian Islands experienced the largest decline in pup abundance (39 percent) from 1998 to 2002 (Sease and Gudmundson 2002).

The most recent comprehensive census of the U.S. portion of the western population of Steller sea lions was conducted in 1998 and 1999. Combining pup counts (9,373) and non-pup counts (26,658) with an estimate for unsurveyed sites (757) resulted in a minimum abundance estimate of 38,788 sea lions for the U.S. portion of the western population in 1998 (Angliss and Lodge 2002). The June 2002 survey of all surveyed sites for the western population resulted in a total count of 26,602 non-pup sea lions. Combining pup counts from 2001 (3,927) and 2002 (5,650) and non-pup counts from 2002 resulted in a minimum abundance of 36,179 sea lions for the western population in 2002 (Sease and Gundmundson 2002). These estimates are considered minimums because they do not account for animals that may have been at sea during the counts.

For the Russian and Japanese portion of the western population of Steller sea lions, recent and historic counts in the Russian Federation indicate that the present number of animals is about one-third of historic levels (NMFS 1992). In some instances, the decrease in numbers has been accompanied by complete disappearance of rookeries (Perlov 1991). Numbers of adults and juvenile sea lions at major rookeries and haulouts in the Kuril Islands declined 74 percent, from 14,076 in 1969 to 3,615 in 1989 (Merrick *et al.* 1990). Most of the decline occurred between 1969 and 1974. The numbers since 1974 appear to have remained relatively stable. Pup numbers have declined 60 percent, from 3,673 in 1963 to 1,476 in 1989. Based on 1989 counts, Burkanov *et al.* (1991) estimated that the total number of sea lions, including those on haulouts, rookeries and those observed swimming in the water near the site at the time of the survey, along the Kamchatka Peninsula and Commander Island was between 3,500 and 3,800. Estimates for this region between 1982 and1985 were 1.6 to 3.5 times larger. This decline is similar to what has occurred in the U.S. portion of the western population in the Bering Sea, and is thought likely to continue (Perlov 1991). There are about 2,000 sea lions on a few small islands in the Sea of Okhotsh, where numbers are reduced from previous levels, but stable (Perlov 1991).

Eastern Distinct Population Segment of Steller Sea Lions

The earliest abundance estimate for what is now known as the eastern population of Steller sea lions is derived from surveys conducted in southeast Alaska in 1996 (10,907 non-pups and 3,714 pups for a total of 14,621 sea lions), British Columbia in 1994 (8,091 non-pups and 1,186 pups for a total of 9,277 sea lions), and the combined coasts of Washington, Oregon, and California in 1996 (5,464 non-pups and 1,091 pups for a total of 6,555 sea lions). The total of these 1994 to 1996 counts was 30,453 sea lions in the eastern population, which is considered a minimum estimate because there was no correction for animals that may have been at sea during the surveys (Angliss *et al.* 2001). In the southeast Alaska part of the range alone, surveys conducted in 1998 and 2000 yielded a minimum estimate of 12,417 non-pups and 4,257 pups for a total of 16,674 sea lions.

Loughlin *et al.* (1992) described southeast Alaska as the only region of Alaska in which the Steller sea lion population appeared to be stable in 1989. Based on a series of counts at index, or "trend", sites, the numbers of non-pup sea lions (adults and juveniles combined) in southeast Alaska increased by an average of 3.5 percent to 4.0 percent per year from 1985 to 1989 for an overall increase of about 16 percent. Calkins *et al.* (1999) estimated that the Steller sea lion population in southeast Alaska increased by an average of 5.9 percent per year from 1979 to 1997, based on pup counts at the three rookeries in the region. The increase was lower than the average over the longer time period. From 1989 to 1997, pup numbers increased by only 1.7 percent and counts of non-pups at 12 index sites were stable (average change of +0.5 percent per year). The Steller Sea Lion Recovery Team employed a different set of index sites for monitoring population status (NMFS 1992, NMFS 1995b). Counts of non-pup sea lions at these three rookeries and ten haulout trend sites showed an overall increase of 29.3 percent from 1990 to 2000, or an average annual increase of 1.9 percent (Sease *et al.* 2001). Pup counts in 2002 suggest that numbers of pups in southeast Alaska increased by about 11 percent from 1998 to 2002, consistent with the average rate of about 3 percent per year over the last decade (Sease and Gudmundson 2002). Despite differences in individual index sites or model type (e.g., based on counts of pups versus non-pups), the conclusion is that numbers of Steller sea lions in southeast Alaska are stable or increasing.

Steller sea lions in southeast Alaska are not an isolated population, as demonstrated by genetic data and by the movement of branded and tagged animals from southeast Alaska to British Columbia and Washington (Raum-Suryan *et al.* 2002). The number of non-pup sea lions in British Columbia is similar to southeast Alaska, and increased by about 2.5 percent per year during the last decade (Figure 3.8-4). Pup numbers in British Columbia have increased by about 1.5 percent per year during the same time (personal communication from P. Olesiuk, Pacific Biological Laboratory, Nanaimo, British Columbia). Counts of Steller sea lions in Oregon and northern California have been stable during recent decades at about a third as many animals as in either British Columbia or southeast Alaska. Counts of non-pups and pups in central and southern California have been low and decreasing at about 4.5 percent to 5.0 percent per year since 1982 or as much as 10 percent per year since 1990 (NMFS 1995b, Calkins *et al.* 1999, Ferrero *et al.* 2000, Angliss *et al.* 2001). Despite the observed declines in southern and central California, the eastern population as a whole is stable or increasing.

Trophic Interactions

In the BSAI and GOA, the Steller sea lion diet consists of a variety of schooling fishes (e.g., pollock, Atka mackerel, Pacific cod, flatfish, sculpin, capelin, Pacific sand lance, rockfish, Pacific herring, and salmon), as well as cephalopods, such as octopus and squid (Calkins and Goodwin 1988, Lowry *et al.* 1982, Merrick and Calkins 1995, Perez 1990). An analysis of 1990 to 1998 trends in prey consumption across the western population showed pollock and Atka mackerel as the two dominant prey species, followed by Pacific salmon and Pacific cod (Sinclair and Zeppelin 2002). Other primary prey species consistently occurring in Steller sea lion scats at frequencies > 5 percent include arrowtooth flounder, Pacific herring, Pacific sand lance, Irish lord, squid, and octopus (Sinclair and Zeppelin 2002). Steller sea lion prey varies in adult body size. Pollock and Atka mackerel, for instance, range in body length from approximately 10 to 70 cm. (Zeppelin *et al.* in press). The most recent diet study of the western population (Sinclair and Zeppelin 2002) indicates that prey remains in scat are primarily from late stage juvenile to adult size fish. Seasonal and regional patterns in prey consumption by western population Steller sea lions indicate that they target prey which are densely schooled in spawning aggregations nearshore, over or near the continental shelf, or along oceanographic boundaries (Sinclair and Zeppelin 2002).

Merrick *et al.* (1997) documented Steller sea lion consumption from scat samples throughout their range and identified seven prey categories in the GOA: 66.5 percent are gadids (pollock, Pacific cod, Pacific hake, and unidentified gadids), 20.3 percent are Pacific salmon, 6.1 percent are small schooling fish, 3.9 percent are flatfish, 2.9 percent are squid or octopus, and 0.3 percent are Atka mackerel. Merrick and Calkins (1996) determined 70 percent of the stomachs collected from animals in the GOA during the 1970s and 1980s also contained gadids.

Recent analyses of fecal samples collected on Steller sea lion haulouts and rookeries suggest that Atka mackerel is particularly important for Steller sea lions in the central and western Aleutian Islands. Over 70 percent of the animals' summer diet in this area is Atka mackerel. Pollock represents over 60 percent of the diet in the central GOA, 29 percent in the western GOA and eastern Aleutian Islands, and over 35 percent in parts of the central Aleutian Islands (Merrick and Calkins 1995). Small pollock (less than 20 cm) appear to be more commonly eaten by juvenile sea lions than older animals (Merrick and Calkins 1995). Pollock are also a major prey species in southeast Alaska where the population has showed an increase over the last ten years (Winship and Trites 2002).

The most recent analysis of Steller sea lion diet compares trends in prey species consumption among seasons and areas with different rates of sea lion decline (Sinclair and Zeppelin 2002, Winship and Trites 2002). Regions of diet similarity closely correspond to the Steller sea lion metapopulations defined by York *et al.* (1996), suggesting that diet differences and population trends of Steller sea lions are linked. Overall, where population trends are most positive, diet diversity is highest but more supporting data is needed to draw firm conclusions. Recent data from more intensive sampling at rookeries and haulouts suggest sea lions have a much more diverse diet than previously thought (Wynne, unpublished). Regional diet patterns generally reflect regional foraging strategies learned at or near the natal rookery site, with sea lions concentrating on seasonally dense prey patches characteristic of that area (Sinclair and Zeppelin 2002).

Steller sea lion foraging distribution is inferred from at-sea sightings or observations of presumed foraging behavior (Fiscus and Baines 1966, Kajimura and Loughlin 1988, NMML unpublished data[a] from the Platform of Opportunity Program [POP]), records of incidental take in fisheries (Perez and Loughlin 1991), and satellite telemetry studies (Merrick *et al.* 1994, Merrick and Loughlin 1997). Three foraging areas were designated as critical habitat for Steller sea lions based on observations and incidental takes in the vicinity of Seguam Pass, the southeastern Bering Sea, and Shelikof Strait (Loughlin and Nelson 1986, Perez and Loughlin 1991).

The value of a given area for foraging sea lions depends not only on the nutritive quality of the prey available but also on the energetic effort required to obtain that prey. Foraging efficiency, as a function of net energy gain, thus depends in part on how far sea lions must travel, how deep they must dive, and how much time they must spend to catch prey. These parameters have been and continue to be studied with satellite telemetry techniques. The NMFS Alaska Ecosystem program and the ADF&G Steller sea lion research program collaborated to produce a "white paper" on the use of satellite telemetry to study Steller sea lion movements and foraging behavior (ADF&G and NMFS 2001). The limitations of this data and its use in establishing protective measures for sea lions is described in the Steller sea lion protection measures FEIS and the associated BiOp (NMFS 2001b and NMFS 2001c). NOAA Fisheries has completed a supplement to the 2001 BiOp which presents recent telemetry data, how that scientific information was interpreted with relation to foraging needs of Steller sea lions, and its relevance to the efficacy of sea lion protection measures (NMFS 2003). These telemetry studies suggest that foraging distributions vary by individual, size, age, season, site, and reproductive status (Merrick and Loughlin 1997, ADF&G and NMFS 2001, Loughlin *et al.* 2003).

Compared to other pinnipeds, Steller sea lions tend to make relatively shallow dives, with few dives recorded to depths greater than 250 m. Foraging patterns of adult females differ during summer months when females are with pups versus winter periods when considerable individual variation has been observed. Trip duration (the period between haulouts) for females with young pups in summer is approximately 18 to 20 hours. Dives are typically shallow (mean = 21 m), of short duration (mean = 1.4 min), and frequent (mean = 13/h). Trip length averages 17 km, and sea lions dive approximately 4.7 hours per day. In winter, females with young of the year (5 to 10 months of age) have trips averaging almost one day in duration while females with yearlings (17 to 22 months of age) had trips averaging 2.3 days (Loughlin *et al.* 2003). During winter, mean trip length is about 130 km, and dives total about 5.3 hours per day (Merrick and Loughlin 1997). In winter, yearling sea lions' foraging trips average 30 km in distance and 15 hours in duration, with less effort devoted to diving than adult females during their trips (mean of 1.9 hours per day). Estimated home ranges are 320 km^2 for adult females in summer, about 47,600 km^2 (with large variation) for adult females in winter, and 9,200 km^2 for yearlings in winter (Merrick and Loughlin 1997).

Recent telemetry studies have examined the movement patterns of immature sea lions (6 - 22 months of age) whose survival rate is considered an important component in the Steller sea lion decline (Loughlin *et al.* 2003). Young-of-the-year sea lions (6 to 12 months of age) had dives that were more brief in duration and more shallow than yearlings (13 to 22 months of age). The length of trips taken by sea lions less than 10 months of age was much shorter than trips taken by older juveniles (means = 7.0 km and 24.6 km respectively). The length of foraging trips, dive characteristics, and depth of dives, began to increase substantially after 9 months of age, corresponding with the presumed age of weaning (Loughlin *et al.* 2003). This study also compared the diving characteristics of sea lions from Washington with those from Alaska and found that the Washington animals spent more time diving and dove deeper than Alaska sea lions. These differences were attributed to localized differences in where their prey are concentrated (Loughlin *et al.* 2003). The recent telemetry data suggests that the areas of highest use are within 0 to 10 nm of rookeries and haulouts. However, both older juveniles and adult females may utilize the 10 to 20 nm zone of critical habitat to a greater extent in the winter. NOAA Fisheries concluded that the 0 to 10 nm zone was of "high" concern from potential overlap with fisheries, the 10 to 20 nm zone was "low to moderate", and beyond 20 nm was of "low" concern (NMFS 2003).

A brief review of predation on Steller sea lions by killer whales was presented in the 2000 BSAI and GOA FMP groundfish BiOp (NMFS 2000a).

Based on stomach contents of six stranded killer whales and feeding habit studies in PWS and British Columbia, sea lions were estimated to comprise 5 to 20 percent of transient killer whale diet in these areas (Matkin *et al.* 2001). In a study dedicated to tracking killer whales in PWS between 1984 and 1996, of the 31 documented marine mammal kills by transient killer whales, none were Steller sea lions (Saulitas *et al.* 2000). In the northern GOA, only 9 of the 49 known or suspected transient killer whales in the area have been observed to prey on or harass sea lions (Matkin *et al.* 2003). This may indicate that there is some predatory specialization among transient killer whales, with only a portion of transient killer whales attempting to capture sea lions (Matkin *et al.* 2003). Based on surveys of researchers, fishermen, tour boat operators and others, killer whale predation on sea lions may occur more frequently in the Aleutian Islands compared to other parts of Alaska (Barrett-Lennard *et al.* 1995).

The decline of the western population of Steller sea lions has prompted researchers to explore whether killer whale predation has played a major or minor role in the decline. Estimates vary in how many transient killer whales regularly hunt in the BSAI/GOA and how many sea lions they might eat. According to NOAA Fisheries latest marine mammal stock assessment (Angliss and Lodge 2002), preliminary photographic and genetic data indicate that there are approximately 86 transient killer whales in the range of the western population of Steller sea lions (PWS, GOA, and western Alaska). Matkin et al. (2001) give a conservative estimate of 125 to 175 transients in the same area, although they acknowledge that there has been little photographic research conducted in the western Aleutians. These authors calculate a range of predation rates on sea lions and conclude that killer whale predation was insufficient to cause the historical decline of sea lions but may be an important factor in limiting their recovery (Matkin *et al.* 2001, Matkin *et al.* 2003).

In contrast, a recent paper estimates that there are many more killer whales than previously believed, including at least 272 transients in the Aleutian archipelago alone, and that killer whale predation could be more than ten times the level necessary to cause the historic Steller sea lion population decline (Springer *et al.* 2003). According to this top-down hypothesis, killer whales may have been forced to eat more pinnipeds and sea otters after their preferred prey, great whales, were decimated by post-World War II industrial whaling. Although additional research is needed to corroborate their population estimates and dietary assumptions, these authors conclude that killer whale predation may be responsible for the population declines not only of Steller sea lions, but of harbor seals, northern fur seals, and sea otters in the Aleutians (Springer *et al.* 2003).

One complication for all top-down hypotheses that seek to explain the decline of the western population of Steller sea lions is the need to compare and reconcile the proposed mechanisms with the increasing population trend of the eastern population of Steller sea lions. If increased killer whale predation (or any other top-down mechanism) has contributed to a massive collapse of the western population, what is the mechanism that prevented the same thing from happening with the smaller eastern population of Steller sea lions? There are many transient killer whales in the range of the eastern population of Steller sea lions (219 transients, Angliss and Lodge 2002) and they appear to make up a much higher percentage of all killer whales (35 percent) than in western Alaska waters (7 to 12 percent) (Matkin *et al.* 2001, Springer *et al.* 2003). It is currently not known whether western Alaska transient killer whales are taking a much higher percentage of sea lions in their diet than whales in the eastern portion of their range. Unfortunately, data on transient killer whale diet is very limited and difficult to obtain. Therefore, comparisons among different geographic locations are problematic. Additional research on population size and feeding behavior is needed to determine the contribution of killer whale predation to the decline and recovery of Steller sea lion populations.

Attacks by great white sharks have been documented on sea lions at the southern end of their range in California (Ainley *et al.* 1985). Though Alaska waters are north of the normal range of white sharks, sleeper sharks (*Somniosus pacificus*) range throughout the GOA and Bering Sea, and small marine mammals have been documented in sleeper shark stomach contents (Yang and Page 1999). However, no remains of Steller sea lions were found in 13 sleeper shark stomachs collected in the GOA between June and August 1996 in areas near active sea lion rookeries and haulout sites (Yang and Page 1999). In a recent study of sleeper sharks, a total of 198 sleeper shark stomach contents were analyzed from sharks taken near rookeries, and preliminary analysis found no direct evidence of sea lion parts (Hulbert *et al.* 2002).

Management Overview

Steller sea lions are under the management jurisdiction of NOAA Fisheries, Protected Resource Division, as established by the MMPA of 1972. In November 1990, NOAA Fisheries listed Steller sea lions as "threatened" range-wide under the U.S. ESA (55 FR 49204). In 1997, two populations were formally recognized (Bickham *et al.* 1996, Loughlin 1997). The western population, which occurs from 144°W (approximately at Cape Suckling) westward to Russia and Japan, was listed as "endangered" in June 1997 (62 FR 24345). The eastern population, which occurs from southeast Alaska southward to California, remains classified as threatened. Aquatic critical habitat for the western population of the Steller sea lion was designated in 1993 (50 CFR 226.202) and consists of the areas within 20 nm (37 km) of designated rookeries and haulouts and key foraging areas in the Bogoslof District, Seguam Pass, and Shelikof Strait. Designated aquatic critical habitat for the eastern population of the Steller sea lion consists of the areas within 3,000 ft (0.9 km) of designated rookeries and haulouts. Terrestrial critical habitat for both populations consists of areas landward within 3,000 ft (0.9 km) of designated rookeries and haulouts.

Critical habitat designation does not automatically preclude particular activities, such as commercial fishing, but it defines areas that are important to the continued survival and recovery of ESA-listed species. The ESA (Section 7) requires the responsible agency, in this case NOAA Fisheries PRD, to assess whether proposed activities in the range of ESA-listed species would jeopardize the continued existence or recovery of the species or adversely modify its critical habitat. These assessments are made for all federally funded or managed activities that might impact the listed species and the resulting document is called a BiOp. NOAA Fisheries has issued many BiOps regarding the BSAI and GOA groundfish fisheries since 1991. The history of these plans and a summary of their respective findings is detailed in Appendix B and Appendix F-4 of this document.

Under the direction of NPFMC, NOAA Fisheries Office of Sustainable Fisheries has implemented many management measures to protect Steller sea lions and their foraging habitat. These measures are described in Appendix F-4 of this document. The following are examples of the types of management measures that have been taken but are not meant to be comprehensive.

In 1990, coincident with the ESA listing, NOAA Fisheries: 1) prohibited entry within 3 nm of listed Steller sea lion rookeries west of 150°W; 2) prohibited shooting at or near Steller sea lions; and 3) reduced the allowable level of take incidental to commercial fisheries in Alaskan waters (50 CFR 227.12) (Fritz *et al.* 1995). The 1991 to 1995 period saw broad implementation of fishery area and time closures to protect Steller sea lions. Measures taken in this time period to protect Steller sea lions were the first pervasive restrictions on the operations of the fishing fleet. Trawling was prohibited in the BSAI within 10 nm of 37 Steller sea lion rookeries year-round and within 20 nm of five rookeries during the pollock A season (January 20 to April 15). Similar closures were instituted in the GOA. To reduce competition for prey, the pollock TAC was spread over three areas, and limits were placed on the amount of excess pollock that could be taken in a quarter. These groundfish fishery management measures were designed to spread the harvests out over time and space to avoid potential localized depletion of prey for sea lions, and to greatly reduce the amount of harvest from areas designated as critical habitat for Steller sea lions. Additional rookeries and haulout areas were closed to certain types of fishing and the entire Bogoslof and Aleutian Islands management areas were closed to pollock fishing. In 1998, the Atka mackerel fishery in the Aleutian Islands was modified to restrict removals from inside critical habitat, seasonal apportionments were established, and the Aleutian

Islands were closed to pollock trawling. In June 1999, the NPFMC developed a set of measures to protect Steller sea lions and avoid jeopardy and adverse modification under the ESA and implemented these measures. The measures were subsequently challenged in court and were revised. The final set of measures was accepted by the courts and implemented for the following season.

Groundfish fisheries for pollock, Pacific cod and Atka mackerel in the BSAI and GOA presently operate under a suite of restrictions on where, when, and how fish can be taken. Many of these restrictions were imposed to protect Steller sea lions. The most recent BiOp was issued in October 2001 (NMFS 2001c), with a supplement to the BiOp published in June 2003 (NMFS 2003). In conjunction with that BiOp, a series of Steller sea lion protection measures were developed by NPFMC to protect the Steller sea lion from effects of the groundfish fisheries. These protection measures were analyzed in a separate EIS (NMFS 2001b). The NPFMC adopted a preferred alternative and the Steller sea lion protective measures were implemented by emergency rule in January, 2002 (67 FR 956).

Steller sea lions prey on a variety of species and sizes of fish, some of which, such as members of the families of Osmeridae (smelt), Myctophidae (lanternfish) and Clupeidae (Pacific herring), are considered "forage fish" and are not targeted by the groundfish fisheries. Forage fish are thought to be important for certain individuals (i.e., juvenile sea lions) at particular times and places. As part of their efforts to protect the food supplies of sea lions and the ecosystem needs of other species, NPFMC adopted Amendment 36 to the BSAI FMP and Amendment 39 to the GOA FMP in April 1997 to prevent the development of commercial fisheries for forage fish. NOAA Fisheries published the final rule implementing the regulations on March 17, 1998 (63 FR 13009).

Under the 1994 reauthorization of the MMPA, direct human-related mortality is monitored using a formula for the PBR to calculate the maximum number of individuals that can theoretically be taken without adversely affecting the population. Values for PBR have been calculated for both populations of Steller sea lions in Alaska based on the latest minimum population estimates. For the western population, PBR is 208 Steller sea lions per year. For the eastern population, PBR is 1,396 Steller sea lions per year (Angliss and Lodge 2002). These calculations take into account the different status of the populations under the ESA. Any population that is listed under the ESA is automatically considered to be a depleted and strategic stock under the MMPA.

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Little information is available on the fluctuations of Steller sea lion population prior to the 1960s, but it is suspected that decreases in population numbers were likely due to human exploitation (NRC 1996). Commercial harvest of sea lions for hides and meat occurred prior to 1900 and likely depleted some local populations. Over a nine year period, 1963 to 1972, more than 45,000 Steller sea lion pups were taken for commercial purposes (Merrick *et al.* 1987). It is likely that historic commercial harvests also have had residual effects on the present day population-levels of Steller sea lions in certain areas. However, a drastic decline in Steller sea lion numbers has still occurred in some North Pacific regions since commercial hunting was prohibited in 1972 by the MMPA.

The Steller sea lion has been harvested for subsistence purposes throughout history by the indigenous people of the Bering Sea, Aleutian Islands, and GOA regions. Current harvest is primarily in communities within the range of the western population. The eastern population is subject to an average of only two Steller sea lions taken per year from southeast Alaska (1992 through 1997) (Angliss and Lodge 2002). Of those sea lions taken from the western population, most are harvested in the Pribilof Islands. Subsistence take of Steller sea lions during the 1993 to 1995 period was estimated to average 412 animals annually (Angliss and Lodge 2002). Estimates of the total number of Steller sea lions taken (harvested plus struck and lost) declined over the six year period from 1992 to 1998 from 549 to 171 per year (Angliss and Lodge 2002), with an overall mean annual take of 329 sea lions for the entire period. In 2001, subsistence harvest of Steller sea lions was estimated to be 198 individuals (Wolfe *et al.* 2002). This is very close to the calculated value of PBR of 208 for this population (Angliss and Lodge 2002).

Based on a published life table and the current rate of decline, Loughlin and York (2000) estimate the total number of mortalities of non-pup Steller sea lions in 2000 was about 6,425 animals; of those, 4,710 (73 percent) were mortalities that would have occurred if the population were stable, and 1,715 (27 percent) were additional mortalities that fueled the decline. Loughlin and York (2000) classified 438 anthropogenic mortalities and 779 anthropogenic plus some predation mortalities as "mortality above replacement"; this accounted for 25 percent and 45 percent of the estimated total level of "mortality above replacement." The remaining mortality (75 percent and 55 percent, respectively) was not attributed to a specific cause and may be the result of nutritional stress.

Direct Mortality from Incidental Take in External Fisheries

It was not until after the 1950s that large numbers of Steller sea lions were taken in the commercial fisheries in the Alaska region (Alverson 1992). The take of Steller sea lions was substantial after this time with over 20,000 animals believed to have been incidentally killed in the foreign and JV groundfish fisheries from 1966 to 1988, although data from this period is not complete (Perez and Loughlin 1991). Based on telemetry data indicating that sea lions from the western population rarely leave the waters of the U.S. EEZ and on the minimal amount of international net fisheries in nearby waters, NOAA Fisheries has concluded that the current amount of sea lion incidental take from international fisheries is likely to be insignificant (Angliss and Lodge 2002).

Steller sea lions are incidentally taken by commercial fisheries other than groundfish fisheries, including some state-managed nearshore salmon gillnet fisheries and halibut longline fisheries. Based on observer data from 1990 to 1991, an estimated 14.5 sea lions were incidentally taken each year in the PWS drift gillnet fisheries (Wynne *et al.* 1992). Very few state-managed fisheries have been monitored with independent observers but fisherman are required to report incidental takes of all marine mammals. Based on incomplete records of self-reported salmon and longline fisheries, the minimum estimated average take is 5.4 sea lions per year. This is considered to be a minimum estimate because self-reported take data is considered unreliable and negatively biased (Wynne *et al.* 1992).

Direct Mortality from Incidental Take in Groundfish Fisheries

NOAA Fisheries observers monitored incidental take in the BSAI and GOA groundfish trawl, longline, and pot fisheries during 1990-2000. Steller sea lions were observed to be taken in the BSAI and GOA trawl fisheries and in the GOA longline fisheries. No incidental takes were observed in the pot fisheries or in the BSAI longline fishery (Angliss and Lodge 2002). In the BSAI groundfish trawl fisheries, incidental take has declined from about 20 per year in the early 1990s to an average of 7.8 sea lions per year from 1996-2000. Sea lion takes occur less often in the GOA, with an average of 0.6 animals taken per year in the trawl fishery and 1.2 per year in the longline fishery (1996-2000) (Angliss and Lodge 2002). The combined incidental take from BSAI and GOA groundfish fisheries is thus 9.4 sea lions per year based on observer data from 1996-2000.

Direct Mortality from Illegal Shooting

Intentional shooting of Steller sea lions, other than in subsistence hunts, became illegal after the species was listed as threatened under the ESA in 1990. It is thought that shooting used to be a significant source of mortality prior to that time. It is possible that intentional shooting could have contributed to the steep decline in the late 1980s but this is largely speculative. NOAA Fisheries Alaska Enforcement Division has successfully prosecuted two cases of illegal shooting involving four sea lions from the eastern population (Angliss *et al.* 2001). It is not known whether, and to what extent, illegal shooting continues in either population.

Indirect Effects through Changes in Prey Availability

Key prey species of Steller sea lions include species that are targeted or taken as bycatch by the BSAI and GOA groundfish fisheries and parallel fisheries in state waters. This was also true for past foreign and JV groundfish fisheries, and there is partial overlap with other state-managed fisheries. NOAA Fisheries issued a number of BiOps since 1991 that analyzed the key issue of whether the groundfish fisheries were contributing to the decline of sea lion populations or causing adverse impacts to their critical habitat. The NMFS 2001 EIS and BiOp (NMFS 2001b and 2001c) explores this subject indepth.

Although the factors and mechanisms for the decline of the western population of Steller sea lions have been, and continue to be, the subject of intensive research, it is generally thought that the decline is due to a combination of nutritional stress from climate-induced or fisheries-related declines in prey abundance or availability (bottom-up hypotheses), or resulting from human-related mortality and predation (top-down hypotheses) (NRC 1996, NMFS 2001b and 2001c, NRC 2001). The causes of the decline of the western population of Steller sea lion are not clearly understood, and experts agree that these causes have probably changed over time (DeMaster *et al.* 2001, Loughlin and York 2000). Reasons for the steep decline in the 1980s are thought to be related to different factors than those resulting in the more gradual declines during the 1990s (NRC 2001). The marked change in the rate and spatial extent of the decline over the past decade suggests that factors that contributed most strongly to the more rapid declines prior to the 1990s may not be the most significant factors operating today (Bowen *et al.* 2001). In addition to the direct taking of animals through commercial and subsistence harvests and interactions with fisheries, evidence from the 1970s and 1980s supports that sea lions were nutritionally stressed which, resulted in reductions in recruitment and reproductive rates in the first phase of the decline (DeMaster *et. al.* 2001). Hypotheses to explain the second phase or continued decline of the western population of Steller sea lions include potential nutritional stress due to competition with fisheries for prey and/or changes in the ocean environment due to climate change and an increase in the natural predation of Steller sea lions by sharks and killer whales. However, direct evidence for the nutritional stress hypothesis in the second phase of the decline is lacking (DeMaster *et al.* 2001).

It is believed that some of these factors such as nutritional stress may have acted most strongly against juveniles between the time they are weaned and when they are grown to adult size and foraging capability. Adult females may also be negatively affected by these factors because of the physiological stress and limited geographic mobility when caring for pups. Hence, mitigation efforts have focused on protecting the integrity of food supplies near rookeries and haulouts. It is important to realize that the key issue for the survival and reproductive success of sea lions is not the total amount of fish that are present, but how available they are to foraging sea lions. Major changes in the abundance and distribution of preferred prey species may lead to animals not being able to catch enough to eat and/or to spending more time foraging, thus exposing them to increased predation pressure from killer whales and sharks. Since NOAA Fisheries cannot control climate and oceanic changes, such as ENSO, or the behavior of killer whales, their management efforts are focused on human-caused adverse effects to Steller sea lions including fisheries that focus on important sea lion prey. The allocation of TAC among different seasons, areas, and gear types is the main thrust of these management efforts. Minimizing the competitive overlap between the fisheries and Steller sea lions is the primary focus of sea lion protective measures.

Indirect Effects through Contamination by Oil Spills

Other human-controlled factors such as oil spills have had effects on Steller sea lions in past years. A number of Steller sea lion haulouts and rookery sites were affected by the EVOS in PWS in 1989, but insufficient data exists to determine the overall impact of the spill on the population.

Comparative Baseline

Steller sea lions were split into two separate populations in 1997 based on several factors, including major differences in their population trends. The western population was estimated to be approximately 185,000 Steller sea lions in the late 1970s but has declined precipitously to an estimated 34,595 animals in 2002 (Angliss and Lodge 2002). Surveys in 2002 indicated the first region-wide increase in population in over 20 years but it remains to be seen whether this positive trend will continue. The western population was listed as endangered under the ESA in 1997 so it is automatically considered a depleted and strategic stock under the MMPA. According to current estimates, incidental take from the BSAI and GOA groundfish fisheries and other fisheries (29) and subsistence harvest (198) exceeds the PBR (208) for this population (Angliss and Lodge 2002). The eastern population, in contrast, has been stable or increasing in most parts of its range. Current estimates place the eastern population abundance at a minimum of 30,453 sea lions (Angliss and Lodge 2002) but could be as high as 45,000, a historic high for this population (Pitcher *et al.* 2003). The eastern population is listed as threatened under the ESA. Subsistence and incidental take in this population is relatively small.

A great deal of effort has been expended on trying to understand the reasons that the western population declined at the same time that the eastern population grew. The effects of natural factors, such as climate and oceanographic fluctuations, as well as human-influenced factors, including commercial fishing, have been studied on their own and are increasingly studied as part of complex models. While research continues, fishery management efforts have focused on trying to minimize the spatial and temporal competition between the fisheries and sea lions, which have a very substantial overlap of preferred prey with species taken in the groundfish fisheries as both target species and non-target species taken as bycatch. The past/present effects on Steller sea lions are summarized in Table 3.8-1.

Status for Cumulative Effects Analysis

Because the eastern and western populations of Steller sea lions are listed as threatened and endangered, respectively, under the ESA, have very different population trends, and are subject to very different intensities of interaction with the groundfish fisheries, each population will be considered separately in the analysis of Alternative FMPs in Chapter 4.

3.8.2 Northern Fur Seal (*Callorhinus ursinus*)

Life History and Distribution

The northern fur seal ranges throughout the North Pacific Ocean from southern California north to the Bering Sea and west to the Okhotsk Sea and Honshu Island, Japan. The species is strongly sexually dimorphic, meaning that mature males and females look very different. Females weigh about 135 pounds (61 kg) and reach 4.5 ft (1.4 m) in length while males average about 600 pounds (270 kg) and reach 6 ft (1.8 m) in length (Burt and Grossenheider 1976). Northern fur seals have a highly polygynous mating system, breeding in dense colonies on islands located near highly productive marine areas (Gentry 1998). Breeding is restricted to only a few sites: the Pribilof Islands (where 74 percent of the population breeds), Commander Islands (Russia), Bogoslof Island, and San Miguel Island (California) (Gentry 1998, Angliss *et al.* 2001).

The northern fur seal breeding cycle is highly stable, with adult males arriving on land during May and June to establish territories at traditional breeding areas (Bigg 1986). Females and juvenile males arrive on the breeding islands in late June through August with arrival times occurring progressively earlier as seals increase in age. Northern fur seals exhibit strong site fidelity and philopatry (Baker *et al.* 1995, Gentry 1998). The tendency to return to land at the natal area increases with age for both juvenile male and female northern fur seals (Baker *et al.* 1995). Female northern fur seals give birth to a single pup within 1 to 2 days after arrival on land and mate within 4 to 7 days after parturition (Bartholomew and Hoel 1953). Northern fur seal females undergo a period of delayed implantation characteristic of all pinnipeds (Boyd 1993); the embryo does not implant in the uterus and begin to develop until late November (York and Scheffer 1997). Approximately 7 to 8 days after giving birth, lactating females begin a series of foraging trips to sea alternating with 1 to 2 days on land to nurse their pups (Gentry *et al.* 1986). Pups are weaned in October and November, at about 125 days of age, and go to sea soon afterward (Gentry and Kooyman 1986).

Most females, pups, and juveniles leave the Bering Sea by late November and are pelagic in the North Pacific Ocean during the late fall and winter, migrating south as far as Southern California in the eastern North Pacific and Japan in the western North Pacific, until they begin returning to the rookeries in March (Bartholomew and Hoel 1953). In 1989 through 1990, radio-tagged pups departed St. Paul Island in mid-November and entered the North Pacific Ocean through the Aleutian Islands from Samalga Pass to Unimak Pass an average of 10 to 11 days later (Ragen *et al.* 1995). Of four fur seal pups tracked by satellite during 1996, two pups left the Bering Sea after 10 and 13 days, while two other pups traveled northwest of St. Paul Island and remained in the Bering Sea for 50 and 68 days until late January (D. DeMaster, AFSC, personal communication.). Adult males appear to migrate only as far south as the GOA and Kuril Islands (Kajimura and Fowler 1984, Loughlin *et al.* 1999).

Two separate stocks of northern fur seals are recognized within U.S. waters: an eastern Pacific stock, which includes all the animals in the BSAI and GOA, and a San Miguel Island (California) stock. Population estimates for the eastern Pacific stock are calculated by estimating the number of pups at rookeries and then multiplying by an expansion factor (4.5) that approximates a life table analysis (Angliss and Lodge 2002). Since 1990, pup counts have been made every other year on St. Paul and St. George Islands, but less frequently on Sea Lion Rock (a small reef just off St. Paul Island) and Bogoslof Island. Based on pup counts made during 2000, the most recent estimate of the number of fur seals in the eastern Pacific stock is 941,756 (Angliss and Lodge 2002).

Population Trends

Until the mid-1970s, northern fur seal population trends could be explained largely by commercial harvest patterns in the NPO. Large population declines coincided with large harvests of female and juvenile fur seals. The fur seal population has shown a resiliency to sustained harvests of adult males when females and juveniles were not harvested. The history of pelagic sealing (1875 - 1909), its impact on the fur seal population, and a subsequent treaty banning pelagic sealing is found in Gentry (1998). At the peak of pelagic sealing (1891 to 1900), more than 42,000 fur seals (mostly lactating females) were taken annually in the Bering Sea (Scheffer *et al.* 1984). Because the takes were greatly reducing the fur seal stock, Great Britain (for Canada), Japan, Russia, and the United States ratified the Treaty for the Preservation and Protection of Fur Seals and Sea Otters in 1911. With the signing the treaty, commercial pelagic harvests ended.

The population grew rapidly after the cessation of pelagic sealing until the mid 1940s. There was no commercial harvest from 1912 to 1917. From 1918 to about 1941, the Pribilof Island fur seal stock grew at eight percent per year under a land based harvest of males that ranged from 15,862 in 1923 to 95,016 in 1941 (NMML unpublished data[b]). The Alaska population of fur seals peaked at a high of approximately 2 million during the 1950s. In 1957, the signatories of the 1911 Treaty ratified a new agreement. During those negotiations, calculations presented by the U.S. suggested that maximum sustained productivity would occur at lower female population-levels than those of the early 1950s. Consistent with that analysis, from 1956 to 1968, a total of about 300,000 female fur seals were killed on the Pribilof Islands (York and Hartley 1981). Concurrently, 30,000 to 96,000 juvenile males were harvested each year and a pelagic collection of about 16,000 females was taken for research purposes by the United States and Canada. This harvest of females and juveniles caused a large population decline into the late 1960s.

With the cessation of female and juvenile harvests, the population increased only briefly into the mid-70s. The population then began a steady decline of 6 to 8 percent per year into the 1980s; the cause for this decline has not been determined. By 1983 the population was estimated to be 877,000 seals (Angliss *et al.* 2001). Annual pup production on St. Paul Island remained relatively stable between 1981 through 1998, indicating that the population had not changed very much. Since 1998, population estimates from pup surveys indicate that the population is declining at a rate of more than five percent per year. The cause for this decline is unknown.

Trophic Interactions

Studies on northern fur seal diets began with the work of Lucas (1899). The most extensive research was based on the pelagic sampling of over 18,000 fur seals between 1958 and 1974 (Perez and Bigg 1986). Of the fur seal stomachs collected, 7,373 contained food and an additional 3,326 had trace remains. Based on the frequency of occurrence, the diet consisted of 67 percent fish (34 percent pollock, 16 percent capelin, 6 percent Pacific herring, 4 percent deep-sea smelt and lantern fish, 2 percent salmon, 2 percent Atka mackerel, and no more than one percent eulachon, Pacific cod, rockfish, sablefish, sculpin, Pacific sand lance, flatfish, and other fish) and 33 percent squid (Perez 1990). These data showed marked seasonal and geographic variation in the species consumed. In the EBS, pollock, squid, and capelin accounted for about 70 percent of the energy intake. In contrast, sand lance, capelin, and herring were the most important prey in the GOA. However, no fur seal stomach samples have been collected following the decline in abundance of forage fish in the GOA after the regime shift in the mid 1970s.

One study of gastrointestinal contents of 73 northern fur seals collected from the Bering Sea in the early 1980s indicated that a positive correlation exists between pollock year-class strength and the frequency of pollock in fur seal diets (Sinclair *et al.* 1994). The same report concluded that northern fur seals are size-selective midwater feeders during the summer and fall in the eastern Bering Sea. Since 1987, studies of northern fur seal diets have been based on fecal samples (scat). A comparative study of fur seal diets based on the current method of scat analysis versus stomach content analysis from the 1980s collections demonstrated that the different methods yield very similar results (Sinclair *et al.* 1996). Based on diet studies conducted since the early pelagic collections (Sinclair *et al.* 1994, Sinclair *et al.* 1996, Antonelis *et al.* 1997), some prey items, such as capelin, have disappeared entirely from fur seal diets in the eastern Bering Sea and squid consumption has been markedly reduced. At the same time, pollock consumption has tripled and the age category of pollock eaten has decreased.

Recent studies have used bio-chemical methods to study the diet of northern fur seals. Kurle and Worthy (2000) used carbon and nitrogen isotope analysis of fur seal skin and whole prey to investigate the feeding ecology of female and juvenile male northern fur seals during the spring migration and of lactating female fur seals during the breeding season. Their results suggest that lactating females eat prey at trophic levels equivalent to 2 to 4 year-old walleye pollock and small Pacific herring during the fall. Nitrogen isotope ratios used to determine the trophic level of prey did not indicate a diet of juvenile pollock. During the northward spring migration, nitrogen isotope ratios indicated that the diet of both pregnant females and juvenile males consisted of prey at the same trophic level as capelin, herring, or adult pollock. Carbon isotope ratios suggested that migrating adult females fed in coastal areas while juvenile males and females were feeding further offshore. Using fatty acid signature analysis of fur seal milk to study the foraging patterns of lactating females on the Pribilof Islands, Goebel (2002) determined that prey of shallow-diving seals foraging off the continental shelf differs from shallow divers on-shelf, and that prey of deep diving females differs from both types of shallow divers. Milk of deep diving seals had fatty acid signatures most similar to fatty acid signatures of walleye pollock. The results of this study indicate that different dive patterns and foraging locations of lactating females likely result from exploitation of different prey resources. In waters over the continental shelf, adult walleye pollock are generally found near the bottom while juvenile pollock are usually concentrated in the surface layer above the thermocline (Bailey 1989) suggesting that the diet of deep diving fur seals in these areas includes adult pollock.

Management Overview

Northern fur seals are managed by NOAA Fisheries and by co-management agreements with Alaska Native Organizations under Section 119 of the MMPA. Northern fur seals were listed as depleted under the MMPA in 1988 because population-levels had declined to less than 50 percent of those observed in the late 1950s (NMFS 1993a). The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives.

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Commercial harvest of fur seals were a major source of human-induced mortality for over 200 years and the abundance of fur seals fluctuated greatly in the past, largely due to this commercial harvest (NMFS 1993a). Commercial harvest of fur seals peaked in 1961 with over 126,000 animals, but was halted in 1985. Commercial harvests of females from 1956 through 1968 likely contributed to the decline of the population from the 1950s to the 1970s, and may have had lingering effects after it's cessation (York and Hartley 1981). The population increased slightly in the early 1970s, though, and declines since then are difficult to explain. At present, the PBR for this population is 17,138 animals per year (Angliss and Lodge 2002).

Alaska Natives are allowed to harvest fur seals for subsistence purposes, with a take range determined by annual household surveys. From 1986 to 1996, the average annual subsistence take was 1,605 from St. Paul and St. George. From 1995 to 2000 this average take dropped to 1,340 seals per year, which represents about 8 percent of PBR. Only juvenile males are taken in the subsistence hunt, which minimizes the impact of the hunt on population growth. Subsistence take in other areas besides the Pribilofs is known to occur, but is thought to be minimal (Angliss and Lodge 2002).

Intentional killing of fur seals by commercial fishermen, sport fishermen, and others likely occurs but the magnitude of this mortality is not known. Intentional take is illegal under the MMPA except for subsistence uses of Alaska Natives.

Direct Mortality from Incidental Take in External Fisheries

Incidental take of fur seals from the foreign and joint venture groundfish fisheries averaged 22 animals per year from 1978 to 1988 (Perez and Loughlin 1991). The high seas driftnet fisheries killed thousands of fur seals every year, including an estimated 5,200 fur seals in 1991, the last year before these fisheries were outlawed by United Nations Resolution (46/215) (Hill and DeMaster 1999). Illegal driftnet fishing apparently continues at low levels, but no quantitative information is available on incidental take.

Based on self-reported mortalities, state-managed salmon fisheries took an average of 15 fur seals per year from 1990 to 1998. Most of these mortalities came from the Bristol Bay salmon drift gillnet fishery. Self-reported data are considered negatively biased, so these results are taken as minimum estimates (Angliss *et al.* 2001).

Another mechanism for incidental take of fur seals is through entanglement with fishing gear, packing bands, and other debris lost or ejected from fishing vessels, shipping vessels, and shoreside sources. Some gear may continue to circulate in the environment for many years. The contribution of particular fisheries to this problem is not known. The numbers of animals entangled at sea that never make it back to land are not known, but this issue has been cited as making a significant contribution to the decline of the population in the 1970s and early 1980s (Fowler 1987). Surveys of fur seals on St. Paul indicated that the proportion of animals with debris wrapped around part of their bodies decreased from 0.4 percent in 1976 to 1985 to 0.2 percent in 1988 to 1992 and 1995 to 1997 (Angliss *et al.* 2001). Some efforts have been made by NOAA Fisheries and Pribilof Island villagers to capture and remove debris from fur seals, with over 100 seals treated each year from 1995 through 1997.

<u>Direct Mortality from Incidental Take by MSA Groundfish Fisheries</u>

The incidental take of northern fur seals is uncommon in the groundfish fisheries. The last recoreded mortality in any Alaskan groundfish fishery occurred in 1996, when the take rate was one animal per 1,862,573 mt of groundfish harvested. Observer Program data from 1990 to 1998 indicate that fur seals were taken incidentally only in the BSAI groundfish trawl fishery, despite observer placement in pot, longline, and trawl fisheries in both the BSAI and GOA. Estimated average take in trawls is less than one seal per year (Angliss *et al.* 2001). This level of take contributes little to the northern fur seal PBR and is inconsequential to population trends. The contribution of the MSA groundfish fisheries to gear and debris that causes entanglement of fur seals is unknown.

<u>Indirect Effects through Changes in Prey Availability</u>

Ecological interactions between northern fur seals and the groundfish fisheries are caused by spatial and temporal overlap between fur seal foraging areas and groundfish fisheries and from competition for target and bycatch species taken by the fisheries. The diet of northern fur seals includes a wide range of fish species, with less apparent dependance on Pacific cod and Atka mackerel compared to Steller sea lions. However, both adult and juvenile pollock occur in the diet of northern fur seals and consumption rates vary according to the abundance of different age classes of pollock in the foraging environment (Swartzman and Haar 1983; Sinclair *et al.*, 1996). Evaluation of the indirect effects of fisheries on northern fur seals focuses less on removals of Pacific cod and Atka mackerel and more broadly on removals of pollock and small schooling fishes.

Fishing effort displaced by Steller sea lion protection measures may be concentrated in areas important to fur seals. The proportion of the total June through October pollock catch in fur seal foraging habitat (defined as the combined home ranges of females from the Pribilofs) increased from an average of 40 percent between 1995 and 1998 to 69 percent from 1999 to 2000 (NMFS 2001b). There is a particular concern for the potential impact of this increased fishing pressure on lactating females from St. George Island where catch rates were consistently higher than in areas used by females from St. Paul Island.

Comparative Baseline

Northern fur seals are numerous in the BSAI and GOA, with an estimated population of over 940,000 animals. However, they are listed as a "depleted" stock under the MMPA because of major population declines from 1950s to the late 1960s and again from the mid 1970s through the early1980s. Subsistence hunts make up the great majority of anthropogenic mortality, but these levels are well below PBR. Incidental take in the groundfish fisheries hovers around zero, but there is still concern about potential competitive interactions on prey availability, especially as fishing effort is diverted from Steller sea lion habitat to areas around the fur seal rookeries on the Pribilof Islands. Pup counts in 2000 were significantly less than in 1990. The past/present effects on northern fur seals are summarized in Table 3.8-2.

Status for Cumulative Effects Analysis

Because of their "depleted" status under the MMPA and potential for competitive overlap for prey with the groundfish fisheries, northern fur seals will be considered as a separate species in the analysis of Alternative FMPs in Chapter 4.

3.8.3 Pacific Walrus (*Odobenus rosmarus*)

Life History and Distribution

The Pacific walrus occurs primarily in the shelf waters of the Bering and Chukchi Seas (Allen 1880, Smirnov 1929). Most of the population congregates during the summer at the southern edge of the Chukchi Sea pack ice between Long Strait, Wrangell Island, and Point Barrow (Fay *et al.* 1984). The remainder of the population, primarily adult males, stays in the Bering Sea during summer (Brooks 1954, Burns 1965, Fay 1955, Fay 1982, Fay *et al.* 1984). Females and subadult males migrate toward Bering Strait in the autumn when the pack ice begins to re-form (Fay and Stoker 1982a). Walruses use terrestrial haulout sites when suitable haulout sites on ice are unavailable. The major haulout sites are located along the northern, eastern, and southern coasts of the Chukchi Peninsula, on islands in the Bering Strait, on the Punuk Islands, on Round Island in Bristol Bay (Lentfer 1988), and at Cape Seniavan on the north side of the Alaska Peninsula.

The population of Pacific walrus has never been known very precisely and has fluctuated substantially over the past 150 years, presumably as a result of changes in human exploitation. Prior to commercial hunting in the late 1700s, the population was estimated at 200,000 to 250,000 but decreased to an estimated 50,000 to 100,000 in the 1950s (USFWS 2002a). After U.S. and Soviet protection measures reduced hunting pressure, the population increased dramatically. A series of cooperative aerial surveys between the U.S. and the Soviet Union (and later, Russia) from 1975 to 1985 yielded population estimates of about 221,000 to 246,000 (USFWS 2002a). The survey methodology had technical problems so the results should be considered rough estimates. The most recent cooperative aerial survey was made in 1990 and yielded an estimate of just over 200,000 animals. However, this survey did not include an area that had been used by walrus in previous years and should be considered conservative. These cooperative surveys were discontinued after 1990 because of financial limitations and because of continuing technical difficulties in survey methodology (USFWS 2002a). The current size and trend of the Pacific walrus population are unknown but efforts have been made in recent years to improve survey methodology.

Trophic Interactions

Walrus feed almost exclusively on benthic invertebrates (bivalve mollusks) which they locate with their vibrissae and dislodge prey with jets of water and suction and sucking the meat out of the shells (Fay 1982, Fay and Stoker 1982a and 1982b). Feeding occurs in depths of 10 to 50 m, with a maximum depth of about 80 m (Fay and Stoker 1982a, Vibe 1950). Walrus diets in the EBS are more than 97 percent invertebrates and less than one percent fish. Some walruses, primarily males, occasionally feed on seals (Lowry and Frost 1981).

Management Overview

In contrast to the other pinnipeds, management of the Pacific walrus is the responsibility of the USFWS. The species is protected under the MMPA but it is not considered a "depleted" or "strategic" stock. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. In 1997, the USFWS entered into a cooperative agreement with the Eskimo Walrus Commission to facilitate the participation of subsistence hunters in the conservation and management of walrus in Alaska. This agreement has strengthened harvest monitoring programs and promoted locally-based subsistence harvest guidelines (USFWS 2002a). Based on the 1990 population estimate of 200,000 animals, but recent current populations size is not known, therefore, a PBR can't be calculated. (USFWS 2002a). The accuracy of this value for present use is not known. Round Island, south of Togiak in Bristol Bay, is an important haulout site and is part of the Walrus Islands State Game Sanctuary. FRs prohibit entry of fishing vessels inside 12 miles of this sanctuary (672.22[a][4]).

Past and Present Effects and Management Actions

<u>Direct Mortality: Harvest and Other Intentional Take</u>

Walrus are an important subsistence species for certain coastal communities in western Alaska and Russia, being used for meat, hides, and ivory. The combined Russian-Alaskan subsistence harvest of walrus has ranged from 3,200 to 16,100 animals per year with an average of about 7,000 per year for the past forty years (USFWS 2002a). These numbers include a correction factor to account for the number of walrus shot but lost during the hunt. An analysis of hunting success concluded that approximately 42 percent of animals struck by bullets were lost and that very few of them survived their injuries (Fay *et al.* 1994). Recent subsistence harvests have been smaller than the historic average, perhaps for a variety of reasons. The estimated harvest during 1996 to 2000, adjusted for animals shot but lost, was about 5,798 walrus per year (USFWS 2002a).

<u>Direct Mortality from Incidental Take in External Fisheries and Research</u>

There are no data on incidental take from Russian fisheries but it is to be believed to be very low. Between 1996 and 2000, 15 mortalities were associated with research activities, including 5 orphaned walrus calves. This data leads to an estimated loss of four walrus per year from research (USFWS 2002a).

<u>Direct Mortality from Incidental Take by MSA Groundfish Fisheries</u>

Walrus have been reported to be taken incidentally in the Bering Sea groundfish trawl fisheries. NOAA Fisheries observer data collected from 1992 to 1996 indicate that approximately 17 animals were caught each year (USFWS 2002a). Between 1996 and 2000, 63 walrus were caught (USFWS 2002a). However, the great majority of animals caught in trawls were already decomposed, indicating that many of the mortalities were unrelated to fisheries interactions. These carcasses came from animals that were either lost during subsistence hunts or from natural mortality. It is estimated that the amount of incidental take directly related to the fishery is about two walrus per year (USFWS 2002a).

Comparative Baseline

There is no reliable estimate of the current population of walrus in Alaska waters and there is little to indicate the current trend. Walrus eat benthic clams so their prey do not overlap with species caught in the groundfish fisheries. Incidental take in the groundfish fisheries is a rare occurrence. The species is an important subsistence resource for Alaska Natives. The past/present effects on walrus are summarized in Table 3.8-3.

Status for Cumulative Effects Analysis

Because there is little indication of a positive or negative trend in the walrus population and they infrequently interact with the groundfish fisheries, Pacific walrus will be considered in the "other pinniped" group in the analysis of Alternative FMPs in Chapter 4.

3.8.4 Harbor Seal (*Phoca vitulina*)

Life History and Distribution

The harbor seal is a widespread species in both the north Atlantic and Pacific Oceans and is found in Alaska along the coast from British Columbia north to Kuskokwim Bay and west throughout the Aleutian Islands. Adults weigh about 180 pounds (82 kg) with males somewhat larger than females. Sexual maturity occurs between 3 and 7 years. Maximum ages estimated from annual rings in their teeth are 26 years for a male and 32 years for a female. In Alaska, single pups are born between May and mid-July. The young pups are able to swim almost immediately after birth. They normally remain with their mothers about one month, after which they are weaned and separate from their mother. Births of harbor seal pups are not restricted to a few major rookeries (as is the case for many species of pinnipeds) but occur at many hauling sites (ADF&G 1994b).

Satellite radio-collar and tagging studies indicate that harbor seals do not appear to make long annual migrations but undertake considerable local movements. Most harbor seals are associated closely with coastal waters although there have been occasional observations of seals up to 50 miles (81 km) from shore. Harbor seals haul out of the water periodically to rest, give birth, and nurse their pups. Reefs, sand and gravel beaches, sand and mud bars, and glacial and sea ice are commonly used for hauling sites. Harbor seals are sometimes found in rivers and lakes, usually on a seasonal basis (present in summer, absent in winter) (ADF&G 1994b).

State and federal biologists have been collecting harbor seal count data sporadically since the 1940s. However, until the past decade most of these counts have been incidental to other ongoing studies. With the reauthorization of the MMPA in 1988, an increased effort began on federal and state levels to establish reliable population estimates for Alaska pinnipeds. In 1991, the National Marine Mammal Laboratory (NMML) initiated a survey project to generate a minimum population estimate for Alaska harbor seals. The surveys represent the first state-wide attempt targeting harbor seals throughout their Alaskan range. Aerial census procedures have been developed and are being updated annually using state-of-the-art imaging, mapping, and computer technologies. NMML biologists have also developed new capture techniques for tagging studies in order to generate correction factors to improve the accuracy of Alaska harbor seal abundance estimates. For budgetary and logistical reasons, the state is divided into five survey regions, only one of which is surveyed each year on a rotating basis. Hence, population estimates for the entire state are produced once every five years (AFSC 1999).

NMML aerial surveys are conducted in cooperation with ADF&G surveys and are scheduled to coincide with the Alaska harbor seal's annual molt in August, the longest time the animals spend hauled out on land or ice. During the second or third week in August, a tidal cycle is selected when the tides are low during daylight hours and the cycle of near-minus tides lasts from 8 to 10 days. Surveys are flown within 2 hours on either side of low tide when the greatest number of seals is expected to be hauled out (AFSC 1999).

For the past 30 years, three separate harbor seals stocks have been recognized in Alaska waters: (1) the Bering Sea stock, including all waters north of Unimak Pass; (2) the GOA stock, occurring from Cape Suckling to Unimak Pass, including animals throughout the Aleutian Islands; and (3) the southeast Alaska stock, occurring from the Alaska/British Columbia border to Cape Suckling (Hill and DeMaster 1999). Note that this stock division is different than that used in the fisheries. Population sizes and mortality rates in fisheries have been calculated separately. However, new genetic research indicates that there may be as many as 14 genetically isolated stocks of harbor seals in Alaska. NOAA Fisheries is presently working with the Alaska Native Harbor Seal Commission and ADF&G to redefine harbor seal stocks (Angliss *et al.* 2001, 67 FR 54792).

Bering Sea

The Bering Sea stock was surveyed during the autumn molt of 1995 throughout northern Bristol Bay and along the north side of the Alaska Peninsula (Withrow and Loughlin 1996). The estimated abundance, corrected for animals in the water, is 13,312 (Hill and DeMaster 1999).

Land-based counts at Nanvak Bay (in northern Bristol Bay) are used as an index to estimate local population trends (Pitcher 1990). Trends were estimated and adjusted for covariates (date, time of day, tide, weather variables, and count quality). In 1975, the first year standardized counts were conducted , maximum counts during pupping and molting were 375 and 2942 respectively. In the early 1990s, maximum counts during pupping were 2-3 times less than in 1975 but counts during molting were 6 times less than 1975. By 2000, the maximum count during pupping (477) was greater than in 1975 while the maximum count during molting (575) was still 5 times lower than in 1975 (Jemison *et al.* 2001). Annual surveys were conducted from 1990 through 2000 (excluding 1999). Results from this period indicate that total seal numbers increased 9.2 percent per year during the pupping period and 2.1 percent per year during the molting period (ADF&G 2001b).

At Otter Island (in the Pribilof Islands), pupping period surveys were made for all seals and for pups in 1974, 1978, and 1995. Maximum counts of all seals declined progressively from 1175 seals in 1974, to 707 seals in 1978, and to only 202 seals in 1995. This represents an 83 percent decline from 1974 to 1995. Maximum counts of pups went from 228 pups in 1974, to 114 pups in 1978, and to only 28 pups in 1995. This represents an overall decline in pups of 88 percent. This decline may have been exacerbated by the increasing presence of Northern fur seals that began to haul out on Otter Island in the early 1980s and reached numbers greater than 1000 by 1995 (Jemison *et al.* 2001).

A new ADF&G trend survey route was established in 1998 along the north side of the Alaska Peninsula from Port Moller northeast to Kvichak Bay. This new "Bristol Bay" trend route was flown again in 1999, with subsequent annual surveys planned to estimate population trend in this southeast region of the Bering Sea. A preliminary comparison between NOAA Fisheries counts in 1995 and ADF&G's counts in 1999 indicates that harbor seal numbers were stable for the Bristol Bay trend route area during 1995 through 1999. However, this crude comparison does not take into account all the differences between the NOAA Fisheries and ADF&G survey logistics that are known to substantially influence the number of seals hauled out (ADF&G 2001b).

GOA/Aleutian Islands

The GOA/Aleutian Islands stock was assessed by photographic aerial surveys in sections during the autumn molt in 1994 and 1996. Using a correction factor to account for harbor seals in the water (i.e., not accounted for in aerial photographs, the estimate was 29,175 (Hill and DeMaster 1999).

Tugidak Island (40 kilometers southwest of Kodiak Island) offers one of the most important data sets for population trend analysis because it has one of the largest concentrations of harbor seals in Alaska, it can be surveyed from land, and it has been surveyed since 1976 (by ADF&G). At Tugidak, seal counts decreased by 90 percent from 1976 to 1992 (NMFS and ADF&G 2000). This major population decline appears to have turned around in the early 1990s. From 1994 to 1999, the trend estimate turned positive with an increase of 4.9 percent during the molting period. The trend estimate for the 30 haulout sites that comprise the ADF&G's survey route on the east side of Kodiak Island for 1993 to 1999 was a positive 5.6 percent per year, representing the first documented increase in harbor seal numbers over a relatively broad area in the GOA. Despite increasing trends, the population remains greatly reduced from the 1970s (ADF&G 2001b).

<u>Prince William Sound</u>

The ADF&G began systematic surveys in 1984. For the period between 1984 and 1997, the population estimate decreased by 63 percent in this area (NMFS and ADF&G 2000).

<u>Southeast Alaska</u>

The most recent comprehensive aerial surveys of the southeast Alaska stock were conducted during the autumn molt in 1997 and 1998. Using a correction factor to account for harbor seals in the water (i.e., not accounted for in aerial photographs), the combined population estimate for southeast Alaska is 77,917 (Hill and DeMaster 1999).

In contrast to population trends in the GOA and Bering Sea, harbor seal populations in southeast Alaska did not undergo large declines in the 1970s and 1980s, but have generally increased over this period. Population trends have not been consistent in all areas, ranging from slight declines in the Glacier Bay area to 7 percent increases in southern southeast Alaska and similar increases along the coast to California (Jemison *et al.* 2001). In the Sitka area, the number of harbor seals increased in the 1984 to 1999 period by 1.1 percent per year. In the Ketchikan area, the number of harbor seals increased 7.4 percent per year during 1983 to 1998, followed by a slightly lower rate of growth (5.6 percent per year) during the more recent 1994 to 1998 period (ADF&G 2001b).

Trophic Interactions

Harbor seals generally feed in waters less than 80 m in depth, although they are able to dive to depths exceeding 600 feet (183 m) and can remain submerged for over 20 minutes (Stewart 1984). They have a relatively diverse diet that appears to vary by seasonal and local availability. Scat and stomach analyses indicate that harbor seal diets include sand lance, smelt, sculpins, herring, capelin, shrimp, mysids, octopus, pollock, and flatfishes (Lowry *et al.* 1982). Based on an average of data for the Aleutian Islands and EBS, harbor seal diet composition is approximately 75 percent fish (12 percent pollock, 9 percent Atka mackerel, 9 percent sculpin, 8 percent greenling, 8 percent Pacific cod, 5 percent capelin, 5 percent Pacific herring, 4 percent eulachon, 4 percent Pacific sand lance, 3 percent flatfish, 3 percent saffron cod, 2 percent other fish, and no more than one percent Arctic cod, eelpouts, rockfishes, and Pacific salmon) and 25 percent invertebrates (Perez 1990). Daily consumption rates of 6 to 8 percent of total body weight have been estimated for captive harbor seals. For a 180 pound seal, this would translate into a daily consumption of 11 to 14 pounds of food. Food consumption by captive subadult harbor and spotted seals, as reported by Ashwell-Erickson and Elsner (1981), was about 4 percent of body weight in March through August, and about 8 percent of body weight in the winter.

Prey quality may also be an important factor in harbor seal diets. Studies on captive animals have shown that certain blood parameters change when harbor seals consume different prey. The significance of these findings on wild populations of seals is unknown but is under investigation (NPFMC 2001).

Harbor seals are known to be prey of killer whales, Steller sea lions, and sharks. The impact of these predators on harbor seal populations is unknown but may be significant, especially when seal numbers are low (Frost 1997). There is some concern that the decrease in Steller sea lion populations, a favorite prey of killer whales, has led the whales to prey more heavily on harbor seals than when sea lions are less abundant.

Management Overview

Most marine mammals, including harbor seals, fall under the jurisdiction of the NOAA Fisheries and are protected under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. In 1994, an amendment to the MMPA included provisions for the development of cooperative agreements between the USFWS, NOAA Fisheries, and Alaska Native organizations to conserve marine mammals, and provide for co-management with Alaska Natives. NOAA Fisheries has entered into an agreement with the Alaska Native Harbor Seal Commission (ANHSC) for co-management of the seals. In addition, the ADF&G has management authority in state waters (less than 3 nm from shore) which includes much of the seal's habitat.

The ANHSC is a consortium of Native communities organized in 1995 to strengthen the role of Alaska Natives in resource policy and management decisions concerning harbor seals. ANHSC collaborates with federal and state agencies in scientific studies and educates the public on traditional Native uses of marine mammals (ANHSC 2002).

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Fifty years ago, the harbor seal was so abundant in Alaska (and perceived to be in conflict with commercial salmon fisheries) that the state issued a bounty for the animal (ADF&G 1994b). State-sponsored bounties and predator control programs, as well as commercial harvest of harbor seals, occurred on a regular basis throughout the animal's range until the passage of the MMPA. Both adult seals and pups were harvested for pelts (Pitcher and Calkins 1979). An estimated 3,000 seals, mostly pups, were harvested annually for their pelts along the Alaska Peninsula between 1963 and 1972, accounting for 50 percent of the pup production (Pitcher 1986).

Harvest of harbor seals for subsistence purposes is likely the highest cause of anthropogenic mortality for this species since the cessation of commercial harvests in the early 1970s. Between 1992 and 1998, the state-wide harvest of harbor seals from all stocks ranged between 2,546 and 2,854 animals, the majority of which were taken in southeast Alaska (Wolfe and Mishler 1993, 1994, 1995, 1996, 1997, and 1998; Wolfe and Hutchinson-Scarbrough 1999). Aside from their value as a food source, harbor seals play an important role in the culture of many Native Alaskan communities (ANHSC 2002). The Bering sea stock of harbor seals is approximately 13,000 animals, and the calculated PBR is 379 animals. The annual subsistence harvest from this stock from 1994 to 1996 was approximately 161 animals, 42 percent of PBR for this species (Wolfe and Mishler 1995, 1996, and 1997). In 1998, 178 harbor seals from this stock were taken in the subsistence harvest (Wolfe and Hutchinson-Scarbrough 1999). For the GOA stock, the calculated PBR is 868 animals (Hill and DeMaster 1999). The average annual subsistence harvest from the GOA between 1992 and 1996 was 791 animals, representing 91 percent of the PBR for this stock (Wolfe and Mishler 1995, 1996, and 1997). The latest available harvest data from 1998 (792) is comparable to the average subsistence harvest of harbor seals from previous years (Wolfe and Hutchinson-Scarbrough 1999). For the southeast stock, the calculated PBR is 2,114 animals (Hill and DeMaster 1999). The average annual subsistence harvest from southeast between 1992 and 1996 was 1,749 animals, representing 83 percent of the PBR for this stock.

Direct Mortality from Incidental Take in External Fisheries

Foreign and JV groundfish fisheries in the 1960s and 1970s have likely contributed to some level of direct harbor seal mortality from entanglement in gear, but there is no data on the actual effects. Based on the near-shore distribution of harbor seals, minimal direct interaction seems likely between the early foreign fisheries and harbor seals, and mortality from those fisheries is believed to have been very low.

Harbor seal mortality in the state-managed salmon drift and set net fisheries has been estimated to average about 31 animals per year over a 6-year period in the 1990s for the Bristol Bay area, one of the most heavily fished areas (Hill and DeMaster 1999). In the GOA, a minimum estimate of incidental take is 36 seals per year. In southeast, the minimum estimate is 35 seals per year, mostly from the Yakutat area. However, these fisheries self-report harbor seal mortality and actual take of animals in these fisheries is likely to be under reported (Angliss *et al.* 2001).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

Observer Program data from 1990 to 1996 yield minimum estimates of harbor seals taken incidentally in groundfish gear. In the Bering Sea, 4 harbors seals are estimated to be killed each year in all groundfish gear combined. In the GOA, less than one harbor seal per year is estimated to be killed in trawls. In southeast Alaska, 4 harbors seals are estimated to be killed each year on longlines (Angliss *et al.* 2001).

Indirect Effects through Changes in Prey Availability

Harbor seals have a varied diet and may compete directly with various fisheries for their natural prey. Climate and oceanographic fluctuations also impact prey populations. The relative contributions of fisheries and natural influences on prey availability is unknown. As a precautionary measure in the face of this uncertainty, NPFMC established a forage fish category and allocated a zero harvest quota to that category specifically to benefit marine mammals (FMP Amendments BSAI 36 and GOA 39).

Indirect Effects through Contamination by Oil Spills

The EVOS adversely affected harbor seals in the PWS area. An estimated 300 seals died in the immediate months following the spill from direct contact with oil in the water and on beaches. Toxicological effects were documented for a couple years after the spill but dissipated as seals molted oiled fur and oil was washed from the beaches. The accident apparently exacerbated the existing local seal population declines, at least in the short-term (Frost *et al.* 1999).

Comparative Baseline

Harbor seal populations suffered a major decline in the Bering Sea and GOA during the 1970s and 1980s. In situations similar to Steller sea lions, the southeast Alaska stock appeared to be stable or increasing during this same period. The causes of this massive decline in one part of their range while an adjacent population prospers are still a matter of debate and intensive scientific research. Populations of harbor seals in the groundfish FMP areas seem to have turned the corner in the late 1980s and early 1990s and now appear to be stable or increasing, albeit at much lower levels than their historic numbers. Subsistence take is the largest source of direct anthropogenic mortality. Groundfish takes of this predominately nearshore species are minimal. There is some overlap of prey species with targeted groundfish but harbor seals have many alternative prey and forage species mostly inshore of MSA groundfish operations. The past/present effects on harbor seals are summarized in Table 3.8-4.

Status for Cumulative Effects Analysis

Because harbor seals have undergone major population declines in the GOA, interact with the groundfish fisheries on an infrequent but regular basis, and have some direct competition for prey, they will be considered as a separate species in the analysis of Alternative FMPs in Chapter 4.

3.8.5 Spotted Seal (*Phoca largha*)

Life History and Distribution

Spotted seals are distributed along the continental shelf of the Beaufort, Chukchi, Bering, and Okhotsk Seas south to the northern Yellow Sea and western Sea of Japan (Shaughnessy and Fay 1977). They are also known to occur around the Pribilof Islands, Bristol Bay, and the eastern Aleutian Islands. Of eight known breeding areas, three occur in the Bering Sea. Only the Alaska stock is recognized in U.S. waters.

Pups are born in the pack ice during March and April and the seals move to coastal habitats after the ice retreats (Fay 1974, Shaughnessy and Fay 1977, Braham *et al.* 1984). From August to October, spotted seals inhabit coastal and estuarine habitats in the northen Bering and Chukchi Sea (Braham *et al.* 1984, Lowry *et al.* 2000). Availability of food nearby and freedom from disturbance seem to be important criteria for selection of coastal haulout sites (Lowry 1982). Satellite tagging studies indicate that spotted seals summering along the Chukchi Sea coast migrate south in October and pass through the Bering Strait in November (Lowry *et al.* 1998), moving south into the Bering Sea with the ice edge through December (Lowry *et al.* 2000). Preferred habitat for spotted seals in Alaska from January to April is the "front zone" of pack ice (the transition zone between the southern fringe of ice and the heavier southward-drifting pack ice, generally on rectangular floes 10 to 20 m in diameter with brash ice or open water in between (Burns *et al.* 1981a, Lowry *et al.* 2000).

Early estimates of the world population of spotted seals were in the range of 334,000 to 450,000 animals (Burns 1973). The population of the Bering Sea, including Russian waters, was estimated to be 200,000 to 250,000, based on the distribution of "family" groups (mother and pup, with attending male) on ice during the mating season (Burns 1973). However, comprehensive systematic surveys were not conducted to obtain these estimates. Reliable estimates of current population abundance and past trends are not available (Angliss and Lodge 2002).

Trophic Interactions

Adult spotted seals eat fish, crustaceans, and cephalopods. Their diet varies with region, season, and age. Spotted seals along the Sakhalin Island coast in Russia consume pink salmon, kundzha *(Salvelinus leucomaenis)*, redfin (*Leuciscus brandti*), *Myoxocephalus* sp., pleuronectids, and crab (Makhnyr and Perlov 1988). In the Bering Sea, they eat pollock, capelin, Arctic cod, and crustaceans. In winter, pollock, capelin, sand lance, Arctic cod, and shrimp are common in spotted seal diets (Sobolevskii 1996). During March through June, principal prey vary by region: pollock and eelpout in the central Bering Sea; capelin, small pollock, and herring in the southeast Bering Sea; Arctic cod, capelin, and saffron cod in the northern Bering Sea; and herring and smelt in both the southeastern Chukchi Sea and southwestern Seward Peninsula (Bukhtiyarov *et al.* 1984, Sobolevskii 1996). In summer, young seals eat mostly small crustaceans and euphausiids (Sobolevskii 1996). In the Bering Sea, the estimated diet composition of spotted seals is 96 percent fish and 4 percent invertebrates (Lowry *et al.* 1982, Bukhityarov *et al.* 1984). Spotted seal are preyed on by a number of larger predators such as killer whales, sharks, polar bears, brown bears, and to some extent Steller sea lions and walrus (Burns 1973).

Management Overview

Spotted seals are jointly managed by the ADF&G and the NOAA Fisheries PRD, and they are protected under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. Because there is no evidence that subsistence hunting is adversely affecting this stock, and because of the minimal interactions between spotted seals and any U.S. fishery, the Alaska stock of spotted seals is not classified as a "depleted" or "strategic" stock under the MMPA (Angliss and Lodge 2002). Because there are no reliable estimates of population abundance, no value for PBR has been calculated for this stock.

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Spotted seals are an important species for Alaskan subsistence hunters, primarily in the Bering Strait and Yukon-Kuskokwim regions, with estimated annual harvests ranging from 850-3,600 seals (averaging about 2,400 annually) taken during 1966 to 1976 (Lowry 1984). Recent estimates of subsistence take from ADF&G surveys indicate that an average of 5,265 spotted seals is taken every year by Alaska Natives, which is a substantial increase from previous estimates (Angliss and Lodge 2002, Wolfe *et al.* 2002) .

Direct Mortality from Incidental Take in External Fisheries

One source of information on the number of spotted seals killed or injured incidental to external fishing operations is the logbook reports maintained by vessel operators in the Bristol Bay salmon drift gillnet and set gillnet fisheries during 1990 to 1993 (Angliss and Lodge 2002). These reports indicate an annual mean of 1.5 mortalities from interactions with commercial fishing gear, but these estimates are considered minimum, because logbook records are likely negatively biased (Credle *et al.* 1994).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take in the 1990 to 1999 BSAI groundfish trawl, longline, and pot fisheries. Observed incidental takes in the Bering Sea trawl fishery (three seals killed in 1996) form the basis for an estimated annual mortality of one incidental take per year over the 1995 to 1999 period (Angliss and Lodge 2002). Some of these observations may be harbor seals rather than spotted seals, due to the difficulty in distinguishing between the two species. However, the proximity of the observations to the sea ice indicate that at least two of these observations were probably spotted seals.

Comparative Baseline

There is no reliable estimate of the spotted seal population in Alaska waters, but they appear to be common and are believed to be stable. Spotted seals eat a variety of fish and have a partial overlap of prey with species caught in the groundfish fisheries. Incidental take in the groundfish fisheries has been documented but appears to be a rare occurrence. The species is an important subsistence resource for Alaska Natives. The past/present effects on spotted seal are summarized in Table 3.8-5.

Status for Cumulative Effects Analysis

Because their population appears to be stable and they infrequently interact with the groundfish fisheries, ringed seals will be considered in the “other pinniped” group in the analysis of Alternative FMPs in Chapter 4.

3.8.6 Bearded Seal (*Erignathus barbatus*)

Life History and Distribution

Bearded seals are circumpolar in their distribution, extending from the Arctic Ocean south to Hokkaido in the western Pacific. Only the Alaskan bearded seal stock is recognized in U.S. waters. In Alaskan waters, bearded seals occur on the continental shelves of the Bering, Chukchi, and Beaufort Seas (Burns 1981a, Johnson *et al.* 1966, Ognev 1935). The majority of bearded seals move south with the advancing sea ice in winter. Pups are born in the pack ice from March through mid-May. In summer, many of the seals that winter in the Bering Sea move north through Bering Strait during April through June, and are distributed along the ice edge in the Chukchi Sea during the summer. Some seals, particularly juveniles, may spend the summer in open-water areas of the Bering and Chukchi seas (Burns 1967 and 1981a).

Early estimates of the Bering-Chukchi Sea population range from 250,000 to 300,000 (Popov 1976, Burns 1981a, Burns *et al.* 1981). Aerial surveys in 1999 and 2000 yielded conflicting results, so additional surveys will be required to obtain reliable estimates of abundance. Reliable data on population trends are likewise unavailable although there is no indication that the population is declining.

Trophic Interactions

Bearded seals are primarily benthic feeders, and their distribution appears to be strongly linked to areas of shallow water and high prey biomass. They appear to be limited to feeding depths of less than 200 m but prefer depths of 25 to 50 m (Kosygin 1966, Burns 1981a, Stirling *et al.* 1982, Kingsley *et al.* 1985). Crabs, shrimp and mollusks make up most of the diet, although a wide variety of invertebrates and fish is also included. In the Bering Sea, the estimated diet composition of bearded seals is 23 percent fish and 77 percent invertebrates (Lowry *et al.* 1979, 1980a, 1981a, 1981b, Smith 1981, Burns and Frost 1983). Fish species most common in the diet are sculpins, Arctic cod , and saffron cod, although pollock are also eaten in the EBS (Lowry *et al.* 1996).

Management Overview

Bearded seals are jointly managed by the ADF&G and the NOAA Fisheries PRD, and they are protected under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. Due to a lack of information suggesting subsistence hunting is adversely affecting this stock, and because of the minimal interactions between bearded seals and any U.S. fishery, the Alaska stock of bearded seals is not classified as a strategic stock under the MMPA (Angliss *et al.* 2001). Since reliable population estimates are not available, no value for PBR has been calculated.

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Bearded seals are an important species for Alaskan subsistence hunters, with estimated annual harvests of 1,784 seals from 1966 to 1977 (Burns 1981a). Between August 1985 and June 1986, 791 bearded seals were harvested by hunters from five villages in the Bering Strait region (Kelly 1988a). The ADF&G estimates the average number of bearded seals currently taken by Alaska Natives for subsistence at approximately 6,788 seals per year (Angliss and Lodge 2002, Wolfe *et al.* 2002) . This number is substantially higher than previous estimates of harvest based on a limited sample of villages.

Direct Mortality from Incidental Take in External Fisheries

Logbook reports maintained by vessel operators in the Bristol Bay salmon drift gillnet fishery from 1990 to 1993 indicated that 14 mortalities and 31 injuries occurred to bearded seals in the Bristol Bay salmon drift gillnet fishery. However, these reports are suspect because it is unlikely that bearded seals would have been in the Bristol Bay vicinity during the summer salmon fishing season (Angliss *et al.* 2001).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take in the BSAI groundfish trawl, longline, and pot fisheries during 1990 to 1999. The only fishery with observed incidental takes was the Bering Sea trawl fishery (three in 1991, four in 1994, one in 1998, and two in 1999). These records form the basis for an estimated mean annual mortality of 0.6 bearded seals per year from the groundfish trawl fishery. The estimated minimum mortality rate incidental to commercial fisheries is 0.6 bearded seals per year, based on observer data (Angliss *et al.* 2001).

Comparative Baseline

There is no reliable estimate of the bearded seal population in Alaska waters, but they appear to be abundant and are believed to be stable. Bearded seals eat a variety of fish and invertebrates and have a partial overlap of prey with species caught in the groundfish fisheries. Incidental take in the groundfish fisheries has been documented but appears to be a rare occurrence. The species is an important subsistence resource for Alaska Natives. The past/present effect on bearded seal are summarized in Table 3.8-6.

Status for Cumulative Effects Analysis

Because their population appears to be stable and they infrequently interact with the groundfish fisheries, bearded seals will be considered in the "other pinniped" group in the analysis of Alternative FMPs in Chapter 4.

3.8.7 Ringed Seal (*Phoca hispida*)

Life History and Distribution

Ringed seals are found throughout the arctic in areas of seasonal sea ice as well as in areas covered by the permanent polar ice cap (McLaren 1958, Smith 1987, Kelly 1988b, Ramsay and Farley 1997, Reeves 1998). In the North Pacific Ocean, they are found in the Bering Sea and range as far south as the seas of Okhotsk and Japan. Most ringed seals overwinter, breed, give birth, and nurse their young within the shorefast sea ice, although some breeding seals (and pups) have been observed in pack ice (Smith and Stirling 1975, Finley *et al.* 1983). Only the Alaskan ringed seal stock, in the Chukchi, Bering, and Beaufort seas, is recognized in U.S. waters.

In the Chukchi and Beaufort seas, ringed seals haul out in highest densities in shorefast ice during the May-June molting season, immediately following the March-April pupping season (Johnson *et al.* 1966, Burns and Harbo 1972, Frost *et al.* 1988, 1997, 1998, and 1999). Little is known about the distribution of ringed seals during the "open water" season, from July to October, but ringed seals have been seen both hauled out on pack ice and foraging in open water some distance away from the nearest sea ice (Smith 1987). Whether ringed seals foraging in open water commute from ice edge haulout sites or forage in open water all summer long without hauling out is currently unknown. Ringed seals migrate north and south with the retreat and advance of the sea ice edge, but some seals in areas of seasonal shorefast sea ice may be sedentary (Burns 1970, Smith 1987, Heide-Jørgensen *et al.* 1992, Kapel *et al.* 1998, Teilmann *et al.* 1999). In addition to ice-associated migrations, ringed seals, particularly young seals, can also travel long distances east or west (greater than 2000 km) (Smith 1987, Kapel *et al.* 1998).

Crude estimates of ringed seal abundance in Alaskan waters range from 1 million to 3.6 million, based on aerial surveys conducted in 1985, 1986, and 1987 (Frost 1985, Frost *et al.* 1988). A reliable estimate for the current abundance of ringed seals in Alaska is not available (Angliss *et al.* 2001). Reliable data on population trends is also unavailable, although there is no evidence of declining population-levels (Angliss *et al.* 2001).

Trophic Interactions

Ringed seals prey primarily on fish (saffron cod, smelt, herring, and Arctic cod) during the fall and winter (November-April) and consume crustaceans (shrimps, amphipods, and euphausiids) and some fish (saffron cod) during the spring and summer (McLaren 1958, Fedoseev 1965, Johnson *et al.* 1966, Lowry *et al.* 1980b). In the Bering Sea, the estimated diet composition of ringed seals is 85 percent fish and 15 percent invertebrates (Kenyon 1962, Lowry *et al.* 1978, 1980b, and 1982, Lowry and Frost 1981).

Management Overview

Ringed seals are jointly managed by the ADF&G and the NOAA Fisheries PRD, and they are protected under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. Due to a lack of information suggesting subsistence hunting is adversely affecting this stock, and because of the minimal interactions between ringed seals and any U.S. fishery, the Alaska stock of ringed seals is not classified as a strategic stock under the MMPA (Angliss *et al.* 2001). Since reliable population estimates are not available, no value for PBR has been calculated.

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Ringed seals are an important species for Alaska Native subsistence hunters. The annual subsistence harvest in Alaska dropped from 7,000 to 15,000 during the period of 1962 to 1972 to an estimated 2,000 to 3,000 in 1979 (Frost 1985). Based on data from two villages on St. Lawrence Island, the annual take in Alaska during the mid-1980s likely exceeded 3,000 seals (Kelly 1988b). The ADF&G estimates that the average harvest of ringed seals by Alaska Natives, as of 2000, is 9,567 animals per year (Angliss and Lodge 2002, Wolfe 2001).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take in the BSAI groundfish trawl, longline, and pot fisheries during 1990 to 1999. Incidental take was only observed in the Bering Sea trawl fishery with two seals in 1992. No mortalities have been observed since then, so the estimated mean annual mortality due to trawl fisheries in the Bering Sea is zero seals per year (Angliss *et al.* 2001).

Comparative Baseline

There is no reliable estimate of the ringed seal population in Alaska waters, but they appear to be abundant and are believed to be stable. Ringed seals eat a variety of fish and invertebrates and have a partial overlap of prey with species caught in the groundfish fisheries. Incidental take in the groundfish fisheries has been documented but appears to be a rare occurrence. The species is an important subsistence resource for Alaska Natives. The past/present effects on ringed seal are summarized in Table 3.8-7.

Status for Cumulative Effects Analysis

Because their population appears to be stable and they infrequently interact with the groundfish fisheries, ringed seals will be considered in the "other pinniped" group in the analysis of Alternative FMPs in Chapter 4.

3.8.8 Ribbon Seal (*Phoca fasciata*)

Life History and Distribution

Ribbon seals inhabit the North Pacific Ocean and adjacent fringes of the Arctic Ocean, most commonly in the Okhotsk and Bering seas (Burns 1981b). During the breeding season, ribbon seals are found only in the pack ice of the Okhotsk and Bering seas (Kelly 1988c). Only the Alaskan stock is recognized in U.S. waters.

In Alaska waters, ribbon seals are found in the open sea, on the pack ice, and only rarely on shorefast ice (Kelly 1988c). Ribbon seals in Alaska range northward from Bristol Bay in the Bering Sea into the Chukchi and western Beaufort seas (Burns 1970, Burns 1981b, Braham *et al.* 1984, Moore and Barrowclough 1984). They inhabit the northern part of the Bering Sea ice front from late March to early May and move north with the receding ice edge in May to mid-July (Shustov 1965a, Tikhomirov 1966, Burns *et al.* 1981). Ribbon seals are thought to be associated with the Anadyr massif, a remnant of the pack ice that extends from the Gulf of Anadyr toward St. Matthew Island (Burns *et al.* 1981). Little is known of the distribution of ribbon seals after the ice recedes from the Bering Sea. They are presumed to be solitary and pelagic in summer and fall but their distribution is unknown (Burns 1981b, Kelly 1988c). Single ribbon seals have been observed during the summer (June-August) within 84 miles of the Pribilof Islands (Burns 1981b), near Cordova (Burns 1981b), and south of the Aleutian Islands (Stewart and Everett 1983).

The worldwide population of ribbon seals was estimated at 240,000 in the mid-1970s, with an estimate of 90,000 to 100,000 in the Bering Sea (Burns 1981b). Reliable data on stock structure, trends in population abundance, and current population estimates for the Alaska stock of ribbon seals are unavailable, although there is no evidence that population-levels are declining (Angliss *et al.* 2001).

Trophic Interactions

Ribbon seals eat crustaceans, cephalopods, and fish (Arsen'ev 1941, Shustov 1965b, Frost and Lowry 1980). Two ribbon seals collected in winter (February) had been feeding entirely on cod and pollock (Burns 1981b). Fish consumed in the Bering Sea in spring (March to June), when most animals have been collected, include pollock, Arctic cod, saffron cod, capelin, eelpout, sculpins, and flatfish. There appear to be regional differences in that small pollock and eelpout were most commonly eaten in the south-central and EBS, while Arctic cod were eaten only by seals taken in the northern Bering Sea (Frost and Lowry 1980, Lowry *et al.* 1996). Few data are available on seasonal variations in the diet, as the distribution of ribbon seals during the open water season (July to November) is poorly known. Knowledge of ribbon seal feeding habits is also limited by small sample sizes, as most of the seals sampled in spring (March to June) were not actively feeding.

Management Overview

Management of ribbon seals is the responsibility of the NOAA Fisheries PRD, and they are protected under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. Ribbon seals are an important target species for some Alaska Native subsistence hunters. Reliable estimates of the minimum population, PBR, and human-caused mortality and serious injury are currently not available. However, due to a lack of information suggesting that subsistence hunting is adversely affecting this stock, and because of the minimal interactions between ribbon seals and any U.S. fishery, the Alaska stock of ribbon seals is not classified as a strategic stock under the MMPA (Angliss *et al.* 2001).

Past and Present Effects and Management Actions

<u>Direct Mortality: Harvest and Other Intentional Take</u>

Ribbon seals are an important species for Alaska Native subsistence hunters, primarily from villages in the vicinity of the Bering Strait and to a lesser extent at villages along the Chukchi Sea coast (Kelly 1988c). The annual subsistence harvest was estimated to be less than 100 seals annually from 1968 to 1980 (Burns 1981b). In the mid-1980s, the Alaska Eskimo Walrus Commission estimated the subsistence take to be less than 100 seals annually (Kelly 1988c). A reliable estimate of the annual number of ribbon seals currently taken by Alaska Natives for subsistence is unavailable.

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take in the BSAI groundfish trawl, longline, and pot fisheries during 1990 through 1999. The Bering Sea trawl fishery was the only fishery to have observed incidental take of ribbon seals with one taken in 1990, one in 1991, and one in 1997. No ribbon seal mortalities were recorded in logbook reports from all Alaska fisheries. The estimated minimum mortality rate incidental to commercial fisheries is one ribbon seal per year, based exclusively on observer data (Angliss *et al.* 2001).

Comparative Baseline

The population of ribbon seals in Alaska waters has not been reliably estimated, but is thought to be stable. Incidental take in the groundfish fisheries has been documented but appears to be a very rare occurrence. Diets of ribbon seals are not well known, but do include fish targeted by the groundfish fisheries. The past/present effect on ribbon seals are summarized in Table 3.8-8.

Status for Cumulative Effects Analysis

Because their population trend is unknown and they infrequently interact with the groundfish fisheries, ribbon seals will be considered in the "other pinniped" group in the analysis of Alternative FMPs in Chapter 4.

3.8.9 Northern Elephant Seal (*Mirounga angustirostris)*

Life History and Distribution

Northern elephant seals range throughout the northeast Pacific Ocean from central Baja California, Mexico, to the GOA and eastern Aleutian Islands, with occasional sightings in the southern Bering Sea. Breeding occurs on islands from central Baja California north through central Oregon. Pupping and mating occurs on isolated islands and mainland rookeries during January and February. Following the breeding season, adults go to sea and forage until they return to rookery islands to molt in April (females) and July (males). Following the molt (which requires 4 to 6 weeks to complete), adults again return to foraging areas, where they feed until returning for the following breeding season.

Elephant seals complete two long distance migrations each year, with males traveling an average of 13,020 miles (21,000 km) and females 11,160 miles (18,000 km) (Stewart and DeLong 1995, LeBoeuf *et al.* 2000). Adult males and females occupy different foraging areas. Females forage in an area generally bounded by 38°N to 45°N, off the North American continental shelf, westward to the central Pacific Ocean. Adult males are distributed farther north than females, primarily occupying pelagic waters from Oregon northward to British Columbia, through the GOA, and westward to the eastern Aleutian Islands.

In Alaska, males that traveled to the Aleutian Islands showed a preference for Amutka Pass and Amchitka Pass (LeBoeuf *et al.* 2000) and deep water south of the eastern Aleutian Islands (Stewart and DeLong 1994).

The existing population of northern elephant seals is descended from perhaps 100 animals that survived in Mexico after the species was nearly exterminated by commercial hunting in the 19th century (Carretta *et al.* 2002). The population has expanded rapidly since hunting was halted. An estimated population of 127,000 northern elephant seals existed in U.S. and Mexican waters in 1991, of which 95,000 were in U.S. waters (Stewart *et al.* 1994). Approximately 101,000 animals were estimated to make up the U.S. population in 2001 (Carretta *et al.* 2002).

Trophic Interactions

All of the published food habits data on northern elephant seal are from California: adult males and females under anesthesia were lavaged on San Miguel Island (Stewart and DeLong 1993, Antonelis *et al.* 1987), and stomach contents were collected from dead animals along the southern California Bight northward through central California (Hacker 1986, Condit and LeBoeuf 1984). Cephalopods occurred in all animals containing food with 15 squid species occurred in 10 percent or more of the stomachs. Pacific hake occurred in 39 percent of the samples and was the only teleost fish that occurred in greater than 10 percent of the samples (Antonelis *et al.* 1994). The food habits of elephant seals while in Alaskan waters are unknown. Diving patterns of males feeding in Alaska imply that they are pursuing benthic prey (LeBoeuf *et al.* 2000). The adults that are feeding in very deep water off the continental shelf are probably primarily taking squid, as they do in California. The degree to which the smaller fraction of the northern elephant seal population frequenting areas on the continental shelf feed on demersal teleost fishes is unknown.

Males foraged in areas close to or over the continental shelf break during intense feeding (LeBoeuf *et al.* 2000) while females tended to forage in deeper waters off the continental shelf (Stewart and DeLong 1994, LeBoeuf *et al.* 2000). In these waters, elephant seals dive to average depths of 1312 ft (400 m), apparently feeding on organisms associated with the deep scattering layer. Some adult and subadult males occupy more coastal habitats where dive records suggest feeding on or near the bottom. While the proportion of the population using coastal habitats is unknown, most adult males and females appear to feed in the water column over very deep water.

Management Overview

Management of the northern elephant seal is the responsibility of the NOAA Fisheries PRD, and they are protected under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. Northern elephant seals are not an important target species for Alaska Native subsistence hunters. Because their annual human-caused mortality is much less than the calculated PBR for this stock (2,513), they are not considered a “strategic” stock under the MMPA (Carretta *et al.* 2002).

Past and Present Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

As mentioned above, commercial harvest of elephant seals nearly exterminated the species at the end of the 1800s.

Direct Mortality from Incidental Take in External Fisheries

An average of 86 elephant seals are taken each year in various gillnet fisheries from California to Washington (Carretta *et al.* 2002). Data from other external fisheries are not available, but the amount of incidental take of elephant seals is thought to be minimal.

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take in the 1990 to 1999 BSAI and GOA groundfish trawl, longline, and pot fisheries. Observed incidental kills included one in the Bering Sea trawl fishery in 1990, two in the GOA trawl fishery in 1990, and three in the GOA longline fishery in 1990. One juvenile elephant seal, originally misidentified as a bearded seal, was taken in the Bering Sea trawl fishery in 1991 (Angliss *et al.* 2001).

Comparative Baseline

The population of northern elephant seals in U.S. waters continues to expand and is presently over 100,000 animals. Male elephant seals spend part of their year in Alaska waters, but there is little information on their Alaska diet. Incidental take in the groundfish fisheries has been documented, but appears to be a very rare occurrence. The past/present effect on northern elephant seal are summarized in Table 3.8-9.

Status for Cumulative Effects Analysis

Because their population appears to be increasing and they infrequently interact with the groundfish fisheries, northern elephant seals will be considered in the "other pinniped" group in the analysis of Alternative FMPs in Chapter 4.

3.8.10 Sea Otter (*Enhydra lutris*)

Life History and Distribution

Adult male sea otters weigh 70 to 100 pounds (32-45 kg) while females average 40 to 60 pounds (18-27 kg). Unlike seals, which rely on a heavy layer of blubber for protection against cold water, sea otters depend on air trapped in their fur for maintaining body temperature. Sea otters mate at all times of the year, and young may be born in any season, but most pups in Alaska are born in late spring. Females can produce one pup a year, but in areas where food is limited, they may produce pups every other year. Sea otters seldom travel far unless an area has become overpopulated and food is scarce. They are gregarious, sometimes resting in pods of 10 to more than 1,000 animals. Many sea otters live for 15 to 20 years (Schneider 1994).

Sea otters inhabit shallow coastal waters of the North Pacific Ocean and the southern Bering Sea (Estes 1980, Estes and Van Blaricom 1985, Estes and Palmisano 1974). Habitat is generally shallow (less than 34 m) nearshore marine waters with sandy or rocky bottoms supporting substantial populations of benthic invertebrates. In some areas, large numbers of sea otters occur offshore. For example, in the Copper River Delta and inside PWS, sea otters are often present more than 8 km from shore (Garshelis and Garshelis 1984). Large aggregations have also been observed more than 30 km north of Unimak Island in the Bering Sea (Kenyon 1969).

Historically, sea otters occurred all across the North Pacific Rim and were estimated to number between 150,000 and 300,000 in the early 1700s. Following the arrival of Russian explorers in 1741, commercial harvest of otters for fur nearly resulted in their extinction. When sea otters were finally afforded protection under the International Fur Seal Treaty in 1911, there were probably fewer than 2,000 animals remaining in thirteen remnant colonies (Kenyon 1969).

Three genetically and geographically distinctive stocks of sea otters are recognized in Alaska: the southwest Alaska stock, which extends from the Bering Sea, Aleutian Islands, and Alaska Peninsula to the western shore of Cook Inlet; the southcentral Alaska stock, which extends from Cook Inlet east to Cape Yakataga, including Kachemak Bay, the Kenai Peninsula coast, and PWS; and the southeast Alaska stock, which extends from Cape Yakataga to the southern boundary of Alaska (Gorbics and Bodkin 2001).

Southwest Alaska

The first systematic aerial surveys for sea otters in southwest Alaska were conducted from 1957 to 1965. Those surveys indicated that the otter population was growing and that they were recolonizing former habitat. However, the population appears to have started a major decline in the 1980s. In the 1980s, the population of sea otters in the Aleutian Islands was estimated between 55,100 and 73,700 animals (uncorrected for sightability of otters). In 1992, USFWS conducted another systematic count of the Aleutians and the (uncorrected) population estimate was only 8,042 otters. This survey was repeated in 2000 and yielded an (uncorrected) estimate of 2,442 otters. This represents a 70 percent decline from 1992 and about a 95 percent decline from the 1980s (Doroff *et al.* 2003). Other sectors of the southwest stock have also declined over the same period. Comparing similar counts from aerial surveys in 1986 and 2000, USFWS estimates that sea otter populations declined 93 to 94 percent along the south shore of the Alaska Peninsula, and 27 to 49 percent along the north shore. Aerial surveys in the Kodiak Archipelago indicate a 40 percent decline in the population between 1994 and 2001 (USFWS 2002b, Doroff *et al.* submitted, Burn and Doroff submitted).

The most recent estimates of sea otters in southwest Alaska are based on aerial and boat-based surveys in 2000 and 2001 and have been corrected for sightability of otters under different conditions (and hence are different than the uncorrected estimates above). The combined estimate is 23,967 sea otters in the southwest Alaska stock, including the Aleutians (8,742), Alaska Peninsula (north side 5,756, south side 3576), and the Kodiak archipelago (5,893) (USFWS 2002b).

Southcentral Alaska

The most recent estimates of sea otter abundance in southcentral Alaska are based on a variety of aerial and small-boat surveys from 1989 to 1999. Combining corrected counts from various surveys with one small uncorrected count, the estimated abundance of sea otters in southcentral is 21,749. Although rates of population growth vary among locations, the trend for the southcentral stock is generally one of growth (USFWS 2002c).

Southeast Alaska

After being essentially extirpated by the fur trade, sea otters in the southeast Alaska stock result from a translocation of 412 animals from PWS and Amchitka Island in the late 1960s. The population has increased rapidly since that time. The most recent estimates of the sea otter population in southeast are based on small-boat and aerial surveys in 1994 and 1995. Combining corrected and uncorrected counts yields an estimated abundance of 8,807 sea otters. Although rates of population growth vary among locations, the trend for the southeast stock is one of growth (USFWS 2002d).

Trophic Interactions

Sea otters eat a wide variety of slow-moving benthic invertebrates, including sea urchins, clams, mussels, crabs, snails, octopus, squid, and epibenthic fishes (Kenyon 1969, Estes and Van Blaricom 1985, Reidman 1987). The sea otter's diet consists of an estimated 82 percent invertebrates and 18 percent fish (Kenyon 1969, Kenyon 1981, Lowry *et al.* 1982). The fish component includes lumpsuckers, sculpin, rock greenling, Atka mackerel, rockfish, sablefish, Pacific cod, and pollock. Captive animals require a daily food intake equal to one-quarter of their body weight. Of the total estimated annual fish consumption, commercial groundfish comprise 8 percent, which is considered a trace amount of the standing biomass of commercial groundfish consumed annually (by all predators) in the EBS (Perez and McAlister 1993).

Bald eagles prey on newborn pups, and killer whales prey on adults. In past years, predation rates were considered insignificant in regard to population growth (Schneider 1994). However, as noted above, sea otter populations in some areas have decreased dramatically in the past decade. Estes *et al.* (1998) suggested that increased predation by killer whales is the likely cause of these declines. Further, the authors speculate that the increased predation may have resulted from declines in the populations of other killer whale prey, namely Steller sea lions and harbor seals. If this hypothesis is correct, then any impact the groundfish fisheries may have on Steller sea lion recovery could also be considered a factor in the sea otter declines, in so far as they may have contributed to a shift in predator-prey relationships. Having said that, very little data currently exist to test the validity of this hypothesis. Surveys of Native Alaskan hunters in the False Pass area of the Aleutians failed to provide any support for killer whale predation on sea otters. The Alaska Sea Otter and Steller Sea Lion Commission continues to research this hypothesis (Jack 2000).

Sea otters also play an important ecosystem role in maintaining nearshore kelp bed habitats. In the Aleutian archipelago, sea urchins are a dominant herbivore and an important food source of sea otters (Estes *et al.* 1978). As has been demonstrated by historic sea otter declines, when sea otters disappear from an area, sea urchin populations are released from the control of sea otter predation and soon overgraze the attachments of bull kelp. Detached kelp is swept away, exposing remaining fish, crustaceans, and bivalves. A secondary consequence of the decline in sea otter populations in southwest Alaska is that kelp forests in many areas may also be in decline (Estes *et al.* 1998, USFWS 2002b).

Management Overview

The early Russian settling of Alaska was largely a result of the sea otter industry which greatly reduced the numbers of sea otters. Sea otters continued to be heavily exploited after Alaska was sold to the U.S. and became alarmingly scarce. Finally in 1911, when so few animals were left that it was no longer profitable to hunt them, sea otters were given full protection under the International Fur Seal Treaty. In 1960, the State of Alaska assumed management authority for sea otters. The management program conducted by the state included the successful reintroduction of sea otters to unoccupied habitat in southeast Alaska, British Columbia, and Washington. The MMPA transferred management authority to the USFWS in 1972 (Schneider 1994).

The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. The USFWS has cooperative agreements with the Alaska Sea Otter and Steller Sea Lion Commission, a consortium of 51 Alaska Native community groups. The Marking, Tagging, and Reporting Program is a USFWS program used throughout coastal Alaska to monitor the harvest of sea otters by Alaska Natives (Jack 2000).

Because of concerns about the severity and unknown cause(s) of the population decline in the southwest Alaska stock, the USFWS published a notice in the FR on November 9, 2000 designating the southwest Alaska stock of sea otters as a candidate species for protection under the ESA. In February 2004, the USFWS proposed listing the southwest Alaska DPS, which corresponds to the range of the southwest stock of sea otters under the MMPA, as threatened under the ESA due to their precipitous decline in numbers (69 FR 6600-6630 [11February 2004]). Critical habitat for these otters has not been designated under the proposed rule. The southwest Alaska stock of sea otters is not presently listed as depleted under the MMPA (USFWS 2002b).

The PBR for the southwest stock is calculated to be 830 animals. PBR for the southcentral stock is calculated to be 1,951 animals, and for southeast, PBR is calculated to be 871 animals (USFWS 2002b, 2002c, and 2002d).

Past and Present Human Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Commercial exploitation for pelts had a huge impact on sea otters dating from the mid-1700s to the late 1800s, causing them to become nearly extinct (Bancroft 1959, Lensink 1962). Protective measures instituted in 1911 have allowed remnant groups to increase and reoccupy much of the historic sea otter range in Alaska (Kenyon 1969, Estes 1980). Residual effects from this early harvest likely persist in several areas.

Alaska Natives have hunted sea otters for pelts and meat throughout history. Data on the subsistence harvest of sea otters has been collected by USFWS since 1988. For the southwest stock, the numbers of sea otters taken has varied from 25 to 175 animals each year with an average of 97 animals taken between 1996 and 2000, representing 9 percent of PBR (USFWS 2002b). For the southcentral stock, subsistence take has ranged between 25 and 425 animals per year with an average of 297 otters between 1996 and 2000, representing 15 percent of PBR (USFWS 2002c). For the southeast stock, subsistence take has ranged between 90 and 825 animals per year with an average of 301 otters between 1996 and 2000, representing 35 percent of PBR (USFWS 2002d).

Direct Mortality from Oil Pollution

Exploration, development, and transportation of oil and gas can adversely impact sea otters if these processes contaminate nearshore waters. Estimates of sea otters killed during the EVOS ranged from 750 to 2,650 in PWS (Garshelis 1997, Garrot *et al.* 1993) and additional thousands were killed elsewhere in the GOA because of the spill (DeGange *et al.* 1994). The EVOS demonstrated that spilled oil can travel long distances and kill large numbers of sea otters far from the point of initial release. There is no evidence that routine oil and gas development and transport have a direct impact on otter populations. At present, estimates of sea otter numbers in some areas of PWS are still below pre-spill estimates, indicating a possibly lingering effect from the catastrophe (USFWS 2002d).

Direct Mortality from Incidental Take in External Fisheries

Sea otter interactions with fishing gear of any type are infrequent. In the southcentral area, only a small fraction (2 to 5 percent) of the commercial salmon fisheries is covered by any observer program. No fishery-related sea otter injuries or mortalities have been observed in this area in the past decade and only one kill has been self-reported (USFWS 2002c). No fisheries operating in southeast Alaska are subject to the NOAA Fisheries observer program. Although the records are incomplete, there have been no self-reported injuries or fatalities related to commercial fishing in southeast in the past decade (USFWS 2002d). Laist (1997) reported that sea otter entanglement in marine debris is rare.

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

In 1992, fisheries observers reported eight sea otters taken incidentally by the Aleutian Island sablefish pot fishery. During that year, only a third of the fisheries were observed, yielding an estimate of 24 otters killed in pot gear in the sablefish fishery. No other sea otter takes were reported from observed fisheries in the range of the southwest stock from 1993 through 2000. In 1997, the BSAI groundfish trawl fishery reported one sea otter taken (USFWS 2002b).

Comparative Baseline

Sea otters have played an important role in the history and culture of Alaska. Their numbers have fluctuated greatly over time because of both major declines from relentless hunting pressure and tremendous growth from intentional reintroduction efforts. Current population trends parallel the situation for Steller sea lions and harbor seals in that sea otter numbers have declined dramatically from the Alaska Peninsula to the Bering Sea, but have remained stable or increased in southcentral and southeast Alaska. Unlike the historic population fluctuations, there is little agreement in the scientific community regarding the cause(s) of the present dynamic. There is only a small amount of overlap between their prey and the groundfish harvest. The species is an important subsistence resource for Alaska Natives, but take from the declining southwest stock is relatively low. The past/present effects on sea otters are summarized in Table 3.8-10.

Status for Cumulative Effects Analysis

Because their population in southwest Alaska is being considered for listing under the ESA and they interact with the groundfish fisheries on a regular basis, sea otters will be considered as a separate species in the analysis of Alternative FMPs in Chapter 4.

3.8.11 Blue Whale (*Balaenoptera musculus*)

Distribution and Abundance

The IWC recognizes only one stock of blue whales in the North Pacific (Donovan 1991, Best 1993), but some evidence suggests that there may be as many as five separate stocks, two of which are relevant to this analysis: the central stock near the Aleutian Islands, and the eastern GOA stock (Rice 1992, Calambokidis *et al.* 1995, Gilpatrick *et al.* 1996, Barlow 1995, Calambokidis and Steiger 1995, NMFS 1998c, Stafford *et al.* 1999). Analysis of whaling records from 1929 to 1965 indicates that there is a western stock off Kamchatka and the Kuril Islands that is separate from the central Aleutian Islands stock (Forney and Brownell 1996). Sightings of blue whales in Alaskan waters have been infrequent (Forney and Brownell 1996). Sightings reported in the Platform of Opportunity database (from 1960 to 1995) occurred primarily during the summer months. However, acoustic data collected from 1995 to 1999 from hydrophone arrays showed blue whales calling in Alaskan waters during all seasons, with the majority of calls in the GOA occurring in the fall and winter (Watkins *et al.* 2000a and 2000b). Surprisingly, blue whales did not appear to migrate and were numerous over deepwater regions in the North Pacific (Watkins *et al.* 2000a and 2000b). Blue whale range does not extend north of the Aleutian Islands, except rarely in the far southeastern corner of the Bering Sea (Rice 1998).

Estimates of abundance in the North Pacific Ocean have ranged from 1,400 to 1,900 individuals (Nishiwaki 1966, Omura and Ohsumi 1974, Rice 1978a, Tillman 1975), although these estimates are now considered outdated (Perry *et al.* 1999a). More blue whales are thought to be distributed on the east side of the North Pacific than on the west side (Omura 1955, Tomilin 1967). There are no reliable population estimates for blue whales in the south EBS or the GOA A minimum abundance estimate of 3,300 has been proposed for the North Pacific as a whole, including about 2,000 whales that breed in California waters (Wade and Gerrodette 1993, Forney *et al.* 2000). However, recent surveys conducted in previous commercial hunting areas in Alaska and Russia failed to find any blue whales (Forney and Brownell 1996).

Trophic Interactions

Blue whales are found both in coastal waters of the continental shelf and far offshore in pelagic environments. Blue whale distribution is likely governed largely by food requirements, as reported in two fine-scale studies of blue whale ecology offshore of southern California (Fiedler *et al.* 1998, Croll *et al.* 1998). Blue whales are almost exclusively euphausiid eaters, concentrating on *Thysanoessa inermis, T. longipes*, and *T. spinifera* in the Bering Sea (Tomilin 1957, Nemoto 1957, Klumov 1963, Nemoto and Kawamura 1977, Kawamura 1980). Blue whales occasionally consume copepods, pelagic gastropods, pelagic schooling squid, and fish such as sardines, capelin, and sand lance (Mizue 1951, Sleptsov 1955, Klumov 1963). A blue whale of average size, 23.5 to 24.5 m long and weighing 54 to 64 mt, eats about 1.8 to 2.3 mt of food per day (Klumov 1963). Estimates of total prey consumption are not available for this species.

Management Overview

Management of blue whales is the responsibility of the NOAA Fisheries PRD. Blue whales are listed as endangered under the ESA, and a recovery plan was finalized in 1998 (NMFS 1998c). The long-term goal of this plan is to promote the recovery of the blue whale to the extent that it is removed from ESA-listing. One of the primary means of achieving this goal is to minimize or eliminate human-caused mortality. Critical habitat has not been designated for the species. Its endangered status also means that the species is automatically classified as a depleted and strategic stock under the MMPA. The IWC instituted a ban on harvest of blue whales in 1966.

Past and Present Human Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

At least 9,500 blue whales were taken by commercial whalers from 1910 to 1965 in the North Pacific (Carretta *et al.* 2001). Blue whales were hunted by the Japanese along the south side of the Aleutian chain from 1952 to 1965 (Forney and Brownell 1996). Catches averaged 80 whales per year until 1961, after which annual catches included 67, 404, 119, and 121 whales (Forney and Brownell 1996). The IWC banned the hunt of blue whales in 1966, although it is likely that Soviet whaling continued and that Soviet catch reports under-represented the true harvest (Yablokov 1994).

Direct Mortality from Incidental Take in External Fisheries

The potential for human-caused mortality (from ship strikes and interactions with fisheries) exists, but few incidents have been reported and none have occurred in Alaskan waters (Forney *et al.* 2000).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

No blue whales have been reported taken in the groundfish fisheries since the Observer Program was initiated in 1989.

Comparative Baseline

Blue whales are an endangered species, but the number of whales that actually live in waters affected by the BSAI and GOA groundfish fisheries is unknown. Their diet does not overlap with species taken by the fisheries, and they do not appear to interact with the fleet on a regular basis (Table 3.8-11).

Status for Cumulative Effects Analysis

Because of their endangered status under the ESA and their documented presence in the action area, blue whales will be considered in the analysis of Alternative FMPs in Chapter 4. However, since they interact so infrequently with the groundfish fisheries, blue whales will be considered in the baleen whales species group.

3.8.12 Fin Whale (*Balaenoptera physalus*)

Distribution and Abundance

Fin whales are divided into three stocks for management purposes, including stocks in California and Hawaii. The northeast Pacific stock of fin whales ranges throughout the BSAI and GOA area (Angliss *et al.* 2001). Recent vessel surveys have documented large concentrations of fin whales in the central Bering Sea in July. Acoustic detections of fin whale calls indicate that fin whales also aggregate near the Aleutian Islands in summer (Moore *et al.* 1998). Some whale calls continue to be detected in northern latitudes throughout the winter with no noticeable migratory movement south (Watkins *et al.* 2000a and 2002b).

Pre-whaling estimates for the northeast Pacific stock of fin whales range from 42,000 to 45,000 whales, and post-whaling estimates range from 14,620 to 18,630 whales. However, these estimates are not considered reliable, and current abundance or population trends of fin whales are not available (Angliss *et al.* 2001). One recent survey yielded a regional estimate of abundance of 4,951 fin whales (95 percent confidence interval = 2,833-8,653) for the central Bering Sea shelf in the summer of 1999 (Angliss *et al.* 2001; Moore *et al.* 2000).

Trophic Interactions

Prey includes planktonic crustaceans (euphausiids and copepods), squid, fish (herring, cod, mackerel, pollock, and capelin), and cephalopods (Gambell 1985a). The total estimated annual food consumption by the EBS population is 57,500 mt, of which 9,200 mt (16 percent) is fish (Perez and McAlister 1993).

Management Overview

Fin whales fall under the jurisdiction of the NOAA Fisheries PRD. Fin whales are listed as endangered under the ESA and are therefore considered a depleted and strategic stock under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. A draft joint Recovery Plan has been develop in 1998 which covers both the fin and sei whales (NMFS 1998d). The long-term goal of this plan is to promote the recovery of these species to the extent that they are removed from ESA-listing. One of the primary means of achieving this goal is to minimize or eliminate human-caused mortality.

Past and Present Human Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

As noted above, commercial whaling about 100 years ago had a major impact on fin whale populations, including the northeast Pacific stock. Commercial whaling continued into modern times with 1,000 to 1,500 fin whales taken annually from the mid-1950s to the mid 1960s. Thereafter, catches declined sharply and ended altogether in 1976 when commercial whaling was outlawed (Angliss *et al.* 2001). There are no reports of subsistence takes of fin whales from either Alaska or Russia. Since population estimates are unreliable, no value for PBR has been calculated.

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

Prior to 1999, no fin whale mortalities were recorded by observers in the BSAI and GOA groundfish trawl, longline, and pot fisheries (Hill and DeMaster 1999). However, in 1999, one fin whale was killed incidental to the BSAI trawl fishery, resulting in an extrapolated take of three whales from this fishery in 1999 (Angliss *et al.* 2001). From this one recorded take, the average incidental take of fin whales is estimated to be 0.6 whales per year between 1995 and 1999. There are no records of fin whale entanglement in fishing gear.

Comparative Baseline

Fin whales are an endangered species due to commercial whaling prior to 1976. There are no reliable population estimates or trend information for the northeast Pacific stock. They are not hunted for subsistence purposes. Diets of fin whales overlap to a small extent with species taken by the groundfish fisheries, but they do not appear to interact with the fleet on a regular basis (Table 3.8-12).

Status for Cumulative Effects Analysis

Because of their "endangered" status under the ESA and their residence in the action area, fin whales will be considered in the analysis of Alternative FMPs in Chapter 4. However, since they interact so infrequently with the groundfish fisheries, fin whales will be considered in the baleen whales species group.

3.8.13 Sei Whale (*Balaenoptera borealis*)

Distribution and Abundance

Sei whales are found in all oceans, but remain in more temperate waters than other baleen whales. They migrate long distances from low latitude winter areas to higher latitude summer grounds, but infrequently venture into cold, polar waters (Gambell 1976 and 1985b, Rice 1998). In the North Pacific Ocean, the summer range extends from southern California to the GOA and across the North Pacific south of the Aleutian Islands, extending into the Bering Sea only in the deep southwestern Aleutian Basin (Gambell 1985b, Rice 1998). There is evidence, from catch data, of differential migration by reproductive class, with pregnant females leading the migration into and out of the feeding grounds (Masaki 1976). There is also evidence of segregation by age, with a higher proportion of older and larger sei whales in the higher latitudes (Gambell 1985b). Sei whales are usually seen alone or in small groups, and the species does not appear to have a well-defined social structure (Tomilin 1957).

The IWC recognizes only one stock of sei whales in the North Pacific for management purposes, although there is evidence that more than one stock exists (Horwood 1987, Masaki 1977, Donovan 1991). Based on data from commercial whaling operations, the North Pacific population of sei whales was estimated to be from 42,000 to 62,000 animals before commercial whaling began in the 1800s. In 1974, after whaling was prohibited, the population was estimated to be between 7,260 and 12,620 (Tillman 1977, Carretta *et al.* 2001). Current abundance or trends are not known for stocks in the North Pacific.

Trophic Interactions

In the northern North Pacific, sei whales feed primarily on copepods (*Calanus cristatus, C. plumchrus*, and *C. pacificus*), euphausiids *(Thysanoessa inermis* and *T. longipes)*, small schooling fish such as saury and squid (Kawamura 1973, Nemoto 1959, Nemoto and Kawamura 1977). Sei whales use both engulfing and skimming feeding strategies, depending on the type of prey (Nemoto 1959 and 1970, Perry *et al.* 1999b).

Management Overview

Sei whales fall under the jurisdiction of the NOAA Fisheries PRD. Sei whales are listed as endangered under the ESA and a joint recovery plan for fin and sei whales was drafted in 1998 (NMFS 1998c). The long-term goal of this plan is to promote the recovery of these species to the extent that they are removed from ESA-listing. Critical habitat has not been designated for the species. Because of its endangered status, the eastern North Pacific stock is automatically considered a depleted and strategic stock under the MMPA. For MMPA stock assessments, sei whales in the eastern North Pacific (east of 180°W) are considered a separate stock; however, there are no abundance estimates for sei whales along the west coast of the U.S. or in the eastern North Pacific (Barlow *et al.* 1997).

Past and Present Human Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Between 1946 and 1987, an estimated 61,500 sei whales were harvested throughout the North Pacific (Carretta *et al.* 2001). However, there is some evidence that Soviet whalers may have over-reported catches of about 3,500 sei whales, presumably to hide illegal catches of other protected species (Doroshenko 2000). Commercial whaling was prohibited in U.S. waters in 1972 by the MMPA, and sei whales were given full protection from hunting by the IWC in 1976.

Direct Mortality from Incidental Take in External Fisheries

Human-caused mortalities (i.e., incidental to commercial fishing operations or from ship strikes) have not been reported in the North Pacific (Perry *et al.* 1999b).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take in the 1990 to 1997 BSAI and GOA groundfish trawl, longline, and pot fisheries, but no mortalities or serious injuries of sei whales were observed (Hill and DeMaster 1999).

Comparative Baseline

Sei whales are listed as an endangered species under the ESA due to commercial whaling in the mid-1900s. Population trends and current status are unknown. Diets of sei whales do not overlap with species taken by the groundfish fisheries, and they do not appear to interact with the fleet on a regular basis. No incidental take from commercial fisheries has been reported (Table 3.8-13).

Status for Cumulative Effects Analysis

Because of their endangered species status and their presence in the action area in summer, sei whales will be considered in the analysis of Alternative FMPs in Chapter 4. However, since they interact so infrequently with the groundfish fisheries, sei whales will be considered in the baleen whales species group.

3.8.14 Minke Whale (*Balaenoptera acutorostrata*)

Distribution and Abundance

Minke whales are distributed worldwide. In the eastern North Pacific, minkes are relatively common in the Bering and Chukchi seas and in the inshore waters of the GOA, but are not considered abundant elsewhere (Stewart and Leatherwood 1985, Mizroch 1992). Minke whales in Alaska are managed as a separate stock from those in California, Oregon, and Washington. However, few data are available on the migratory behavior and apparent home ranges of eastern North Pacific minke whales (Dorsey *et al.* 1990). No estimates have been made for the number of minke whales in the North Pacific. (Angliss *et al.* 2001). In the central Bering Sea, 936 minke whales (95 percent confidence interval 473 to 1852) were observed in 1999 (Moore *et al.* 2000).

No estimates have been made for the number of minke whales in the entire North Pacific. In the central Bering Sea, an estimated 936 minke whale (95 percent confidence interval 473 to 1,852, coefficient of variation = 0.35) were observed during the summer of 1999 (Moore *et al.* 2000). However, this covers only a small portion of the Alaska stocks range. Seabird surveys around the Pribilof Islands indicated an increase in local abundance of minke whales between 1975 to 1978 and 1987 to 1989 (Baretta and Hunt 1994). No data exist on trends in abundance in Alaskan waters (Angliss *et al.* 2001).

Trophic Interactions

Prey preferences of eastern North Pacific minke whales are unknown. Data from western North Pacific minke whales indicate that, depending on season and region, pelagic schooling fishes (herring, pollock, mackerel, anchovy, and saury in particular) make up over 90 percent of the total prey by weight (Kasamatsu and Hata 1985, Tamura *et al.* 1998).

Management Overview

Minke whales fall under the jurisdiction of the NOAA Fisheries PRD and are protected under the MMPA. They are not listed as a depleted or strategic stock and are not listed under the ESA.

Past and Present Human Effects and Management Actions

<u>Direct Mortality: Harvest and Other Intentional Take</u>

Minke whales were not targeted by commercial whalers in the eastern North Pacific. Subsistence takes of minkes by Alaska Natives have been documented but occur only rarely. The last recorded subsistence take was two whales in 1989 (Angliss *et al.* 2001).

Direct Mortality from Incidental Take in External Fisheries

Minke whales have been taken in small numbers incidental to coastal set gillnet and offshore drift gillnet fisheries, but quantitative information is unreliable because these fisheries rely on self-reported interactions rather than independent observers (Angliss *et al.* 2001).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take during the 1990 to 1999 BSAI and GOA groundfish trawl, longline, and pot fisheries. No mortalities were observed during that time. One minke whale mortality was observed at Shelikof Strait in 1989 in a JV groundfish trawl fishery, the predecessor to the current Alaska groundfish trawl fishery (Hill and DeMaster 1999). In September 2000, one minke whale mortality occurred in the Bering Sea groundfish trawl fishery (NMFS 2000b).

Comparative Baseline

Minke whales in the eastern North Pacific are not listed under the ESA and have never been targeted by commercial whaling. Population trends and current status are unknown, although the species is relatively common in the action area based on the frequency of sightings. Diets of minke whales apparently overlap partially with species taken by the groundfish fisheries, but minkes do not appear to interact with the fleet on a regular basis. One minke whale mortality occurred in the Bering Sea groundfish trawl fishery in September 2000 (NMFS 2000b) (Table 3.8-14).

Status for Cumulative Effects Analysis

Because of their presence in the action area and partial overlap in diet with the groundfish fisheries, minke whales will be considered in the analysis of Alternative FMPs in Chapter 4. However, since they interact so infrequently with the groundfish fisheries, minke whales will be considered in the baleen whales species group.

3.8.15 Humpback Whale (*Megaptera novaeangliae*)

Distribution and Abundance

Humpback whales are common in Alaska waters. Their historic summer range in the North Pacific Ocean encompasses coastal and inland waters around the Pacific Rim from California north to the GOA and the Bering Sea and west along the Aleutian Islands to the Kamchatka Peninsula (Johnson and Wolman 1984, Nemoto 1957, Tomilin 1967, Perry *et al.* 1999a). Through a variety of information sources (surveys, photo-identifications, genetics), it has become evident that at least three relatively separate populations exist in the U.S. EEZ. Each population migrates between its respective summer/fall feeding areas and its winter/spring calving and mating areas (Calambokidis *et al.* 1997, Baker *et al.* 1998). These apparent populations are considered as separate stocks for management purposes: the western North Pacific stock, central North Pacific stock, and the Washington-Mexico stock. The western and central North Pacific stocks are seasonally distributed in Alaskan waters. The western North Pacific stock winters in Japanese waters and probably migrates to the BSAI to feed in the summer (Berzin and Rovnin 1966, Nishiwaki 1966, Darling 1991). The central North Pacific stock winters in Hawaiian waters and summers in northern British Columbia, southeast Alaska, PWS, and west to at least Kodiak Island (Baker *et al.* 1986, Baker *et al.* 1990, Perry *et al.* 1990, Calambokidis *et al.* 1997).

The North Pacific population of humpbacks has been estimated at 15,000 animals before commercial whaling began in the late 1800s. By the time whaling was prohibited in 1966, there may have been only 1000 animals left (Rice 1978b). Baker and Herman (1987) estimated that the central North Pacific stock contained about 1,400 animals between 1980 and 1983. That estimate is questionable, however, due to the opportunistic nature of the survey methodology and the small sample size. A more recent abundance estimate was based on data collected by nine independent research groups that conducted photo-identification studies in the three wintering areas (Mexico, Hawaii, and Japan). Using photographs from 1991 to 1993, abundance estimates for the western North Pacific stock and the central North Pacific stock were calculated to be 394 (coefficient of variation = 0.084) and 4,005 (coefficient of variation = 0.095), respectively (Angliss *et al.* 2001; Calambokidis *et al.* 2001). There is no trend information for the western North Pacific stock. The central North Pacific stock appears to be increasing, although the rate of increase is unknown due to the uncertainty of the earlier estimate (Baker and Herman 1987, Hill and DeMaster 1999).

Trophic Interactions

Humpback whales exhibit site fidelity to feeding areas, and return year after year to the same feeding location (Baker *et al.* 1987, Clapham *et al.*1993). There is very little interchange between feeding areas (Baker *et al.* 1986, Calambokidis *et al.* 1996, 2000, 2001, Waite *et al.* 1999, Urban *et al.* 2000). Prey in the North Pacific and Bering Sea include small schooling fishes, euphausiids, and other large zooplankton (Nemoto 1959, Bryant *et al.* 1981, Dolphin and McSweeney 1983). Euphausiid prey include *Thysanoessa inermis. T. longipes, T. spinifera* and to a lesser extent *T. raschii* (Kawamura 1980, Tomilin 1957). Fish preference include Atka mackerel, pollock, herring, anchovy, eulachon, capelin, saffron cod, sand lance, Arctic cod, rockfish, and salmon species (Nemoto 1959, Tomilin 1957, Kawamura 1980). Atka mackerel ranging in size from 5.9 to 11.7 inches (15 to 30 cm) were considered the preferred prey of humpback whales in the Aleutian Islands west of Attu Island and south of Amchitka Island (Nemoto 1959). Distribution of whales in the inland waters of southeast Alaska appears to be determined primarily by distribution of their main prey: herring and euphausiids. Humpbacks use a variety of feeding behaviors to catch food including exhalation of columns of bubbles that concentrate prey, herding of prey, and lunge feeding. Humpbacks return year after year to the same feeding location with very little interchange between feeding areas (Baker *et al.* 1986, Calambokidis *et al.* 1996, Waite *et al.* 1999, Urban *et al.* 2000).

Management Overview

Humpback whales fall under the jurisdiction of the NOAA Fisheries PRD. They are listed as endangered under the ESA and are automatically considered a depleted and strategic stock under the MMPA. An ESA recovery plan has been written (NMFS 1991b). The primary goal of this plan is to assist humpback whale populations to grow and occupy areas where they were historically found. Critical habitat has not been designated for this species.

Past and Present Human Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Intensive commercial whaling took more than 28,000 humpbacks from the North Pacific during the 1900s (Rice 1978b). This is likely an underestimate because of under-reporting of Soviet catches (Yablokov 1994).

At the present time, the calculated PBR for the western North Pacific stock of humpbacks is less than one animal per year while PBR for the central North Pacific stock is 7.4 animals per year (Angliss *et al.* 2001).

Direct Mortality from Incidental Take in External Fisheries

Brownell *et al.* (2000) found records of six humpbacks taken as bycatch by Japanese and Korean fisheries between 1995 and 1999. In addition, two strandings were reported during this period that are assumed to be the result of fishery entanglement. Samples of whale meat sold in Japanese and Korean markets also indicate that humpbacks are being sold. Although there are questions regarding the nature of these mortalities, the data indicate a minimum incidental take of 1.1 to 2.4 humpbacks per year from the western North Pacific stock (Angliss *et al.* 2001).

A small proportion of various Hawaiian fisheries has also been monitored by independent observers. One humpback was observed entangled in longline gear in 1991 and is presumed to have died. Another humpback was taken in Hawaiian longline gear in 1993. In southeast Alaska, purse seine and drift gillnet salmon fisheries have reported incidental takes of humpbacks in 1989, 1994, and 1996. In addition, over 25 humpbacks were found stranded or swimming with entangled fishing gear in Hawaii and Alaska between 1994 and 1999. Some of the whales were freed, apparently uninjured, but others are considered to have died. All fishery-related takes in Alaska and Hawaii, excluding the federal groundfish fisheries, are estimated to average 3.1 whales per year. These mortality rates from both Hawaii and Alaska are considered to be minimums based on the small number of observers and the unreliability of self-reported data (Angliss *et al.* 2001).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take in the 1990 to 1999 BSAI and GOA groundfish trawl, longline, and pot fisheries. One humpback whale mortality was observed in the BSAI trawl fishery in 1998 and one in 1999, resulting in an extrapolated average mortality of 0.4 humpbacks per year during this period. It is not known whether these incidental takes derived from the western or central stocks so the takes are counted against the PBRs for both stocks (Angliss *et al.* 2001).

Direct Mortality from Ship Strikes

Ship strikes and interactions with vessels unrelated to fishing have also accounted for humpback mortality. In the central North Pacific stock, four ship strikes were recorded between 1995 and 1999 for an average of 0.8 humpback mortalities per year (Angliss *et al.* 2001).

Indirect Effects from Disturbance

Coincident to fishing activity, as well as vessel transit, is the routine use of various sonar devices. The sounds produced by these devices may be audible to baleen whales and suggest disturbance sources. Wintering humpback whales have been observed reacting to sonar pulses by moving away (Maybaum 1990, 1993), although few other reactions have been documented. There is concern that noise generated by vessels as well as for research (such as the U.S. Navy's Low Frequency Active sonar program and NOAA's Acoustic Thermometry of Ocean Climate program) may be impacting humpback whales throughout their range. Research on this issue is underway (Angliss *et al.* 2001).

Humpbacks are also subject to a growing whale-watching industry in both Hawaii and Alaska. Regulations concerning minimum approach distances and operation guidelines for whale-watching vessels have been established, but there is still concern that the whales may abandon preferred habitats to avoid persistent whale-watching activity (Angliss *et al.* 2001). This issue is attracting attention in certain popular visitor areas such as Glacier Bay National Park in Alaska.

Comparative Baseline

Humpback whales are listed as an endangered species under the ESA due to commercial whaling in the 1900s. Recent population estimates for the western and central North Pacific stocks are 394 and 4,005 respectively. Trends for the western stock are unknown. The central stock is thought to be increasing but at an unknown rate. Diets of humpback whales do not generally overlap with species taken by the groundfish fisheries. There have been numerous cases of incidental take related to commercial fisheries in the past ten years, including two observed mortalities from BSAI groundfish trawls since 1998 (Table 3.8-15).

Status for Cumulative Effects Analysis

Because of their endangered species status and their presence in the action area in summer, humpback whales will be considered in the analysis of Alternative FMPs in Chapter 4. However, although they interact frequently with commercial fisheries, and the effects among management alternatives would be difficult to discern from other baleen whales, humpback whales will be considered in the baleen whales species group.

3.8.16 Gray Whale (*Eschrichtius robustus*)

Distribution and Abundance

Gray whales (*Eschrichtius robustus*) occur across the coastal and shallow water areas of both the eastern and western reaches of the North Pacific Ocean, as well as the Bering, Chukchi, and Beaufort seas. Two stocks are recognized: the western Pacific or Korean stock, which is considered rare and endangered, and the eastern North Pacific stock, which was removed from the list of endangered wildlife in 1994 (Rugh *et al.* 1999). Only the eastern North Pacific stock is found in the BSAI and GOA groundfish management areas.

The eastern North Pacific Ocean population winters in the warm coastal waters of Baja California and the southern Gulf of California. From late February to May, the whales begin a northward migration, following the coast closely. They enter the Bering Sea, primarily through Unimak Pass, mostly in April and May, and continue moving along the coast of Bristol Bay. After passing Nunivak Island, they head toward St. Lawrence Island, arriving there in May or June. The whales disperse to spend the summer feeding in shallow waters (usually less than 200 ft deep) of the northern and western Bering Sea and the Chukchi Sea. Gray whales begin their southward migration in mid-October, passing through Unimak Pass between late October and early January. They arrive in Baja California mainly in December and January (Frost 1994).

Gray whales were nearly exterminated by commercial whaling in the 1800s and 1900s, and may have numbered only in the hundreds by the time whaling was prohibited in 1946 (Angliss *et al.* 2001). Since then, they have recovered to pre-exploitation abundance. The eastern North Pacific stock abundance has been estimated by conducting shore-based counts of whales migrating past the coast of California. For the 1997 to 1998 census period this estimate was 26,635 whales (coefficient of variation = 10 percent) (Hobbs and Rugh 1999). This estimate was significantly greater than the estimate from 1992 to 1993 (17,674). Some of the difference could be attributed to survey or migration pattern variations rather than real changes in population (Angliss *et al.* 2001). A recent estimate of the population trend calculated an annual rate of increase of 2.4 percent between 1967 and 1998 (Breiwick 1999). However, there are indications that this increase may have leveled off and is perhaps declining as this population reaches the carrying capacity of its environment, estimated to be between 20,000 to 28,000 animals.

On average, there have been about 38 reports of stranded gray whales per year from 1995 to 1998 (Norman *et al.* 2000). However, there were unusually high mortality rates of greater than 270 in 1999 (LeBoeuf *et al.* 2000; Norman *et al.* 2000) and greater than 300 in 2000 (NMML unpublished data[c]). Based on a 5 percent annual natural mortality level for gray whales (Wade and DeMaster 1996), estimated average mortality rates would likely be 800 to 1200 animals for a population of 22,000 to 26,000 (Norman *et al.* 2000). Because stranding reports reflect only a small portion of total mortality, the high rates observed in 1999 and 2000 probably indicate large die-offs in these two years. Reports of emaciated whales (LeBoeuf *et al.* 2000, Perryman and Lynn 2002) and low calf production (Perryman *et al.* 2002) are suggestive of a deterioration in available resources, such as benthic amphipods in primary feeding areas of the Bering and Chukchi seas. This may be associated with the high abundance of gray whales, which may be approaching their carrying capacity (Moore *et al.* 2001). But in 2000 and 2001, relatively few strandings were found, even though the search effort has increased in recent years. Migration counts during 2001 and 2002 resulted in a preliminary abundance estimate of about 17,500 whales. While this number is less than a few years before, scientists expect populations at carrying capacity to fluctuate as environmental conditions change, and the population experiences good years and bad years (NMFS 2002e).

Trophic Interactions

Gray whales are the only baleen whales that are mainly bottom feeders. They feed by sucking up sediment from the sea floor and filtering out food items with their baleen. Gray whales eat primarily benthic amphipods in the Bering and Chukchi seas, while other feeding locations may provide more opportunistic feeding (Nerini 1984). Several studies have found *Ampelisca macrocephala, Lembos arcticus, Anonyx nugax, Pontoporeia femorata, Eusirus* spp., and *Atylus* spp. to be the most dominant species in stomach contents (Zimushko and Lenskaya 1970, Rice and Wolman 1971, Tomilin 1957, Nerini 1984, Lowry *et al.* 1982). The ratio of each species varied between areas but one of the amphipod species usually accounted for 80 to 90 percent of the food intake for each meal. Other stomach contents included small percentages of sponges, ascidians, hydrozoans, anthozoans, polychaetes, priapulids, sipunculids, isopods, decapod crustaceans, gastropods, bivalves, holothuroidians, echinoderms, cumaceans, fish larvae, sand, mud, algae, wood fragments, silt, pebbles, and kelp, probably ingested incidental to bottom feeding (Zimushko and Lenskaya 1970, Rice and Wolman 1971, Tomilin 1957, Nerini 1984, Lowry *et al.* 1982). There were no significant differences found in prey species between immature and adult whales or between males and females. The total estimated food consumption by the population in the EBS is 271,500 mt, which included only a trace amount of fish (Perez and McAlister 1993). Concentrations of 12,000 to 20,000 amphipods per square yard have been found in the southern Chukchi Sea and northern Bering Sea where the whales feed. The estimated daily consumption of an adult gray whale is about 2,600 pounds. In the approximately five months spent in Alaska waters, one whale eats about 396,000 pounds of amphipod crustaceans (Frost 1994). Previous studies have reported estimates of annual food consumption in the Bering Sea region as 850,000 mt (Zimushko and Lenskaya 1970), 2,700,000 mt to 3,240,000 mt (Frost and Lowry 1981), and 571,000 mt to 1,674,000 mt (Nerini 1984). In general, gray whales feed little during their annual migration (Rice and Wolman 1971).

Management Overview

Gray whales fall under the jurisdiction of the NOAA Fisheries PRD, and are protected under the MMPA. Gray whales were originally listed as endangered under the ESA, but were delisted in 1994 (Rugh *et al.* 1999). The IWC sets an annual quota for subsistence take by aboriginal peoples but no other intentional take is permitted.

Past and Present Human Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

In the 1800s and early 1900s gray whales were heavily hunted. First on their calving grounds and later, with the advent of modern technology, in other areas. It is estimated that by the 1930s only a few hundred to a few thousand remained. In 1948 the International Convention for the Regulation of Whaling banned all hunting of gray whales except by aboriginal people (Frost 1994).

Subsistence hunters from Alaska and Russia have traditionally harvested whales from this stock. In Alaska, Native hunters took only two gray whales in the past decade, both in 1995 (Angliss *et al.* 2001). Russian subsistence hunters took an average of 76 gray whales per year between 1994 and 1998. The 1968 to 1993 average take for Russian and Alaska Natives combined was 159 whales per year (Angliss *et al.* 2001). In 1997, the IWC approved a 5-year quota of 620 gray whales (140 per year maximum) for these Native hunters. The calculated PBR for the eastern North Pacific stock is 575 whales per year (Angliss *et al.* 2001).

Direct Mortality from Incidental Take in External Fisheries

In state-managed and tribal gillnet fisheries along their migration corridor, small numbers of gray whales become entangled in the nets and are either lost or injured as a result. The total number of gray whale incidental takings averages about 6 per year, including about 4 per year that are found entangled in fishing gear that cannot be attributed to a specific fishery. These numbers are considered minimal estimates since these types of fisheries are not monitored by observers in most areas, including Canada and Alaska (Angliss *et al.* 2001).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take on the 1990 to 1998 BSAI and GOA groundfish trawl, longline, and pot fisheries. No gray whale mortalities were observed (Hill and DeMaster 1999).

Indirect Effects through Changes in Prey Availability

Bottom trawls on the EBS shelf operate during the summer when most of the eastern stock of gray whales uses that area as a feeding ground. The impact of bottom trawling activity on the availably of benthic prey, the primary food source for gray whales, is unclear. However, population-level impacts do not appear to have occurred in light of increasing gray whale populations concurrent to decades of bottom trawling on the EBS shelf (Rugh *et al.* 1999).

Comparative Baseline

Gray whales were once an endangered species under the ESA due to whaling but their population has been increasing, and they were delisted in 1994. They are rarely taken for subsistence by Alaska Natives, but are still hunted by Natives in Russian waters. Diets of gray whales do not overlap with species taken by the groundfish fisheries, and they do not appear to interact with the fleet on a regular basis (Table 3.8-16).

Status for Cumulative Effects Analysis

Because of their protected status under the MMPA and their residence in the project area in summer, gray whales will be considered in the analysis of Alternative FMPs in Chapter 4. However, since they interact so infrequently with the groundfish fisheries, gray whales will be considered in the "baleen whales" species group.

3.8.17 Northern Right Whale *(Eubalaena japonica)*

Distribution and Abundance

Right whales historically summered in Alaska waters, mostly between 50° and 60°N from April to September, with a peak in sightings in coastal waters in June and July (Maury 1852, Townsend 1935, Omura 1958, Klumov 1962, Omura *et al.* 1969). Important historical concentration areas in Alaska appear to have been located in the GOA, especially south of Kodiak Island (Rice and Wolman 1982), and in the eastern Aleutian Islands and southern Bering Sea shelf waters (Braham and Rice 1984, Scarff 1986). Migration and winter distribution patterns are unknown, but a few sightings have been made as far south as 27°N in the eastern North Pacific and near Hawaii. Data from the NMMLs POP (1997) include right whale sightings in Alaskan waters (from 1979 to 1997) during all seasons except winter. Vessel and aerial surveys conducted during July from 1997 to 2000 reported lone animals or small groups of right whales in western Bristol Bay (Perryman *et al.* 1999, Moore *et al.* 2000, LeDuc *et al.* 2000, Angliss *et al.* 2001).

The IWC currently recognizes two species of northern right whales: *Eubalaena glacialis* in the North Atlantic and *E. japonica* in the North Pacific (IWC 2000), based upon the findings of recent genetic analyses (Rosenbaum *et al.* 2000). Stock structure in the North Pacific is unknown, and there are insufficient data about where calving and breeding take place to confirm or deny the existence of more than one stock in the North Pacific (Perry *et al.* 1999a). The pre-exploitation population estimate for this stock was approximately 11,000 animals (NMFS 1991a). Only a few individuals are believed to have survived the period of commercial whaling (Rice 1974). There have been only 14 individuals photographed in 1998 to 2000 aerial surveys, and two of these were repeats. This mark-recapture ratio is consistent with a very small population (Angliss *et al.* 2001). A reliable estimate of current abundance for the North Pacific right whale stock is not available (but is expected to be very small), nor is there any estimate of population trend (Ferrero *et al.* 2000, Angliss *et al.* 2001).

Trophic Interactions

Right whales in the North Pacific are known to prey on a variety of zooplankton species including *Calanus marshallae, Euphausia pacifica, Metridia* spp., and copepods of the genus *Neocalanus* (Omura 1986). Zooplankton sampled near right whales seen in the EBS in July 1997 included *Calanus marshallae*, *Pseudocalanus newmani*, and *Acartia longiremis* (Tynan 1999).

Management Overview

Northern right whales fall under the jurisdiction of the NOAA Fisheries PRD. They are listed as endangered under the ESA and are automatically considered a depleted and strategic stock under the MMPA. The 1991 ESA Recovery Plan for northern right whales (NMFS 1991a) is currently undergoing revision to include recent findings. Critical habitat has not been designated for this species. However, in November of 2000, NOAA Fisheries received a petition from the Center for Biological Diversity to designate critical habitat for this species. The petitioners asserted that the southeast Bering Sea shelf from 55 to 60° N should be considered critical habitat. On June 1, 2001, NOAA Fisheries found the petition to have merit (66 FR 29773) and is considering whether the petition is warranted under the ESA (Angliss and Lodge 2002). In February 2002, NOAA Fisheries determined that the petition was not warranted, but agreed to reevaluate the petition after a review of 2002 right whale surveys and research. Currently, NMML and NOAA Fisheries Alaska Region are reviewing the data and will schedule a meeting with NOAA Fisheries Northeast Region to discuss appropriate criteria for critical habitat designation for the right whales in the Pacific and Atlantic Oceans. NOAA Fisheries reevaluation of the 2000 petition will commence soon afterwards.

Past and Present Human Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Right whales are large, slow-swimming, tend to congregate in coastal areas, and have a thick layer of blubber which enables them to float when killed. These attributes made them a preferred species for whaling, and their population was decimated by the late 1800s. Between 1835 and 1909, over 15,000 right whales were estimated to be taken by U.S. registered whaling vessels; most of these whales were taken before 1875 (Angliss *et al.* 2001). Since 1931, the northern right whale has been protected from commercial whaling internationally, first under the League of Nations Convention and since 1949 by the IWC. However, reports from Russia indicate that Soviet whalers continued to harvest northern right whales illegally until 1971 (Zemsky *et al.* 1995, Tormosov *et al.* 1998).

Direct Mortality from Incidental Take in External Fisheries

Two right whale deaths reportedly occurred in the Russian gillnet fishery, one in 1983 and one in 1989 (NMFS 1991a, Kornev 1994). No incidental takes of right whales have been reported in other North Pacific fisheries (Ferrero *et al.* 2000, Angliss *et al.* 2001). Ship strikes and entanglement in fishing gear are important sources of mortality in the Atlantic stock of northern right whales, but their rarity in the Pacific has made it impossible to assess the susceptibility of the North Pacific stock to vessel strikes (Angliss *et al.* 2001).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take in the 1990 to 1997 BSAI and GOA groundfish trawl, longline, and pot fisheries, but no mortalities or injuries of right whales were observed (Hill and DeMaster 1999). Any mortality incidental to commercial fisheries would be considered significant (Angliss *et al.* 2001).

Comparative Baseline

Northern right whales are listed as an endangered species under the ESA due to commercial whaling in the 1800s and early 1900s. A recovery plan was finalized in 1991 (NMFS 1991a). The goal of this plan is to assist in the recovery of this species to the point where it is appropriate to remove it from ESA listing. One of the objectives of this plan is to reduce or eliminate injury or mortality caused by fishing and fishing gear. Population trends and current status are unknown although the population is believed to be very small based on the infrequency of sightings. Diets of right whales do not overlap with species taken by the groundfish fisheries, and they do not appear to interact with the fleet on a regular basis. No incidental take from the groundfish fisheries has been reported (Table 3.8-17).

Status for Cumulative Effects Analysis

Because of their endangered species status and their presence in the action area in summer, northern right whales will be considered in the analysis of Alternative FMPs in Chapter 4. However, since they interact so infrequently with the groundfish fisheries, right whales will be considered in the baleen whales species group.

3.8.18 Bowhead Whale (*Balaena mysticetus*)

Distribution and Abundance

The IWC recognizes five stocks of bowhead whales. The western Arctic stock is the only stock found in U.S. waters and is widely distributed in the central and western Bering Sea in winter (November-April). Bowhead whales are generally associated with the marginal ice front and found near the polynyas of Saint Matthew and Saint Lawrence Islands and the Gulf of Anadyr (Moore and Reeves 1993). From April through June, these whales migrate north and east, following leads in the sea ice in the eastern Chukchi Sea until they pass Point Barrow, and reach the southeastern Beaufort Sea where most spend June to September (Shelden and Rugh 1995). By late October and November they arrive in the Bering Sea (Kibal'chich *et al.* 1986, Bessonov *et al.* 1990), where they remain until the following spring migration. Historically, there were many records of bowhead whales in the Bering and Chukchi seas in summer (Townsend 1935), but the area appeared to be abandoned after commercial whaling decimated the population (Bogoslovskay *et al.* 1982, Bockstoce 1986). Some recent sightings in these waters in summer are thought to be whales from the expanding western Arctic stock (Rugh *et al.* 2000).

The western Arctic stock originally numbered about 18,000 whales and was reduced to about 3,000 after commercial whaling ended in the early 1900s (Woodby and Botkin 1993, Breiwick *et al.* 1984). Since 1978, counts of bowheads have been conducted from the sea ice north of Point Barrow during spring migration and have been corrected for whales missed for various reasons. Recent improvements in acoustical sampling have improved the detection and reliability of estimates (Angliss *et al.* 2001). From 1978 to 1993, the western Arctic stock increased from approximately 5,000 to 8,000 whales, a rate of 3.1 percent (Raftery *et al.* 1995). In 1993, the population was estimated to be 8,200 animals (IWC 1997). The most recent estimate derived from spring 2001 census was about 9,860 bowheads (IWC 2003).

Trophic Interactions

Prey species identified from bowhead whale stomach contents have included crustacean zooplankton, particularly euphausiids and copepods, ranging in length from 3 to 30 mm, and epibenthic organisms, mostly mysids and gammarid amphipods. Benthic species were relatively rare in bowhead stomach contents (Lowry 1993). Studies of stable isotope ratios in bowhead baleen suggest that the Bering and Chukchi seas are the preferred feeding habitats, rather than the Beaufort Sea (Lee and Schell 1999).

Management Overview

Bowhead whales fall under the jurisdiction of the NOAA Fisheries PRD. Bowheads are listed as endangered under the ESA and are listed as a depleted and strategic stock under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. In 1994, an amendment to the MMPA included provisions for the development of cooperative agreements between the USFWS, NOAA Fisheries, and Alaska Native organizations to conserve and co-manage marine mammals taken in subsistence hunts, including bowheads. The Alaska Eskimo Whaling Commission, representing ten whaling villages in northwestern Alaska, has signed a co-management agreement with NOAA Fisheries. Quotas for the bowhead hunts are established annually by the IWC.

Past and Present Human Effects and Management Actions

<u>Direct Mortality: Harvest and Other Intentional Take</u>

Bowheads have been a favored whale for hunting for at least 2,000 years because they produce large quantities of oil, baleen, meat, and muktuk (skin with blubber). They are also slow, non-aggressive, and float when they are killed. Bowheads are the most important subsistence animal, both culturally and nutritionally, for most northwestern Alaska Inupiaq and Yupik people. Alaska Eskimo whalers use handheld weapons and skin boats propelled by paddles to pursue bowheads during the spring hunt and motor-driven boats during the fall (Carroll 1994). The IWC has authorized Alaska Natives to strike up to 67 bowheads per year since

1978 but actual strikes have been less than the quota. The calculated PBR for this stock is 77 animals per year (Angliss *et al.* 2001).

As noted above, commercial whaling had a devastating impact on bowhead whale populations, including the western Arctic stock. Between 1848 and 1919, over 20,000 bowheads were estimated to have been harvested from pelagic and shore-based whaling operations in the Bering Sea (Woodby and Botkin 1993). The demand for baleen products, however, decreased dramatically in the early 1900s, largely due to changes in fashion. Fur trading and freighting voyages took the place of whaling ventures. In 1908, the baleen market collapsed, and by 1921, the last bowhead whale was taken at sea (Bockstoce and Burns 1993).

Direct Mortality from Incidental Take in External Fisheries

There are no Observer Program records of bowhead whale mortality incidental to commercial fisheries in Alaska (Hill and DeMaster 1999). However, there have been several cases of entanglements recorded (Philo *et al.*1992). These included three harvested bowheads that had scars attributed to rope entanglements, one bowhead found dead entangled in ropes similar to those used with fishing gear in the Bering Sea, and one bowhead with ropes on it that were attributed to rigging from a commercial offshore fishing pot, most likely a crab pot. There have been two other recent reports of bowheads with gear attached or marks that likely were from crab gear (J.C. George, North Slope Borough, personal communication). Aerial photographs in at least two cases have shown ropes trailing from the mouths of bowheads (NMFS unpublished data).

Indirect Effects through Oil Development

Increasing oil and gas development in the Arctic leads to increasing risk of various forms of pollution and noise from higher levels of boat traffic as well as exploration and drilling operations. There is evidence that bowheads are sensitive to noise from offshore development activities and that they will actively avoid seismic operations during their fall migration (Richardson *et al.* 1995, Davies 1997). In a recent ESA Section 7 consultation regarding the impact of the proposed Liberty oil development project in the Beaufort Sea, NOAA Fisheries acknowledged these impacts, but noted that the bowhead whale population was increasing and concluded that the development was not likely to jeopardize the continued existence of the bowhead whale (NMFS 2002f).

Comparative Baseline

Bowhead whales are an endangered species due to commercial whaling in the 1800s and early 1900s, but their population has been increasing in the project area since commercial whaling was stopped. They are an important subsistence resource for northern Alaska Natives. Diets of bowheads do not overlap with species taken by the groundfish fisheries, and they do not appear to interact with the fleet on a regular basis (Table 3.8-18).

Status for Cumulative Effects Analysis

Because of their "endangered" status under the ESA and their residence in the project area, bowhead whales will be considered in the analysis of Alternative FMPs in Chapter 4. However, since they interact so infrequently with the groundfish fisheries, bowhead whales will be considered in the baleen whales species group.

3.8.19 Sperm Whale (*Physeter macrocephalus*)

Distribution and Abundance

The sperm whale is one of the most widely distributed of any marine mammal species with their northernmost boundary at approximately 62°N in the Bering Sea (Leatherwood *et al.* 1982, Omura 1955). They are a pelagic species, known to dive deeper than 1,000 m and remain submerged for an hour or more. Females and young sperm whales usually remain in tropical and temperate waters year-round while males are thought to move north in the summer to feed in the BSAI and GOA area (Rice 1989).

For management purposes, the IWC has divided sperm whales in the North Pacific into eastern and western stocks. However, this division is not based on genetic or morphological differences, and the movement patterns of sperm whales are poorly known (Angliss *et al.* 2001). For stock assessment purposes, NOAA Fisheries has divided the North Pacific population into three management stocks (Angliss *et al.* 2001), only one (the Alaska stock) of which is considered relevant to this review. Sperm whales inhabit deeper pelagic waters as well as the broad continental shelf of the eastern Bering Sea, and nearshore environs in the eastern Aleutian Islands, GOA, and southeast Alaska (Rice 1989). Current and historic estimates of abundance, and therefore population trends, are considered unreliable. The abundance of sperm whales in the North Pacific, including whales from the separate California/Oregon/Washington stock, was reported to be 1,260,000 prior to whaling in the early 1900s, which was reduced to 930,000 whales by the late 1970s (Rice 1989). The number of sperm whales occurring within Alaskan waters is unknown.

Trophic Interactions

Sperm whales feed primarily on mesopelagic squid, but also consume octopi, other invertebrates, and fish (Tomilin 1967, Berzin 1971). Fish consumption becomes more evident near the continental shelf break and along the Aleutian Islands (Okutani and Nemoto 1964). Diet of sperm whales in the Bering Sea is comprised of 70-90 percent squids and 10-30 percent fish (Kawakami 1980). Fish eaten in the North Pacific included salmon, lantern fishes, lancetfish, Pacific cod, pollock, saffron cod, rockfishes, sablefish, Atka mackerel, sculpins, lumpsuckers, lamprey, skates, and rattails (Tomilin 1967, Kawakami 1980, Rice 1986a). Food consumption rates were calculated to be 3 percent of their total body weight per day in smaller sperm whales (mostly females and juvenile males) that weighed less than 13.6 mt (Lockyer 1981). Larger males weighing more may eat 3.5 percent of their total body weight per day. This number also increases sharply for pregnant and lactating females. Sperm whales consuming 2 to 4 percent of their total body weight per day equals0.9 to 2.7 mt for a 13 to 14 m animal (Kawakami 1980). The total estimated annual food consumption by the EBS population is 952,800 mt, of which 171,500 mt is fish (Perez and McAlister 1993). This estimate assumes: 1) about 15,000 adult male sperm whales summer in the EBS and Aleutian Islands region, 2) an average body mass of 26 mt, and 3) a diet of 82 percent cephalopods (mostly squid) and 18 percent fish (Perez 1990).

Management Overview

Sperm whales fall under the jurisdiction of the NOAA Fisheries PRD, and are protected under the ESA and the MMPA. Sperm whales are listed as endangered under the ESA and are listed as depleted and strategic under the MMPA. Although abundance estimates for this stock are not available, the species is considered unlikely to be in danger of extinction in the foreseeable future (Angliss *et al.* 2001). There are no critical habitats designated for this species.

Following reauthorization of the MMPA, with its emphasis on direct takes of marine mammals, NOAA Fisheries determined the approximate number of lethal takes each fishery imposed on ESA-listed species and issued exemption certificates for those with minimal impacts. The issuance of the certificates was a federal action subject to Section 7 consultation under the ESA. NOAA Fisheries issued a BiOp concerning the issuance of MMPA exemptions for all commercial fisheries (including the MSA groundfish fisheries) and concluded that the BSAI and GOA groundfish fisheries were not likely to jeopardize the continued existence and recovery of any listed species under the purview of NOAA Fisheries (NMFS 1979). The BiOp contained nine conservation recommendations, including monitoring of interactions.

Past and Present Human Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

Approximately 258,000 sperm whales in the North Pacific were harvested by commercial whalers between 1947 and 1987 (Perry *et al.* 1999a). However, this number may be negatively biased by as much as 60 percent due to under-reporting by Soviet whalers (Brownell *et al.* 1998). In particular, the Bering Sea population of sperm whales (consisting mostly of males) was severely depleted (Perry *et al.* 1999a). Catches in the North Pacific continued to climb until 1968, when 16,357 sperm whales were harvested, after which catches declined, in part through limits imposed by the IWC (Rice 1989). Sperm whales have been protected from commercial harvest by the IWC since 1985, although the Japanese continued to harvest sperm whales in the western North Pacific until 1988 after filing a formal objection with the IWC (Rice 1989, Reeves and Whitehead 1997). Sperm whales have never been reported to be taken by subsistence hunters (Rice 1989).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take of marine mammals in the 1990 to 1999 BSAI and GOA groundfish trawl, longline, and pot fisheries. Sperm whale interactions with longline fisheries operating in the GOA are known to occur and may be increasing in frequency. In 1996, NOAA Fisheries received reports from observers on commercial fishing vessels that sperm whales were preying on sablefish caught on commercial longline gear in the GOA. Three entanglements have been reported in the GOA longline fishery; one in 1997, 1999, and 2000. In two cases (1997 and 2000), the whales were released without serious injury; although the whale entangled in 1999 was alive when released, the extent of injuries to the whale is not known (Angliss *et al.* 2001, NMFS 2000b). Several observer reports have noted efforts by fishermen to deter sperm whales from their lines, including yelling at the whales and throwing seal bombs in the water. A pilot project using fishery observers in 1997 and 1998 was initiated to determine the extent of the interactions between sperm whales and the commercial longline fishery in Alaska (Hill *et al.* 1999).

Indirect Effects through Changes in Prey Availability

Sperm whale diets overlap with commercial fisheries harvests more than any other species of toothed whales, but the degree of overlap is at least partly because of direct interactions with longline gear. In addition to consuming primarily medium- to large-sized squids, sperm whales also consume some fish and have been observed feeding off longline gear targeting sablefish and halibut in the GOA. The interactions with commercial longline gear do not appear to have an adverse impact on sperm whales. Much to the contrary, the whales appear to have become more attracted to these vessels in recent years (Angliss *et al.* 2001).

Comparative Baseline

Sperm whales are divided into several stocks in U.S. waters, including the North Pacific stock that regularly inhabits Alaskan waters, but population estimates are considered unreliable. Sperm whales are listed as endangered under the ESA. No incidental take of sperm whales has been observed or reported in commercial fisheries, including the MSA groundfish fisheries, although there have been reports of fishermen trying to deter sperm whales from their longline catches in the GOA. NOAA Fisheries has issued a BiOp that concludes the groundfish fisheries do not jeopardize the recovery or survival of endangered sperm whales (Table 3.8-19).

Status for Cumulative Effects Analysis

Because of their endangered status under the ESA, sperm whales will be considered in the analysis of Alternative FMPs in Chapter 4. However, since they interact so infrequently with the groundfish fisheries, sperm whales will be considered in the toothed whale species group in the analysis of Alternative FMPs in Chapter 4.

3.8.20 Beaked Whales

- Baird's beaked whale (*Berardius bairdii*)
- Cuvier's beaked whale (*Ziphius cavirostris*)
- Stejneger's beaked whale (*Mesoplodon stejnegeri*), also known as the Bering Sea beaked whale

Distribution and History

Baird's beaked whales inhabit the North Pacific Ocean and adjacent seas, particularly in areas with submarine escarpments and seamounts (Kasuya and Ohsumi 1984, Ohsumi 1983). In the eastern North Pacific Ocean, the species range extends north into the Bering Sea at least as far as Saint Matthew Island and the Pribilof Islands, where stranded individuals have been found (Hanna 1920, Rice 1986b). An apparent break in distribution occurs in the eastern GOA, but there are sighting records from the mid-gulf to the Aleutian Islands and in the southern Bering Sea (Kasuya and Ohsumi 1984). According to Tomilin (1957), Baird's beaked whales arrive in the Okhotsk and Bering seas in April and May and are especially numerous in summer months. Baird's beaked whales are migratory, arriving in continental slope waters during summer and fall months when surface water temperatures are the highest (Dohl *et al.* 1983, Kasuya 1986). Baird's beaked whales are the most commonly observed beaked whales in their range, perhaps because they are relatively large and gregarious, traveling in schools composed of a few to several dozen animals (Balcomb 1989).

Cuvier's beaked whales are distributed in all oceans and most seas and range as far north as the Aleutian Islands (Moore 1963, Rice 1986b). No seasonal changes in distribution are apparent from stranding records, and morphological evidence is consistent with a single panmitic population from Baja California to Alaska (Barlow *et al.* 1997, Mitchell 1968).

Stejneger's beaked whales are rarely observed at sea, and distribution has been inferred from stranded animals (Loughlin and Perez 1985, Mead 1989). They are endemic to the cold temperate waters of the North Pacific Ocean, ranging from the coast of California north through the GOA and Aleutian Islands and into the Bering Sea as far as the Pribilof Islands and Commander Islands (Loughlin and Perez 1985). Stejneger's beaked whales are believed to inhabit deeper waters of the continental slope (Moore 1963, Morris *et al.* 1983) and frequent the Aleutian Basin and Aleutian Trench rather than the shallow waters of the northern or eastern Bering Sea (Mead 1989). This species is not known to enter the Arctic Ocean and is the only species of *Mesoplodon* in Alaskan waters (Loughlin and Perez 1985). Loughlin *et al.* (1982) reported that Stejneger's beaked whales sighted in the central Aleutian Islands were in groups of 5 to 15 individuals.

Due to the rarity of beaked whale sightings at sea, there are no reliable estimates for the number of Baird's, Cuvier's, or Stejneger's beaked whales in Alaska waters (Hill and DeMaster 1999). The abundance of Baird's beaked whales off the Pacific coast of Japan is about 5,000 animals (Kasuya *et al.* 1997, Miyashita 1986, Miyashita and Kato 1993), but it is unclear whether these animals mix with whales in Alaska waters.

Trophic Interactions

Prey species of Baird's beaked whales include benthic and epibenthic creatures such as squid, skate, grenadier, rockfish, and octopus (Pike 1953, Tomilin 1957), as well as pelagic species such as Atka mackerel, sardines, and Pacific saury (Nishiwaki and Oguro 1971). Judging by the benthic habits of their prey species, these whales routinely dive to depths of 1,000 m. Typical dives are 25 to 35 minutes in duration and dives of 45 minutes are not unusual (Balcomb 1989).

Squid are considered to be the primary prey of Cuvier's beaked whales, although few stomach samples have been analyzed. Fiscus (1997) reviewed the prey species identified in the stomach contents of animals found stranded on Amchitka Island and Kodiak Island (Foster and Hare 1990) and concluded that, in Alaskan waters, Cuvier's beaked whales feed mainly on cephalopod species that inhabit mesopelagic and deeper depths in the open ocean. However, he also noted that some of these squid species (mostly gonatids) have been taken in surface gillnets (Fiscus 1997, Fiscus and Mercer 1982, Kubodera *et al.* 1983).

The primary food of Stejneger's beaked whale is probably squid (Moore 1963, Tomilin 1957). Mead (1989) found trace quantities of squid beaks, but no fish in the stomachs of two stranded animals. Stomach samples collected from eleven animals stranded on Adak Island, Alaska, contained primarily cephalophods of the families Gonatidae and Cranchiidae (Walker and Hanson 1999).

Management Overview

All three species of beaked whales fall under the jurisdiction of the NOAA Fisheries PRD, and are protected under the MMPA. The Alaska stocks of Baird's, Cuvier's, and Stejneger's beaked whales are not listed as threatened or endangered under the ESA, nor are they considered depleted or strategic under the MMPA. Since there are no reliable estimates of population size, no values for PBR have been calculated (Hill and DeMaster 1999).

Past and Present Human Effects and Management Actions

Direct Mortality: Harvest and Other Intentional Take

There are no known subsistence hunts for any beaked whales in Alaska. Japanese whalers reportedly took an average of 54 Baird's beaked whales per year from 1992 to 1997, but it is not known whether these whales came from the Alaska stock (Angliss and Lodge 2002).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries observers monitored incidental take in the 1990 to 1997 BSAI and GOA groundfish trawl, longline, and pot fisheries, and no mortalities or serious injuries of Baird's, Cuvier's, or Stejneger's beaked whales were observed (Hill and DeMaster 1999). No other interactions between commercial fisheries and beaked whales have been recorded in Alaska.

Comparative Baseline

Three species of beaked whales are present in the project area but their ecology and population dynamics are very poorly known. There appears to be essentially no direct impacts of the groundfish fishery on these species. The past/present effect on beaked whales are summarized in Table 3.8-20.

Status for Cumulative Effects Analysis

Because they do not appear to interact directly with the groundfish fisheries, the three species of beaked whales will be considered as part of the toothed whales species group in the analysis of Alternative FMPs in Chapter 4.

3.8.21 Pacific White-Sided Dolphin (*Lagenorhychus obliquidens*)

Life History and Distribution

Pacific white-sided dolphins are found throughout the temperate North Pacific Ocean north to the GOA and west to Amchitka in the Aleutian Islands, but are rarely encountered in the southern Bering Sea. They are mostly pelagic but also occur occasionally on the continental shelf (Dahlheim and Towell 1994, Ferrero and Walker 1996, Hobbs and Jones 1993). These gregarious dolphins are found in groups of 5 to 100 individuals but can also occur in large schools of up to 1000 during migration (Evans 1977).

Of two stocks recognized in the North Pacific Ocean, the North Pacific stock is present in the BSAI and GOA management areas (Angliss *et al.* 2001). The most complete population abundance estimate for Pacific white-sided dolphins was calculated from line transect analyses applied to the 1987 to 1990 central North Pacific marine mammal sightings survey data (Buckland *et al.* 1993). That abundance estimate, 931,000 animals, more closely reflects a rangewide estimate rather than one that can be applied to either of the two management stocks off the west coast of North America. However, the portion of the Buckland *et al.* (1993) estimate derived from sightings north of 45°N in the GOA (26,880) can be used as the population estimate for this area. At present, there are no reliable data to estimate population trends for this species (Angliss *et al.* 2001).

Trophic Interactions

Prey of the Pacific white-sided dolphin include a variety of small schooling fish, such as sauries and lanternfish, and also squid, which they feed on at night (Walker and Jones 1993).

Management Overview

Pacific white-sided dolphins fall under the jurisdiction of the NOAA Fisheries PRD, and are protected under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. The calculated PBR for this species is 294 animals per year (Angliss *et al.* 2001). They are not listed as depleted or strategic under the MMPA.

Past and Present Effects and Management Measures

Direct Mortality from Incidental Take in External Fisheries

Between 1978 and 1991, thousands of Pacific white-sided dolphins were killed annually in the high seas driftnet fisheries (Angliss *et al.* 2001). However, these fisheries have been outlawed by international agreement since 1992. Self-reported records from state-managed salmon gillnet fisheries indicate a take of approximately two dolphins per year. However, data on these interactions are incomplete and most likely underestimate actual take (Angliss *et al.* 2001). Records of toothed whale entanglement in derelict fishing gear are almost entirely absent (Laist 1997).

Direct Mortality from Incidental Take in Groundfish Fisheries

Incidental take in the BSAI and GOA groundfish trawl, longline, and pot fisheries was recorded by NOAA Fisheries-certified observers from 1990 to 1998. One dolphin was taken in that time period in the BSAI trawl fishery and one in the BSAI longline fishery (Angliss *et al.* 2001). No dolphins were reported from any other fishery.

Comparative Baseline

The Pacific white-sided dolphin is a fairly common seasonal resident of the BSAI and GOA. There is very little overlap between their prey and species taken in the groundfish fisheries. Incidental take in the groundfish fisheries or other current fisheries is rare. The past/present effects on Pacific white-sided dolphin are summarized in Table 3.8-21.

Status of Cumulative Effects Analysis

Based on the lack of interaction between the groundfish fisheries and the Pacific white-sided dolphin, the low level of effect in other fisheries, and its lack of status under the MMPA or ESA, this species will be discussed only as part of the toothed whales species group in the analysis of FMP alternatives in Chapter 4.

3.8.22 Killer Whale (*Orcinus orca*)

Distribution and Abundance

Killer whales occur in stable social groups called pods. Three types of pods have been identified based on differences in behavior, ecology, and morphology (Bigg *et al.* 1987, Heyning and Dahlheim 1988). Resident pods are seen throughout much of the year in certain areas and concentrate on eating fish. Transient pods appear to move over broad areas and concentrate on marine mammal prey. A third type of killer whale, termed the offshore type, has been observed in southeast Alaska but is found in more southern waters (Angliss *et al.* 2001). Whales from the different pod types are genetically distinct and do not appear to interact with each other.

Killer whales have been observed in all oceans and seas of the world (Leatherwood *et al.* 1982) and are present throughout the BSAI and GOA area (Braham and Dahlheim 1982). They occur primarily in coastal waters, although they have been sighted well offshore (Heyning and Dahlheim 1988). Five stocks of killer whales have been recognized in U.S. Pacific waters, two of which are regularly found in Alaska. The eastern North Pacific northern resident stock (hereinafter referred to as the resident stock) occurs from British Columbia north and west through all Alaskan marine waters. The eastern North Pacific transient stock (hereinafter referred to as the transient stock) occurs from Washington north and west through all Alaskan marine waters (Angliss *et al.* 2001).

During the 1980s, photoidentification techniques were used for the first time in southeast Alaska and in PWS to determine the number of individuals and pods of killer whales occurring in those two areas. Following the EVOS, these studies were expanded and carried out on a more systematic basis. As a result of this research, 216 resident whales have been identified in British Columbia as of 1998; 99 have been identified in southeast Alaska as of 1999; and 362 resident whales have been identified in PWS and Kenai Fjords as of 1998. An additional 68 whales that have ties to other resident pods reside in waters west of Seward and are considered part of the resident stock (745 total known residents). Some whales that have only been studied through photographs have been provisionally determined to be residents, including 241 whales observed in waters west of Seward, so the total resident stock size in Alaska should be considered a minimum value. At present there are no reliable data on resident whale population trends (Angliss and Lodge 2002).

The number of transient killer whales in Alaska waters includes 219 that traverse British Columbia and southeast Alaska, 11 in PWS, and 21 in the eastern GOA (251 total known transients). An additional 14 whales in southeast Alaska and 53 whales in waters west of Seward have been provisionally identified as transients (based on morphological characteristics visible in photographs), so the total transient stock size in Alaska should be considered a minimum value. At present there are no reliable data on transient whale population trends (Dahlheim 2001, Angliss and Lodge 2002).

Trophic Interactions

Resident killer whales appear to feed primarily on a wide variety of fish such as salmon, herring, halibut, and cod. Transient killer whales are opportunistic feeders and have been observed to prey on virtually any large marine animal available (Jefferson *et al.* 1991). Killer whales also have been observed to prey on river otters, squid, and several species of birds. Killer whales may briefly leave the water to grab seals and sea lions from the shore. Animals within a pod often feed cooperatively. When preying on large animals such as gray or humpback whales, the killer whales may attack as a pack, tearing away at the prey animal from several angles. When preying on schooling fish, smaller killer whales may swim close to the beach to drive the fish from shallow waters out to the rest of the pod. Large groups of killer whales are often involved in hunting schools of fish. Smaller groups (two to eight animals) are more often used when preying on marine mammals such as seals or porpoises (Baird 2000).

Killer whales frequently take fish directly from commercial fishing gear as it is retrieved. Interactions with commercial longline fisheries are well-documented throughout the BSAI. Depredation rates of bottomfish by killer whales on longline catches, based on four different methods of calculation, suggested that whales took 14 to 60 percent of the sablefish, 39 to 69 percent of the Greenland turbot, and 6 to 42 percent of the arrowtooth flounder caught in commercial gear (Yano and Dahlheim 1995). Depredation rates can be so high in some areas that fishermen have abandoned particular fisheries even when they are still open.

Management Overview

Killer whales fall under the jurisdiction of the NOAA Fisheries PRD, and are protected under the MMPA. The resident stocks are not considered depleted or strategic, however, in 2003, NOAA Fisheries proposed to designate the AT1 group of killer whales as a depleted stock of marine mammals pursuant to the MMPA and is based on biological evidence that indicates that the group is a depleted population stock as defined by the MMPA (68 FR 206 [60899-60903] 2003). The MMPA established a moratorium on the taking of all marine mammals in the U.S. Killer whales are not taken for subsistence use by Alaska Natives. Because population estimates for killer whales are considered minimums and do not include provisionally classified whales, the calculated values for PBR are considered to be conservative estimates. For the resident stock (including 216 whales resident in British Columbia), the PBR is 7.2 whales per year, and for the smaller transient stock, the PBR is 2.8 whales per year (Angliss *et al.* 2001).

Past and Present Human Effects and Management Actions

<u>Direct Mortality: Harvest and Other Intentional Take</u>

Killer whales have not been targeted by commercial whalers or subsistence hunters.

Direct Mortality from Incidental Take in External Fisheries

Canadian fisheries that are most likely to interact with killer whales are not generally covered by independent observers. In 1994, the salmon gillnet fishery reported one killer whale hitting salmon gillnet gear but not becoming entangled. No killer whale mortalities have been reported in Canadian or state-managed fisheries (Angliss *et al.* 2001). Records of toothed whale entanglement in derelict fishing gear are almost entirely absent (Laist 1997).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries-certified observers monitored incidental take in the 1990 to 1999 BSAI and GOA groundfish trawl, longline, and pot fisheries. Incidental mortality of killer whales occurred in the BSAI groundfish trawl (including four observed takes and one during an unobserved trawl) and longline fisheries (including one observed take and two during unobserved hauls). For the most recent 5-year period, 1995 to 1999, the mean annual estimated mortality is 0.6 killer whales in the BSAI trawl and 0.8 whales in the BSAI longline fisheries. No killer whale mortality was observed in the pot fisheries. The combined mortality from the observed groundfish fisheries was therefore 1.4 whales per year (Angliss *et al.* 2001). While whales interacting with fisheries are most likely from resident pods (since they eat fish), no genetic testing has been done on whales incidentally taken in the groundfish fisheries to ascertain whether they were from resident or transient stocks. Because of this uncertainty, NOAA Fisheries counts the mortality from fisheries against the PBR for each of the stocks in its annual MMPA stock assessments (Angliss *et al.* 2001).

Direct Mortality from Vessel Strikes

In addition to mortalities caused by entanglement, killer whales are also susceptible to injury or mortality through vessel strikes. Several observers have reported large groups of killer whales following trawl vessels in the BSAI, sometimes for days at a time, in order to consume fish-processing wastes (Angliss *et al.* 2001). One killer whale was reported to be killed when it struck the propeller of a BSAI groundfish trawl vessel in 1998 (Angliss and Lodge 2002).

Direct Mortality from Illegal Shooting

Killer whales interact with longline fisheries in the BSAI and GOA where predation on catch, especially sablefish and Greenland turbot, occurs periodically as gear is being retrieved (Dahlheim *et al.* 1996). During the 1992 killer whale surveys in the BSAI and western GOA, 9 of 182 individual whales (4.9 percent) had evidence of bullet wounds, presumably from irate fishermen. Under provisions of the MMPA, it is illegal to shoot or injure killer whales. The relationship between wounding due to shooting and survival is unknown (Angliss *et al.* 2001). In PWS, the pod responsible for most of the fishery interactions experienced a 59 percent decline in its members (from 37 to 15) between 1986 and 1991. These whales are believed to have died but the cause of death, whether from gunshot wounds, the EVOS, or some other factor, is unknown (Dahlheim and Matkin 1994).

Indirect Effects through Changes in Prey Availability

Many factors may affect the abundance and distribution of the various fish species consumed by resident killer whales, including directed fisheries on those species and oceanographic fluctuations. Given the ability of whales to eat a variety of fish species and to hunt over large areas of water, it seems unlikely that resident whales find food limited. However, the large decline in the western stock of Steller sea lions over the past 20 years has led to concerns that transient killer whales may be experiencing a relative shortage of this preferred prey and have been switching to less preferred prey such as harbor seals, northern fur seals, and sea otters. The decline of all these species at the same time has led to concern about possible cascading effects of commercial fishing on predator-prey relationships. However, recent surveys of transient killer whales in PWS, outer Kenai Peninsula and Kodiak indicates the number of killer whales feeding off Steller sea lions is likely quite low (possibly <30). Additional data is needed to determine the actual contribution to the decline or recovery of Steller sea lions (Matkin *et al.* 2003).

Comparative Baseline

Killer whales are divided into two stocks that regularly inhabit Alaskan waters, the eastern North Pacific northern Resident stock (745 known residents) and the eastern North Pacific northern transient stock (251 known transients). Population estimates are made by identifying individual whales through photographic analysis but a substantial numbers of provisional identifications are not included in the estimates, so they should be considered minimums. Resident whales feed on various fish species and are likely the type that interacts directly with the fisheries through depredation of longline catches, incidental take in trawl and longline gear, and other effects. Transient whales concentrate on marine mammal prey and are being investigated for their potential role in the decline of Steller sea lion populations as well as other marine mammal species. The past/present effects on killer whales are summarized in Table 3.8-22.

Status for Cumulative Effects Analysis

Because of their frequent interaction with the groundfish fisheries and their possible role in the decline of several marine mammal species, killer whales will be considered as a separate species in the analysis of Alternative FMPs in Chapter 4.

3.8.23 Beluga Whale (*Delphinapterus leucas*)

Distribution and Abundance

Belugas are distributed throughout seasonally ice-covered arctic and subarctic waters of the northern hemisphere and are closely associated with open leads and polynyas in ice-covered regions (Gurevich 1980, Hazard 1988). Five stocks are recognized in Alaskan waters: Beaufort Sea, eastern Chukchi Sea, EBS, Bristol Bay, and Cook Inlet. The first four stocks winter in the drifting ice of the Bering Sea and segregate into four discrete stocks in the spring, with concentrations in Bristol Bay, Norton Sound, Kotzebue Sound, and Kasegaluk Lagoon (Hazard 1988, O'Corry-Crowe *et al.* 1997, O'Corry-Crowe and Lowry 1997). The Cook Inlet population occurs in the inlet and Shelikof Strait region, although wanderers have been seen east to Yakutat Bay and to Kodiak Island (Angliss and Lodge 2002).

Belugas can move long distances. Some migrate over 1,500 miles from the Bering Sea to the Mackenzie River estuary in Canada. In Bristol Bay, they sometimes swim over 100 miles per day. It is not unusual for belugas to ascend large rivers such as the Yukon, and they seem to be unaffected by salinity changes. Belugas are very vocal animals, producing a variety of grunts, clicks, chirps, and whistles which are used for navigating, finding prey, and communicating. Because of this, they have sometimes been called "sea canaries" (Lowry 1994).

Since belugas are closely associated with ice flows, aerial survey counts of whales must account for the number of animals under the ice or otherwise undetectable during surveys by multiplying actual counts by a correction factor. For belugas, this correction factor typically ranges between 2.5 and 3.27 (Frost and Lowry 1995). The most recent aerial survey of the Beaufort Sea stock was conducted in July 1992 and yielded a corrected estimate of almost 40,000 whales. This stock is considered to be stable or increasing (Hill and DeMaster 1999). Aerial surveys of the Chukchi stock in 1989 to 1991 yielded a corrected estimate of 3,710 whales. Based on comparisons of this data with more recent but less comprehensive surveys, this stock appears to be stable (Hill and DeMaster 1999). Aerial surveys of the eastern Bering stock were conducted yearly between 1992 to 1995 and yielded a corrected estimate of about 8,000 whales. Aerial surveys of Norton Sound were also conducted in 2000. Preliminary analysis of this data yielded a corrected estimate of 18,142 belugas in the eastern Bering stock (Angliss and Lodge 2002). This major difference in population estimates may be more of an artifact of differences in survey routes and conditions between years rather than an actual population change, but it does indicate that the population is at least stable or increasing (Angliss and Lodge 2002). Based on a series of aerial surveys, the corrected abundance estimate for the Bristol Bay stock was 1,555 in 1994, 2,133 in 1999, and 1,642 in 2000. These estimates are at or above the high end of estimates made in the 1950s and in 1983, suggesting that the Bristol Bay stock is at least stable and may be increasing (Angliss and Lodge 2002).

The Cook Inlet population has declined significantly from historic levels. A comprehensive aerial survey conducted in 1979 yielded a corrected estimated population of 1,293 whales (Hill and DeMaster 2000). This stock has been surveyed annually since 1994 and has shown a 50 percent decline from 1994 to 1999. The corrected estimate for this stock was 375 whales in 1999 and 435 whales in 2000 (Angliss and Lodge 2002). Offshore sightings of belugas in upper Cook Inlet have declined since 1994 and sightings in lower Cook Inlet have been dramatically reduced (Angliss and Lodge 2002).

Trophic Interactions

Alaskan belugas feed primarily on a variety of schooling and anadromous fishes that are sequentially abundant in coastal zones (e.g., herring, capelin, smelt, eulachon, cod, and salmon) during the spring and summer. Octopus, squid, shrimps, crabs, and clams are eaten occasionally. Fall and winter diets are not known (Frost and Lowry 1981, Lowry *et al.* 1985). Most feeding is done over the continental shelf and in nearshore estuaries and river mouths. In the shallow waters of Alaska, most feeding dives are probably to depths of 6 to 30 m and last two to five minutes. In captivity, beluga whale food consumption rates were found to vary with age, sex, and season. On average, the larger the animal the smaller the relative food intake; therefore, belugas at 200 kg consumed about 4.5 percent of their body weight per day while belugas at 1,400 kg needed only 1.2 percent (Kastelein *et al.* 1994).

Natural predators of belugas include polar bears and killer whales. They are also a traditionally significant part of Alaska Native subsistence hunts in some coastal communities.

Management Overview

Beluga whales fall under the jurisdiction of the NOAA Fisheries PRD, and are protected under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. In 1994, an amendment to the MMPA included provisions for the development of cooperative agreements between USFWS, NOAA Fisheries, and Alaska Native organizations to conserve and co-manage marine mammals. NOAA Fisheries has signed agreements with the Alaska Beluga Whale Committee for co-management of the four western Alaska beluga stocks and with the Cook Inlet Marine Mammal Commission (CIMMC) for co-management of that population.

The Cook Inlet population has declined significantly from historic levels and has become the subject of intensive co-management actions. NOAA Fisheries decided that listing the population under the ESA was not warranted (64 FR 38778) but did designate the population as depleted and strategic under the MMPA in May 2000 (65 FR 34590). Subsistence hunting was determined to be the immediate cause of the decline, and this activity has been essentially halted until the stock improves (Mahoney and Shelden 2000). None of the other stocks are listed as depleted under the MMPA.

Past and Present Human Effects and Management Actions

<u>Direct Mortality: Harvest and Other Intentional Take</u>

Belugas are harvested by Alaska Natives living in coastal villages from Cook Inlet to Barter Island. Belugas are principally used for human consumption, either as meat or muktuk, which consists of skin and the outer layer of blubber. The oil is used for cooking and for fuel. Belugas are hunted in spring as they travel northward through channels of water through the ice, as well as during the summer and autumn open-water period.

Data on subsistence harvest of beluga whales are provided by the Alaska Beluga Whale Commission. The annual subsistence harvest of beluga whales from the Beaufort Sea stock (1996 to 2000) includes an average of 68 whales per year by Alaska Natives and 109 whales per year by Canadian Natives (Angliss and Lodge 2002). The total average take is thus 177 belugas per year, well below the calculated PBR of 649 animals in this stock (Angliss and Lodge 2002). The annual subsistence harvest of beluga whales from the Chukchi stock (1996 to 2000) averages 60 animals per year. The calculated PBR for this stock is 74 animals per year (Angliss and Lodge 2002). The annual subsistence harvest of beluga whales from the EBS stock (1996 to 2000) averages 164 animals per year. The calculated PBR for this stock is 298 animals per year (Angliss and Lodge 2002). The annual subsistence harvest of beluga whales from the Bristol Bay stock (1996 to 2000) averages 15 animals per year. The calculated PBR for this stock is 32 animals per year (Angliss and Lodge 2002).

As noted above, the decline of the Cook Inlet beluga population is thought to have been the result of subsistence harvests by Alaska Natives. Between 1993 and 1998, the numbers of belugas that were reported to be taken ranged from 21 to 123 animals per year, not including an apparently large number of whales that were struck and lost. Beginning in 1999, subsistence harvest of belugas in this area was prohibited under the MSA, unless a co-management agreement between hunting communities and CIMMC was established. Since 1999, such agreements have been made for the strike of beluga whales by hunters from the Native Village of Tyonek and for Cook Inlet community hunters. In 2001, Native Village of Tyonek hunters harvested one beluga. Cook Inlet community hunters took one in 2002. Future agreements under MMPA allow for one strike for Native Village of Tyonek in 2003 and 2004, and one strike for Cook Inlet community hunters in 2004. The co-management agreements are for strikes only, regardless of whether or not the animal is retrieved (NMFS and CIMMC 2002). The PBR for this stock is calculated to be 2.2 animals per year (Angliss and Lodge 2002).

Direct Mortality from Incidental Take in External Fisheries

Commercial salmon gillnet fisheries in the Bristol Bay area are not subject to any observer program, but are required to self-report interactions with marine mammals. Between 1990 to 2000 there were two reports of beluga mortality in fishing gear. Self-reports are likely to under estimate interactions. In 1983, ADF&G documented 12 beluga whale mortalities in Bristol Bay related to drift and set gillnet fishing (Hobbs *et al.* 2000). State-managed personal use and subsistence salmon fisheries also occur in coastal waters used by belugas, but there are no reporting requirements for these fisheries. However, one beluga was reported to be taken from the eastern Bering stock in 1996, and seven were reported taken in Bristol Bay in 2000. The extent of these non-commercial fishery interactions is unclear given the lack of reporting requirements. It is likely that belugas taken in subsistence nets were themselves used for subsistence purposes by Alaska Natives and may have been counted in subsistence harvest data (Hobbs *et al.* 2000).

In 1999 and 2000, observers were placed on Cook Inlet commercial salmon set and drift gillnet vessels because of the potential for incidental take of belugas. No belugas were observed to be taken in these fisheries in either year or self-reported in the fisheries between 1990 to 2000 (Angliss and Lodge 2002).

Direct Mortality from Incidental Take by MSA Groundfish Fisheries

NOAA Fisheries-certified observers monitored incidental take in the 1990 to 1998 BSAI groundfish trawl, longline, and pot fisheries. No mortality or serious injuries to belugas were observed incidental to these fisheries (Hill and DeMaster 1999). Three different commercial fisheries that could have interacted with beluga whales in Bristol Bay and the EBS were monitored by fishery observers for incidental take during 1990 to 1999: BSAI groundfish trawl, longline, and pot fisheries. Observers did not report any mortality or serious injury of beluga whales incidental to these groundfish fisheries (Angliss *et al.* 2001). A review of all cetacean surveys conducted in the GOA from 1936 to 1999 discovered only 31 sightings of belugas among 23,000 sightings of other cetaceans, indicating that very few belugas occur in the GOA outside of Cook Inlet (Laidre *et al.* 2000) and are therefore unlikely to interact with the GOA groundfish fishery.

Direct Mortality from Strandings

In 1996, 60 belugas were stranded in Turnagain Arm (Cook Inlet), causing at least four deaths. In 1999, another 60 belugas were stranded in Turnagain Arm with five whales subsequently found dead. There was no indication that the strandings were related to any human activity (Moore *et al.* 2000, Angliss and Lodge 2002).

Comparative Baseline

Beluga whales are divided into five stocks including four stocks that winter in the Bering Sea and one that resides year round in Cook Inlet. Population estimates are made by aerial surveys corrected for sightability of the whales. The four Bering Sea stocks appear to be stable or increasing. The Cook Inlet stock declined substantially in the last ten years because of excessive subsistence harvests and was recently listed as depleted under the MMPA. The stock is now under a co-management agreement that greatly controls subsistence harvest. Belugas feed on a variety of fish species, but prefer to forage near coastal waters or near the pack ice. No belugas have been reported to be taken in the groundfish fisheries, but they are infrequently taken in state-managed salmon fisheries. The past/present effects on beluga whales are summarized in Table 3.8-23.

Status for Cumulative Effects Analysis

Because of their infrequent interaction with the groundfish fisheries, beluga whales will be considered as part of the toothed whales species group in the analysis of Alternative FMPs in Chapter 4.

3.8.24 Harbor Porpoise (*Phocoena phocoena*)

Life History and Distribution

Harbor porpoises are found all along the coasts of the BSAI and GOA area and their range extends both north and south of these waters. They occur primarily in coastal waters, but are also found where the shelf extends offshore (Gaskin 1984, Dahlheim *et al.* 2000).

Differences found in genetic samples from California, Washington, British Columbia, and Alaska (Rosel *et al.* 1995) and studies of contaminant levels from California to Washington (Calambokidis and Barlow 1991) show that harbor porpoises do not move or interbreed over great distances. Because regional populations are believed to exist, it was considered prudent to establish three management units within Alaska: southeast Alaska, GOA, and BSAI stocks. Based on aerial surveys corrected for undetected animals and unsurveyed habitat, the most recent estimates of harbor porpoise numbers in these 3 stocks include 10,508 porpoises in southeast Alaska (1997 survey), 21,451 in the GOA (1998 survey), and 10,946 in just the Bristol Bay portion of the BSAI stock (1991 survey). No surveys have been conducted in the Aleutians or in the Bering sea north of Bristol Bay. The GOA survey in 1998 was considerably different than the previous surveys in 1991 to 1993, both in overall area covered and in the specific areas sampled. Largely due to this change in sampling, the corrected estimate from the earlier surveys (8,271) was much less than the 1998 survey (21,451). The 1998 survey is thought to be much more representative of the GOA stock size because it included more of the inshore habitat commonly used by harbor porpoise. No reliable information on abundance trends exists for any of these stocks (Angliss *et al.* 2001).

Trophic Interactions

No prey studies have been conducted in Alaska. However, prey studies in Washington and British Columbia found the diet of harbor porpoise to include cephalopods and a wide variety of fish, including Pacific herring, smelt, eelpout, eulachon, pollock, Pacific sand lance, and gadids (Gearin *et al.* 1994, Walker *et al.* 1998).

The total estimated annual food consumption by the population during summer in the EBS is 1,000 mt, of which 800 mt (85 percent) is fish (based on the estimated average pelagic abundance of 1,500 animals) (Perez and McAlister 1993). Captive, non-lactating harbor porpoises of various age and sex classes were found to consume between 750 and 3,250 grams of fish per day (equivalent to 4 to 9.5 percent of their body weight) (Kastelein *et al.* 1997). Rates of consumption depended on the caloric content of the fish as well as the age, body weight, exercise level, and individual basal metabolic rates. Wild harbor porpoises are expected to need more energy for thermoregulation and locomotion than did the animals in this study.

Management Overview

Most marine mammals, including porpoises, fall under the jurisdiction of the NOAA Fisheries and are protected under the MMPA. Harbor porpoise are not considered a strategic stock under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. However, there is no subsistence harvest of harbor porpoise (Angliss *et al.* 2001).

Past and Present Human Effects and Management Measures

Direct Mortality: Incidental Take in Groundfish Fisheries

The NOAA Fisheries observers monitored incidental take on the 1990 to 1998 BSAI and GOA groundfish trawl, longline, and pot fisheries. During this period, 21 to 31 percent of the GOA longline catch occurred within the range of the southeast Alaska harbor porpoise stock (Angliss *et al.* 2001). No incidental mortalities were recorded by observers, and logbook data for the GOA and Bering Sea harbor porpoise stocks. For all three stocks, a reliable mortality estimate rate incidental to commercial fisheries was considered unavailable because of the absence of observer placements in several fisheries.

Direct Mortality from Incidental Take in External Fisheries

An annual mean take of harbor porpoise is 3 mortalities documented from logbook records from the southeast Alaska salmon drift-gillnet fishery (1990 to 1998). No other fisheries report incidental take of this porpoise.

Comparative Baseline

Harbor porpoise is a common species in the BSAI and GOA but has little interaction with the groundfish fisheries. There is little competitive overlap between the ground fisheries and harbor porpoise prey. Annual incidental take in the groundfish fisheries rarely, if ever, occurs. This species is not classified as a strategic stock under the MMPA and is not an ESA-listed species. The past/present effects on harbor porpoise are summarized in Table 3.8-24.

Status of Cumulative Effects Analysis

The low level of interaction between the harbor porpoise and the groundfish fisheries and lack of incidental take, harbor porpoise will not be considered as a separate species in the analysis of Alternative in Chapter 4, but would be address with the toothed whale groups.

3.8.25 Dall's Porpoise (*Phocoenoides dalli*)

Life History and Distribution

Dall's porpoises are endemic to the northern North Pacific Ocean and adjoining seas, inhabiting both pelagic and nearshore habitats. The species is common along the entire coast of North America as far south as 32°N (Morejohn 1979). In the Bering Sea, sightings are infrequent north of 62°N (Nishiwaki 1966). They are present in the BSAI and GOA area all year round although there may be some seasonal onshore-offshore movements.

One stock of Dall's porpoise is recognized in Alaskan waters (Hill *et al.* 1997), although a separate Bering Sea stock has been suggested, based on differences in reproductive timing and parasite associations (Amino and Miyazaki 1992, Kasuya and Ogi 1987, Walker 1990, Walker and Sinclair 1990) and preliminary genetics analyses (Winans and Jones 1988). The Alaska stock of Dall's porpoise is estimated at 417,000. This number, however, may be overestimated as much as fivefold because of vessel attraction behavior (Hill *et al.* 1997, Turnock and Quinn 1991). There is no reliable data on population trends for this species (Angliss *et al.* 2001).

Trophic Interactions

Food habits data from the western Aleutian Islands suggest a diet composed primarily of cephalopods and myctophid fishes (Crawford 1981). The total estimated annual food consumption by the population during summer in the EBS is 169,000 mt, of which 84,500 mt (50 percent) is fish (Perez and McAlister 1993).

Management Overview

Most marine mammals, including porpoises, fall under the jurisdiction of the NOAA Fisheries and are protected under the MMPA. The MMPA established a moratorium on the taking of all marine mammals in the U.S. except for subsistence use by Alaska Natives. There is no subsistence take of Dall's porpoise by Alaska Natives. Dall's porpoise are not considered a strategic stock under the MMPA nor are they listed as threatened or endangered under the ESA.

Past and Present Human Effects and Management Actions

<u>Direct Mortality from Incidental Take by Groundfish Fisheries</u>

Six different commercial fisheries operating within the range of the Alaska stock of Dall's porpoise were monitored for incidental take by NOAA Fisheries observers during 1990 to 1998. No mortalities were observed in pot fisheries or in the GOA longline fishery. The mean annual (total) mortality was 6.0 for the Bering Sea groundfish trawl fishery, 1.2 for the GOA groundfish trawl fishery, and 1.6 for the Bering Sea groundfish longline fishery (Angliss and Lodge 2002).

Direct Mortality from External Fisheries

The Alaska Peninsula/Aleutian Island salmon drift gillnet fishery took an estimated 28 porpoises in 1990. Other state-managed salmon gillnet fisheries have low occurrences of incidental take but these data are based on limited self-reports and are considered unreliable for quantitative estimates (Angliss and Lodge 2002).

Comparative Baseline

Dall's Porpoise is a common species in the BSAI and GOA and interacts with the groundfish fisheries on a regular basis. Annual incidental take in the groundfish fisheries is relatively low for the large populations size in this region. There is little overlap between the prey of Dall's porpoise and the fish targeted by the groundfish fisheries. This species is not classified as a strategic stock under the MMPA and is not an ESA-listed species. The past/present effects on Dall's porpoise are summarized in Table 3.8-25.

Status of Cumulative Effects Analysis

Considering the low level of incidental take in the groundfish fisheries and their very limited overlap in prey species, Dall's porpoise will not be carried forward as separate species in analysis of Alternatives in Chapter 4 but will be grouped with the toothed whale group.

3.9 Social and Economic Conditions

This section of this Programmatic SEIS provides an overview of the human environment associated with the groundfish fisheries managed by the NOAA Fisheries under the BSAI groundfish FMP and under the GOA FMP. The overview of the human environment is presented in eight sections as described below.

Historical Overview

The introduction and overview section provides a brief history of the groundfish fisheries in the North Pacific from as far back as the 1800s to today. This history includes a discussion of the groundfish fisheries as they evolved from traditional fisheries to commercial fisheries. This information provides a historical link to how the fisheries of the current day have formed. It includes a discussion of important influences from foreign exploitation to technological advances and provides a brief discussion of major amendments and initiatives that have had a significant influence on the domestic groundfish fisheries. This includes management regulations from before the enactment of the 1976 Fishery Conservation and Management Act (renamed the Magnuson-Stevens Fishery Conservation and Management Act [MSA] when amended in 1996) to today. The overview also provides information on fisheries dominated by large offshore foreign fishing and processing vessels, through the days of the joint venture fisheries, to the modern era characterized by U.S.-owned fishing and processing vessels and processing plants located in the coastal regions of Alaska.

Harvesting and Processing Sector Profiles

The harvesting and processing sector profiles section contains summary profiles of nine classes of catcher vessels, five classes of catcher processors, seven classes of inshore processors, and motherships. The sector profiles provide information on each class' involvement and dependence on Alaska groundfish fisheries and link fishing and processing activities to communities and regions in Alaska, Washington, and Oregon. The separate profiles are preceded by an overview of the activities of catcher vessels, catcher processors, inshore processors, and motherships in Alaska groundfish fisheries between 1992 and 2001. The summary profiles are condensed versions of more detailed regional profiles in *Sector and regional Profiles of the North Pacific Groundfish Fisheries—2001* (Northern Economics, Inc. and EDAW, Inc. 2001), with the addition of data for 2001.

Regional Socioeconomic Profiles

The regional socioeconomic profiles section contains summary profiles of six regions in Alaska, Washington, and Oregon that have particular interest in the harvesting and processing of North Pacific groundfish. Four of the regions are in Alaska and cover the coastal areas: the Alaska Peninsula and Aleutian Islands, Kodiak, southcentral Alaska, and southeast Alaska. A single region in Washington State is defined that includes counties bordering the state's inland marine waters. The final region includes three coastal counties in Northwest Oregon. The summary profiles are condensed versions of more detailed regional profiles in *Sector and Regional Profiles of the North Pacific Groundfish Fisheries—2001* (Northern Economics, Inc. and EDAW, Inc. 2001), with additional data for 2001.

Community Development Quota Program

The CDQ Program section provides a brief history of the development and qualifications of the community development quota program. This section covers the communities involved in the groundfish fisheries, as well as their purpose and accomplishments. The summary profile of CDQ communities is condensed from the detailed profile in *Sector and Regional Profiles of the North Pacific Groundfish Fisheries—2001* (Northern Economics, Inc. and EDAW, Inc. 2001), with additional data for 2001.

Subsistence

The subsistence section provides a summary of existing conditions and activity levels for the regionally important groundfish communities of the Alaska Peninsula and Aleutian Islands, Kodiak, southcentral Alaska, and southeast Alaska. It covers the subsistence use of Steller sea lions in relation to the central role Steller sea lion population dynamics have played in recent groundfish fishery management strategies and on some future management approaches. Lastly, this section includes other relevant subsistence activities including subsistence salmon fisheries, and joint production opportunities.

Environmental Justice Existing Conditions

The environmental justice existing conditions section provides an overview of the regulatory context and how it applies to this Programmatic SEIS. This section covers Alaska groundfish communities that have substantial environmental justice implications including communities with the highest level of engagement in and dependence upon groundfish-related activities, demographics of the workforce, population attributes, subsistence, and CDQ issues.

Market Channels and Benefits to U.S. Consumers

This section first provides a summary of the primary products derived from the Alaska groundfish fisheries and a brief overview of secondary processing and product distribution activities. Next, the difficulties of tracking the movement of groundfish products to their final point of sale are examined. Lastly, available data are used to summarize the product flows and markets for pollock, Pacific cod, sole, and rockfish.

Non-Market Goods and Services

The non-market goods and services section provides a discussion of possible non-market goods and services that may be directly or indirectly affected by the Alaska groundfish fisheries. The categories of economic values subsection outlines possible values that individuals attribute to market or non-market goods and services. The next three subsections examine these categories of values as they relate to three particular resources: groundfish, the Steller sea lion and the marine ecosystems of the BSAI and GOA. The alternative value paradigms section discusses values that lie outside the categories of values subject to economic investigation but that may be relevant to decision-making. These values are presented by their proponents as moral imperatives and, thus, do not lend themselves to analyses of economic tradeoffs.

3.9.1 Historical Overview

Development of North Pacific Fisheries (All Species)

<u>1800s to 1930s</u>

The development of the North Pacific fisheries began with the discovery of fisheries for subsistence use. Aboriginal reliance on fish for food and trade existed long before the first Asian and European explorers and exploiters arrived off the shores of Alaska. These Native subsistence fisheries have traditionally focused on nearshore species such as salmon, herring, shellfish (molluscan and crustacean), and a few demersal or groundfish species such as cod, halibut, and rockfish. These subsistence fisheries account for small amounts of fish relative to the commercial fisheries, both of which continue in the present day.

The economic development of Alaska was based on Russian exploitation of fur seals, otters and other fur bearing animals. The first small-scale fishing enterprise began in 1785 at the Karluk River on Kodiak Island to provide dried salmon to the Russian fur traders. Cod is the first commercial fishery reported in 1864 with a catch of nine tons from Bristol Bay by the American vessel *Alert*. In the 1860s, the commercial potential of salmon was discovered and a technique for large-scale canning of salmon was developed. The first salmon canneries were built in Alaska in 1878. In 1882, the Kodiak Island salmon cannery was built. In 1911, the commercial halibut fishery began in southeast Alaska off the south end of Baranof Island. The market demand for halibut grew as the development of ice makers enabled fishermen to preserve the halibut long enough to make it available to markets in the east and midwest U.S.

As more and more fisheries were discovered it became essential to achieve conservation of fishery resources and equitable distribution of their benefits. This became obvious when, after Alaska was purchased from Russia in 1867, it allowed American fishermen to use the common-pool approach and to fish for cod without interference from the Russians. However, the few fisheries management regulations that existed in the early 1900s were focused on salmon fisheries. As the Alaska salmon industry developed, government agents began collecting taxes on processed salmon products. The U.S. Commission of Fish and Fisheries was created in 1871 to determine whether and to what extent commercial marine food fishes of the northeast had declined in abundance. The Commission was also to report to Congress the necessary measures to remedy this decline. It wasn't until 1904, during the Theodore Roosevelt administration, that the Commission's work concerned Alaska. Roosevelt ordered an investigation of the Alaska salmon fishery due to reported inadequacies of existing conservation measures and recommended laws and regulations. In 1924, Congress passed the White Act, which declared congressional intent that not less than 50 percent of the salmon should be allowed to escape the fishery. The White Act gave the Secretary of Commerce broad powers to regulate fisheries in Alaska's territorial waters.

In the late 1800s and early 1900s, Pacific cod, halibut, and to a lesser extent sablefish, were the targeted fisheries. Market demand and the ability to transport fish products to market from remote Alaskan locations at reasonable cost determined whether a specific fishery would develop, rather than the abundance or availability of a particular species to fishermen.

As Canada and the U.S. fished Pacific halibut from northern California through Alaska shortly before World War I, fishery officials, fishermen, and dealers from both countries began to express concern about increasing amounts of gear and decreasing catch per unit of gear. Around 1913, Canadian and U.S. officials began to discuss the possibility of an international research and management agency. On March 2, 1923, the two nations finally ratified a halibut conservation treaty (Browning 1980). This treaty established a four-person International Fisheries Commission, granting it limited regulatory powers and a principal-in-charge to conduct halibut fisheries research. The new Commission imposed an annual closure of the fishery from November 16 to February 15 to protect spawning halibut (Browning 1980). The treaty was renegotiated in 1930 and 1937 to enhance the Commission's regulatory power, and in 1953 a treaty revision changed the name to the IPHC.

Development of Groundfish Fisheries (Dominated by Foreign Fisheries)

1940s-mid 1970s

The increased catching power of trawl gear, coupled with the advent of powered refrigeration and gear-handling equipment, electronic navigation, and other technologies, first posed a threat to the traditional Alaska fisheries for Pacific salmon, Pacific cod, sablefish, and halibut. However, these technologies eventually opened fisheries for lower-valued groundfish species, such as flatfish and pollock, because the trawl gear allowed harvesting of larger volumes of fish. This is reflected in the early fisheries regulations.

The State of Alaska has management authority for fishery resources within state territorial waters (3 miles offshore) by virtue of the Submerged Lands Act of 1953. Prior to statehood in 1959, all regulations affecting the groundfish fisheries were federal and implemented by the Bureau of Commercial Fisheries. These federal regulations focused on implementing licensing and reporting requirements, but also limited the type of gear that could be used at certain times and in certain areas.

A very robust foreign groundfish fishery operated off Alaska long before the MSA was passed in 1976. Japan fished the Bering Sea for pollock from 1933 to 1937, for yellowfin sole during 1940 and 1941, and for flatfish in the early 1950s. Japan also fished the GOA for Pacific ocean perch in 1960 and for flatfish in 1963. The Soviet Union sent exploratory fleets to the Bering Sea in 1958 and commenced commercial operations in 1959 on yellowfin sole and red king crab, and then expanded into Pacific ocean perch and herring in 1960. The Soviets moved into the GOA in 1964 and decimated Pacific ocean perch stocks before moving onto new fishing grounds off Washington and Oregon. The Republic of Korea (South Korea) began fishing in the Bering Sea in 1967 and in the GOA in 1972. Poland sent one stern trawler to fish briefly in the GOA and Bering Sea in late 1973. Taiwan commenced operations off Alaska in 1974 and 1975, trawling for Pollock and gillnetting for salmon in the central and EBS, and longlining for sablefish off southeast Alaska. The late 1960s to the early 1970s represents a period of unregulated overfishing of groundfish resources off Alaska plus gear conflicts between foreign trawl fisheries and domestic pot fisheries for crab and longliner fisheries for halibut.

In the early 1960s, the U.S. had fisheries authority to only 3 miles off Alaska's coast; even within this 3 miles, waters were only closed to all foreign fishing. The U.S. thus had little leverage to restrict large offshore Japanese and Soviet operations during their initial build-up. Exchange of fisheries research and information was initially conducted with Japan and Canada under the auspices of the INPFC. However, the INPFC focused primarily on salmon interception issues.

Other than the limited regulations imposed by the State of Alaska, however, the U.S. had virtually no authority to impose restrictions beyond its territorial sea. The Truman Proclamation of 1945 asserted the nation's right to adopt conservation measures and to require foreign nations to comply with them. However, the U.S. did not extend its jurisdiction over fisheries beyond its 3-mile-wide territorial limit until 1966, when enactment of Public Law 89-658 extended the exclusive jurisdiction of the U.S. over fisheries from 3 miles to 12 miles offshore (Miles *et al.* 1982). Although the establishment of the 9-mile contiguous fishery zone (CFZ) under this law was a harbinger of the ultimate fisheries jurisdiction claim of 200 miles ten years later with the MSA, it was relatively ineffective in controlling the growth of foreign fishing capacity and groundfish harvests off the coast of Alaska.

Transition to Joint Venture Vessels

<u>Mid 1970s-late 1980s</u>

The 1976 Magnuson Fishery Conservation Management Act (renamed the MSA when amended in 1996) established a mechanism to Americanize the off-shore fishery. The MSA assigned the NOAA Fisheries and the regional fishery management councils the responsibility of managing the fisheries in the Fishery Conservation Zone now called the U.S. EEZ that extends out 200 miles from the seaward boundaries of all coastal states. In the North Pacific, NOAA Fisheries and NPFMC took over management of a groundfish fishery that was largely unmanaged and open to all who wished to participate. Americanization of the groundfish fisheries was enhanced by actions of NPFMC and NOAA Fisheries that provided domestic harvesters and processors a priority over foreign interests. The development of the domestic groundfish fishing and processing industries was a high priority of Congress and NPFMC and therefore of NOAA Fisheries. To achieve this, NPFMC developed two FMPS authorized by the MSA. The groundfish FMP for the GOA was approved by NPFMC and adopted and implemented by NOAA Fisheries in 1978. It established broad management goals and principles. The FMP provided regulations that defined groundfish species and prohibited species, and established a process for determining OY and setting harvest guidelines. A similar FMP for the BSAI was approved in 1982.

Figure 3.9-1 dramatically demonstrates the magnitude of the foreign fisheries in the EEZ off Alaska and provides an indication of the development of domestic fishing and processing infrastructure that would be necessary to fully Americanize the groundfish fisheries off Alaska. It shows the total harvests of all major Alaska fisheries by the domestic fishing and processing industry from 1975 through 1980. Domestic harvests were minimal for groundfish during this period compared to salmon and crab, accounting for less than 6,000 of the 262,000 mt harvested in the domestic fisheries. The value of groundfish harvests is estimated to have accounted for only 0.2 percent of the total value of domestic fisheries in Alaska in 1980. Figure 3.9-2 shows the same data for the years 1977-1980, but adds harvests of groundfish in the EEZ by foreign fishing vessels.

From 1976 until the late 1980s, a variety of federal laws and programs were developed to promote the "Americanization" of fisheries inside the U.S. EEZ, especially the rich groundfish resources of the Bering Sea (NMFS 2002g). A start toward this was made in the early 1980s with the advent of what was known as the "Fish-and-Chips" policy. Fish-and-Chips tied foreign fishing privileges in the EEZ to commitments by the foreign entities to purchase the products of the U.S. seafood industry. A parallel program sponsored by NOAA Fisheries, the Fisheries Obligation Guarantee Program, guaranteed more than $150 million worth of loans between 1977 and 1996 for the construction of U.S. catcher processors and inshore floating processors. This program lowered capital investment costs relative to competitive market rates, thereby encouraging capital investment in the North Pacific groundfish fisheries and other U.S. fisheries.

The time period of 1978 to 1990 became a transition period to JV. The MSA enhanced the management actions of NPFMC and NOAA Fisheries. Domestic processors were surveyed in the fall each year. The survey results assisted in allocating the domestic annual processing (DAP) for the year, which was estimated by the total allowable level of foreign fishing (TALFF). Domestic processors were allocated the DAP if it was less than the total allowable harvest. The DAP directly reduced the TALFF. In addition to domestic processing priority, a DAH was created. If U.S. fishing vessels wished to participate in groundfish fisheries, they were also given a priority over TALFF regardless of whether domestic processors were involved. The creation of the DAH led to joint venture processing operations between U.S. fishing vessels and foreign motherships. Under these incentives, the Alaska groundfish fishery transitioned from almost entirely foreign to joint ventures to a completely domestic fishery in 1991, with 100 percent of groundfish harvested and processed by U.S.-owned vessels or shorebased processing plants in Alaskan communities. This dramatic expansion of the domestic fishery was financed, in large part, by a flood of foreign capital into new vessels and processors. (After the passage of the Commercial Fishing Industry Vessel Anti-Reflagging Act of 1987, fishing and processing vessels were required to have at least 50 percent U.S. ownership, but no similar ownership requirements were imposed on shore-based processors—all shorebased processors on Alaskan soil were considered domestic regardless of the actual ownership of the facility).

As shown in Figure 3.9-3, the transition from foreign fishing and processing to U.S. fishing and foreign processing with JV processors occurred in the early 1980s. JV processors operations peaked in 1987 and TALFFs were eliminated by 1988. In 1986 the transition to domestic processing began to accelerate, and by 1989 DAPs exceeded JV processors. The last JV processors operations occurred in 1990.

Much of the early development of domestic processing came in the form of U.S.-owned catcher processors and offshore motherships. In 1990, nearly 1.37 million mt of groundfish were processed at sea by domestic catcher processors and motherships, compared to 0.44 million mt processed by shorebased processing facilities. By 1991, the amount of groundfish handled by domestic processors was nearly 10 times greater than the amount of salmon, crab, halibut, and other species combined. The peak groundfish catch during that year occurred, in part, because blend estimates of catch and bycatch were not yet used to monitor most quotas. If they had been, several fisheries would have been closed earlier in the year (Hiatt *et al.* 2001).

The growth and relative importance of the domestic processing of groundfish is demonstrated in Figure 3.9-4. Between 1992 and 2000, groundfish accounted for approximately 85 percent of the total volume of fishery resources harvested in the commercial fisheries of Alaska. Figure 3.9-5 shows the growth and relative importance of the domestic groundfish fisheries in terms of wholesale product value. From 1977 through 2000, groundfish has developed to be the single most valuable resource for domestic processors, accounting for more than 45 percent of total wholesale value of all Alaska fishery resources.

As noted above, foremost within the overall rapid development of the groundfish fishery was the at-sea processing, or factory trawl fleet (NMFS 2002g). Other sectors, including onshore processing plants and harvesting vessels, existed prior to the development of the domestic pollock fishery, but they were involved in other fisheries. By 1990, there were more than 50 factory trawlers participating in the BSAI pollock fishery, along with several motherships and four major shoreside plants. The new domestic factory trawler fleet alone brought enough capacity to the BSAI pollock fishery to catch and process considerably more pollock than allowed under the TAC. The inshore processing industry, supplied by smaller, mostly independent catcher vessels, also had considerable excess capacity. Estimates of harvesting and processing capacity in the pollock fishery suggested that perhaps two or three times more capacity existed in the fishery than would be required to "efficiently" harvest and process the TAC (NMFS 2002g). Nearly a year-round fishery in the early to mid-1980s, the pollock fishery shrank to less than 60 days by 1992, in the face of a steady, or slightly increasing, quota.

Domestic Fishery and Management Objectives

Early 1990s-Present

During the transition, NPFMC and NOAA Fisheries became increasingly aware that managing a largely foreign fishery and allocating fishery resources among foreign and domestic interests were much easier than managing a purely domestic fishery and allocating fishery resources among competing U.S. interests. When fishery managers impose regulations that may have negative economic consequences for one sector while providing positive economic consequences for another, it becomes difficult to allocate resources between domestic users. The fisheries became fully domestic under a democratic allocation system, a process developed by NPFMC. It was becoming increasingly clear that rapid expansion of the domestic fleet under open access was creating conditions that led to a race for fish. Under TALFF and JV processors fisheries, open access and the race for fish was not a problem. From the perspective of NOAA Fisheries, the foreign fishery was essentially managed with individual quotas, and a race for fish did not exist. Following the NPFMC decision to implement IFQs in the sablefish and halibut longline fisheries and allocate pollock between inshore and offshore processors, they realized that the rapid Americanization of groundfish had created an overcapitalized, open access fishery that generated a profusion of fishery management issues. Some of these issues include allocation conflicts, gear conflicts, deadloss due to ghost fishing by lost or abandoned gear, excessive bycatch and discards, excess harvesting capacity, reduced product quality as reflected in prices, poor safety, lack of economic stability for fishery participants and communities, and a lack of rural coastal community development (NPFMC 1991). The IFQ program for halibut and sablefish was intended to address these issues. The IFQ is one means to limit entry in order to reduce overcapitalization and the wasteful practices that occur under other systems.

As part of the inshore/offshore pollock allocation, the first CDQ program to be implemented was recommended by NPFMC in 1992 (NPFMC 1992a). The NPFMC had previously adopted (in 1991) a CDQ allocation for the Pacific halibut and sablefish fixed-gear fisheries as part of the IFQ program for these fisheries but this was not implemented until 1995. The first CDQ pollock harvests were made in December 1992. Initially 7.5 percent of the BSAI pollock TAC was allocated to the CDQ program. The overall allocations are divided among the communities based on recommendations of the State of Alaska. In 1995, the program was expanded by the NPFMC to include allocations for king crab, Tanner crab, and other groundfish species. The expanded multi-species CDQ program was authorized by Congress in 1996 and fully implemented in 1998 (see Section 3.9.4).

In October 1998, Congress enacted the AFA which has had a profound effect on the management of groundfish fisheries in the BSAI and, to a lesser extent, the groundfish fisheries in the GOA. The AFA subsumed NPFMC action in June 1998 to change the inshore/offshore allocation. After increasing the CDQ allocation of BSAI pollock to 10 percent of the TAC and providing for bycatch amounts in other fisheries, the AFA shifted just over 10 percent of the BSAI pollock TAC from motherships and factory trawlers to inshore processors, which include processing plants on land and floating processors anchored near shore. A profound change brought by the AFA was the creation of a pollock factory trawlers cooperative called the Pollock Conservation Cooperative (PCC). A group of catcher vessels that delivered fish to these factory trawlers also was able to form a separate cooperative. The formation of these cooperatives allowed the factory trawlers, and catcher vessels that deliver to them, to allocate among themselves the offshore factory trawler sector's share of the pollock TAC each year until December 31, 2004.

In response to the rapid Americanization, NPFMC initiated a Comprehensive Rationalization Program in 1992. The NPFMC's main concern was to "maintain the health of the marine ecosystem to ensure the long-term conservation and abundance of the groundfish and crab resources. In addition, NPFMC must address the competing and oftentimes conflicting needs of the domestic fisheries that have developed rapidly under open access, fisheries which have become over capitalized and mismatched to the finite fishery resources available".

In the years following Americanization of the fisheries and initiation of the Comprehensive Rationalization Program, several amendments were approved that have resulted in limiting the number of participants and the types of activities in which they engage.

The ban on roe stripping (Amendment 19 to the GOA FMP and Amendment 14 to the BSAI FMP) and allocation issues would soon become increasingly bitter disputes. The first hint of these consequences occurred with the allocation of sablefish among gear types in the GOA under Amendment 14.

A moratorium on new harvesting vessels entering the groundfish fisheries was implemented through GOA Amendment 28 and BSAI Amendment 23. The moratorium reduced the possibility of significant increases in the number of large-capacity harvesting vessels activity participating in the groundfish fisheries.

Allocations of pollock between inshore and offshore sectors were approved and implemented in 1992. Amendment 18 to the BSAI FMP set aside one half of the pollock reserve (7.5 percent of the BSAI pollock TAC) for CDQ harvest, allocated 35 percent of the remaining BSAI pollock TAC to vessels catching pollock for processing by the inshore component and 65 percent of the remaining BSAI pollock TAC to vessels catching pollock for processing by the offshore component. Amendment 18 also established a catcher vessel operational area in which catcher processors and motherships were prohibited from engaging in directed fishing for pollock during the B Season (September 1 to November 1). Amendment 23 to the GOA FMP allocated 100 percent of the GOA pollock TAC to vessels catching pollock for processing by the inshore component. Amendment 23 also allocated 90 percent of the GOA Pacific cod TAC to vessels catching Pacific cod for processing by the inshore component, and 10 percent of the GOA Pacific cod TAC to vessels catching Pacific cod for processing by the offshore component. The inshore and offshore allocations reduced the possibility that processing by one sector (inshore or offshore) could negatively affect harvesting and processing by the other sector. However, open access conditions and excess capacity continued in both the inshore and offshore sectors resulting in intense competition and potential economic instability.

An allocation of the BSAI Pacific cod harvests between jig, fixed gear, and trawl fisheries was implemented through BSAI Amendment 24. This amendment was reauthorized in 1996 (Amendment 46) with changes in the allocation and an additional split between TCVs and trawl catcher processors. Amendment 64, approved in 1999, further subdivided the fixed gear portion of the BSAI Pacific cod fishery among longline catcher processors, longline catcher vessels (LCV), and pot gear vessels. The Pacific cod allocations in the BSAI provided trawlers and fixed gear vessels a fixed percentage of the fishery, and eliminated the threat that the harvesters of one gear group would impinge on the harvests of the other.

The NPFMC groundfish LLP was approved in 1995, further reducing the number of vessels eligible to participate in the groundfish fisheries. The LLP also added the remaining groundfish species in the BSAI to the CDQ program. Amendments in 1998 and 2000 have placed additional restrictions and qualification criteria on licenses. The CDQ portion of the LLP was implemented in 1998 and first licenses were issued in 2000. The LLP removed additional amounts of the groundfish harvest from the open access fishery and further reduced the possibility of an increase in harvesting capacity that could erode the expectations of currently participating vessels.

With the approval and implementation of the AFA of 1998, the open access nature of the pollock fishery in the BSAI was virtually eliminated. The number of vessels and processors allowed to participate in the fishery was fixed, and each provided access to a fixed portion of the pollock resource through a cooperative. The possibility that an AFA vessel or processor can have negative impacts on the ability of another AFA vessel or processor to participate in the BSAI Pollock fishery was minimized.

Summary of Historical Overview

The enactment of the MSA in 1976 established NPFMC and gave it authority to recommend to the Secretary of Commerce fishery management policies. By 1988, participation in the North Pacific groundfish fishery in the EEZ was limited to domestic fishing vessels and plants and foreign processor vessels in joint venture operations with American-owned catcher vessels. Joint venture operations were then phased out leaving the fishery fully "Americanized" by 1991. However, by 1988 domestic capacity was sufficient to harvest the groundfish TAC and was still expanding rapidly. This led to the race for fish. In 1996, NPFMC enacted the LLP, a more restrictive form of limited access. This in turn allowed in more vessels than were necessary to prosecute the fisheries, leading to several amendments to the BSAI and GOA groundfish FMPs. Amendments to FMPs and the race for fish led NPFMC to focus on limiting catches to sustainable levels and the various user groups to focus on securing shares of the TAC. Table 3.9-125 summarizes the effects of past/present events and actions on the harvesting and processing sectors. This information is also referred to as the comparative baseline.

The FMP amendments have included direct allocations of quotas for particular species or species groups to groups of vessels as delineated by gear type, vessel size, mode of operation, etc.

3.9.2 Harvesting and Processing Sector Profiles

This section presents data that summarize various aspects of the economic status of the groundfish fisheries in the U.S. EEZ off Alaska. Generally, data are presented for the harvesting and processing sectors of the groundfish fisheries for 1992 through 2001. The primary source of the economic information presented here is the document, *Sector and Regional Profiles of the North Pacific Groundfish Fisheries – 2001* (Northern Economics, Inc. and EDAW, Inc. 2001).

Section 3.9.2 is divided into four subsections:

1. Section 3.9.2.1 describes the key indicators used in this analysis to assess economic conditions in the harvesting and processing sectors.

2. Section 3.9.2.2 provides an overview of the major causes of economic change in the harvesting and processing sectors.

3. Section 3.9.2.3 describes the primary sources of economic data used in this analysis.

4. Section 3.9.2.4 presents profiles of the harvesting and processing sector classes identified for this analysis. Specifically, this subsection describes the activities of 1) various classes of catcher vessels — vessels that harvest groundfish and deliver their catch to processors; 2) various classes of catcher processors—vessels that both harvest and process groundfish; and 3) other types of processors—shore-based processors, floating inshore processors (FLP), and motherships that take deliveries of groundfish from catcher vessels.

3.9.2.1 Key Indicators of Economic Conditions in the Harvesting and Processing Sectors

The profiles of the harvesting and processing sectors describe the economic status of the Alaska groundfish fisheries in terms of various quantitative measures of economic activity and output using estimates of the size and composition of the groundfish fleet, the number and type of processing facilities, vessel and plant ownership, the amount of groundfish caught and retained, the ex-vessel value of groundfish landed, the quantity and value of groundfish seafood products, the number of people employed, and the payments to labor (also called labor income). Ex-vessel value is equal to the quantity of fish retained for processing multiplied by the ex-vessel (dockside) per unit price. This value represents both the gross revenues earned by harvesters and the costs of raw fish paid by processors. Gross product value is equal to the quantity of processed product multiplied by the wholesale product price after primary processing. This value represents the gross revenues earned by processors.

Other economic and social indicators examined in this analysis are described in more qualitative terms. These indicators include product quality, product utilization rate, harvesting and processing capacity, and safety of human life at sea. The analysis also includes a qualitative discussion of changes in average costs in the harvesting and processing sectors. However, the firm-level cost data required to estimate changes in net revenues (gross revenues less variable and fixed costs) are unavailable.

It is also important to note that a number of the indicators described above can serve as indicators for economic variables that are difficult to measure directly. For example, an estimate of labor payments is a surrogate measure of the contribution of the groundfish fisheries to a community's employment levels. Similarly, total and groundfish ex-vessel values by region of landing are subject to local and state taxes and, therefore, are indicators of the fishery-generated tax revenue that accrues to local and state governments. They are also a measure of the demand for shoreside support services by the groundfish fisheries.

3.9.2.2 Internal and External Factors Affecting Economic Conditions in the Harvesting and Processing Sectors

The economic performance of the Alaska groundfish fisheries is influenced by a variety of factors. For the purposes of this analysis, the conservation and management measures that regulate the fisheries are considered to be internal factors. As described in Section 3.9.1, certain management measures have dramatically affected economic conditions in the domestic groundfish fisheries as a whole or segments of those fisheries. These management measures include those implemented to prevent overfishing of groundfish stocks and to protect ecosystems as well as those measures designed to allocate the groundfish quota among various user groups and to enhance the economic efficiency of the fisheries.

The economic performance of the Alaska groundfish fisheries is also significantly affected by factors external to the regulatory regime. These factors include the domestic and foreign demand for groundfish products, economic conditions in other Alaska fisheries, the costs of harvesting and processing inputs—such as fuel and labor—and changes in fishing technology. Foreign and domestic demand, in turn, is a function of such factors as consumer preferences, the supply of competing products, foreign exchange rates, international trade agreements, demographics, and national income levels (Kinoshita *et al.* 1993).

The single most important of these demand-related factors is the food preferences of consumers. Shifting tastes in domestic and foreign markets can have a profound effect on the harvesting and processing decisions of fishery participants and the economic health of the industry as a whole. Among U.S. consumers, for example, the increased demand for seafood products that resulted from reports of the health benefits of eating fish and shellfish had a marked positive economic impact on certain segments of the domestic fishing industry, including harvesters and processors of Alaska groundfish. On the other hand, markets for Alaska groundfish thought to be stable and dependable—such as exports of pollock surimi to Japan—may change significantly in the future. One fish buyer interviewed for this analysis suggested that the demand for certain surimi-based products in Japan appears to be declining along with the demand for other traditional foods.

Another especially important variable in the market for Alaska groundfish products is the pollock harvest in Russian waters (NMFS 2001b). Russia has accounted for more than half of total world harvest of pollock, and vessels of other nations fishing in Russian waters also catch significant volumes. These foreign harvests compete directly with U.S. harvests in international markets for Alaska pollock products. In the past several years the TAC in Russia has been reduced each year. However, there is general consensus that the Russian stock of Alaska pollock has been overfished. Adding to this is financial difficulty in the Russian fishing industry. It is likely that harvests from Russian waters will decline even further before they stabilize; one estimate suggests it may be at least 2005 before stocks recover from overfishing The declining trend of harvests from Russian waters suggests a favorable market outlook for pollock from the EEZ off Alaska over the next few years due to tightening world supply.

A third important exogenous factor related to markets for groundfish is foreign exchange rates. With the large amount of groundfish that is exported from the fisheries off Alaska to Japan, the strength of the Japanese yen relative to the U.S. dollar can be a powerful force in the market for groundfish and other Alaska seafood products. The major collapse of the economy in southeast Asia during the late 1990s led to an economic slowdown in Japan, which caused Japanese consumer demand to slow (NMFS 2001b). The yen weakened significantly, and the exchange rate dropped to a low of 144 yen per dollar in August 1998. The weak yen and slackened demand placed great pressure on Alaska producers. The economy has since recovered somewhat, and the Japanese yen has strengthened against the dollar.

The economic status of the Alaska groundfish fisheries is also heavily influenced by other Alaska fisheries. These fisheries may provide fishing opportunities to vessels and processors participating in the groundfish fisheries, intercept or otherwise affect groundfish stocks and harvest quotas, and provide other sources of employment and tax revenue for local communities. The fisheries that have the greatest potential effects are crab (tanner and king), salmon, halibut, and state groundfish fisheries. Several classes of catcher vessels and inshore processors (shore-based processors and FLPs) currently rely to a certain degree on the harvest from these fisheries. In some communities the processing sector handles a range of products (e.g., groundfish, crab, and salmon), while in other communities the processors are more specialized. Fisheries other than those occurring near Alaska, such as the Pacific whiting fishery off Oregon and Washington, are also important for several catcher vessels, catcher processors, and motherships.

Finally, the economies of the communities in which processors are located or from which harvesters operate also have an effect on economic conditions in the Alaska groundfish fisheries. The economic development activities that have the greatest potential effect are State of Alaska and federal oil and gas exploration/ production, defense industry projects, tourism and the construction and operation of marine or air-related transportation facilities. Non-fishing economic activities within coastal communities may compete with the groundfish industry for labor, services, and facilities. Alternatively, they can provide supplementary employment and income-generating opportunities for fishermen, processors, and others involved in the fishing industry.

3.9.2.3 Data Sources and Methodology

The fisheries data collection system used to monitor the groundfish fisheries has changed significantly over the past twenty-five years. When the MSA was implemented in 1976, the groundfish fisheries were dominated by foreign catcher processors and motherships. To monitor fishing activity, NOAA Fisheries required the vessel operators to record activities in logbooks. U.S. observers on the vessels reported catch estimates and logbook entries weekly. This system of reporting continued into the 1980s, when much of the groundfish catch was harvested by domestic catcher vessels and delivered to foreign processing vessels in joint venture operations. Deliveries by domestic catcher vessels to inshore processors were reported by means of ADF&G groundfish fish tickets.[1] Catcher processors were also required to submit fish ticket reports of groundfish catches to the ADF&G, but these vessels could stay at sea for long periods, and thus did not report as frequently as catcher vessels. With the rapid expansion of the domestic catcher processor fleet, it became apparent that a mechanism for timely reporting of catches by this fleet was needed. By 1987, NOAA Fisheries required weekly reports of groundfish caught in the EEZ and processed at sea from all catcher processors and motherships regardless of how long their catch was retained before landing. Currently, both at-sea and inshore processors are required to report estimates of all harvests and deliveries on a weekly basis using the Weekly Production Report (WPR).

In 1990, the groundfish FMPs for the GOA and EBS were amended to establish mandatory observer coverage requirements for vessels and plants involved in the groundfish fisheries. With some exceptions, those amendments require vessels 125 feet or longer to carry an observer 100 percent of the time while fishing for groundfish; vessels 60-124 ft long to carry an observer during 30 percent of their fishing days in each calendar quarter of the year in which they fish more than 10 days; plants processing 1,000 or more metric tons in a month to have an observer in the plant each day they process groundfish; and those processing 500-1,000 mt to have observers 30 percent of the days. Since 1992, NOAA Fisheries has based all estimates of catch in the groundfish fisheries on a blend of observer data and WPR data.

Estimates of total catch for the processor profiles presented in this analysis were derived from the NOAA Fisheries blend data. NOAA Fisheries WPR data were used to derive final product estimates. The product

[1] Fish tickets record landed weight and value by species. A fish ticket is considered a legal document and requires the signature of the permit holder (captain or operator) and the receiver (buyer).

price information provided by NOAA Fisheries was based on data collected by the State of Alaska in the Commercial Operators Annual Reports.

Data for catcher vessels that delivered to inshore processors are primarily from fish tickets collected by ADF&G. Analysts from NPFMC parsed the fish ticket records such that only records of deliveries to inshore processors were included. These data were available for 1988 through 2001.[2] Data for the years before 1988 were not available because it was not feasible to adequately parse the data voluntarily submitted by catcher processors and motherships. Including such information could result in double counting errors.

Fish ticket data do not fully account for fish that have been discarded. To provide a consistent set of information only harvests retained by inshore processors have been included in the catcher vessel profiles. The fish ticket information provided by NPMFC included estimates of the ex-vessel value of each delivery.

While deliveries to inshore processors are recorded on ADF&G fish tickets, at-sea deliveries to motherships are monitored by observers. However, these observers do not routinely record the species composition of deliveries made by individual catcher vessels. To estimate the species composition of deliveries to motherships, observer data for individual catcher vessels were combined with NOAA Fisheries blend data for motherships. The blend data were used to estimate the monthly average species composition for each mothership, while the observer data were used to estimate the monthly catch delivered by each catcher vessel. The average species composition of each mothership was assigned to the catch of each of its catcher vessels so that the sum of the amount of each species delivered by all of the catcher vessels equaled the total quantity of fish received by the mothership.

The ex-vessel value of at-sea deliveries must be estimated. Unlike data for deliveries to inshore processors, there is no regularly collected information on prices paid for deliveries at sea prior to 2000.[3] To estimate at-sea ex-vessel value this analysis used the following formulaic approach validated by industry sources in June and July 2000:

- The at-sea ex-vessel price of pollock and Pacific cod is 87.5 percent of the price paid for deliveries inshore. Payments are only for that portion of the catch retained by the mothership.

- The at-sea ex-vessel price of all other species is 40 percent of the first wholesale value of the mothership's final product. Other than pollock and Pacific cod, few groundfish species were retained by motherships between 1991 and 2001.

Vessel ownership and address information from Commercial Fisheries Entry Commission (CFEC) vessel registration files and NOAA Fisheries Federal permit data was used to assign income and employment estimates from the groundfish fisheries to regions in Alaska, Oregon, and Washington. Processor ownership and address information from NMFS Processor Permit data and from ADF&G Alaska Seafood Processor and Exporter License and Permit data was used to assign processors to regions. Because of inconsistencies in the

---

[2] The catcher vessel profiles use ADF&G fish ticket data from 1992 to 2001 in order to be consistent with processor profiles.

[3] Beginning in 2000, at-sea deliveries by catcher vessels were required to be reported on ADF&G fish tickets.

ownership data in early years, the analysis assigned processors to the region indicated in the most recent CFEC vessel registration or Federal permit data available.

The catch data sets contain many instances of incidental groundfish catch reported by catcher vessels and processors participating in non-groundfish fisheries. Vessels fishing for halibut, for example, are required to land incidental catches of Pacific cod and rockfish. In an effort to focus the analysis on harvesting and processing operations with a significant involvement in the groundfish fisheries, threshold limits were established for catcher vessels and catcher processors. The threshold limits varied by gear and vessel length. Vessels that had landings below these limits were excluded from this analysis. In addition, inshore processors that acted as buying stations or were not associated with a given port were excluded. Unidentified vessels or catcher vessels that made catches below threshold limits accounted for approximately 0.6 percent of the value of the groundfish fisheries from 1992 through 2001.

Employment estimates for catcher processors and motherships are collected by NOAA Fisheries in WPR. For this analysis NOAA Fisheries provided information on the average crew size for each vessel and the number of weeks that each vessel was active between 1993 through 2000. Multiplying crew size by the number of active weeks provided an estimate of the number of crew member weeks for each vessel. Assuming a work year of 52 weeks, crew member weeks were translated into an estimate of Full Time Equivalent (FTE) employment. These estimates were increased by five percent to account for corporate office staff.

Employment estimates for inshore processors were derived in a different manner. WPR provided information on the volume of processed product for each inshore processor. These values were summed to obtain totals for each inshore processor class. The product volumes were then multiplied by coefficients representing the average tonnage of each product type that could be produced per labor hour.[4] The result is the number of labor hours to produce the product volumes. Using 2,080 hours as a standard work year (because many plant employees do not qualify for vacations and work on holidays), the FTE employment for each inshore processor class was estimated. The FTE employment estimates were increased by five percent to account for corporate office staff.

Inshore processing plant employment was assigned to the region in which the plant is located, with corporate office staff allocated to the region of the plant owner's address as indicated in permit files. Catcher processor, mothership, and catcher vessel total employment (vessel and corporate office staff) was allocated to the regions indicated in the CFEC vessel registration or federal permit data. This method of assigning employment to regions is similar to that used by state and federal agencies. Insufficient information exists to provide a more accurate account of regional employment patterns in the groundfish fisheries. The method of assigning employment to regions used in this analysis does not attempt to account for the formal or legal residency of employees.

[4] The coefficients originated in the Fisheries Economic Assessment Model for Alaska (Jensen and Radtke 1990). They were first updated by Northern Economics, Inc. as part of a Fisheries Industry Model (FIM) prepared for the U.S. Department of Interior, Minerals Management Service (Northern Economics, Inc. 1990 and 1994). The coefficients were updated again by Northern Economics, Inc. in unpublished reports prepared for the City of Unalaska and City of King Cove that provided a revenue forecasting system for each community. The coefficients represent averages for processing facilities throughout the state, and substantial variation can occur across processor classes.

Estimates of employment on catcher vessels were derived from previous studies of crew-size for various vessel types and from interviews with industry representatives. Estimates of employment for a particular vessel class were made by multiplying the crew-size estimate by the number of active vessels in the class during each month. Crew member months were converted to crew member hours by assuming that crew members work an average of 16 hours per day for an average of 15 days in every month their vessel is active. The total number of estimated crew member hours was then divided by 2,080 hours to obtain an estimate of FTE employment.

Payments to labor for both offshore and inshore processors were estimated by multiplying total wholesale production value by the percent of that value accounted for by processing labor. Studies by Northern Economics, Inc. (1990 and 1994) indicated that processing labor accounts for 20 to 30 percent of total wholesale production value for the various processor classes. The estimated payments to processing labor were increased by 10 percent to account for the salaries of corporate office staff. Payments to labor for catcher vessels were estimated assuming that labor costs are equal to 40 percent of ex-vessel value. Payments to labor for inshore processors, catcher processors, motherships, and catcher vessels were regionally distributed in the same manner as described above for employment.

3.9.2.4 Sector Profiles

Profile Categories

The groundfish fisheries support a wide array of harvesting and processing operations. This analysis has grouped these operations into three groups representing 1) catcher vessels; 2) catcher processors; and 3) shore-based processors, FLPs, and motherships. These groups have been further subdivided into twenty-one classes as follows:

- Nine classes of catcher vessels defined on the basis of fishing activities in a given year and vessel size.

- Five classes of catcher processors defined on the basis of the predominant product type or gear type associated with these vessels.

- Seven classes of shore-based, floating inshore, and mothership processors defined on the basis on the regional location of the facilities.

More detailed descriptions of each of these categories are presented in Table 3.9-1.

To further facilitate the organization and presentation of fisheries data, groundfish species were aggregated into four main groups, as shown in Table 3.9-2. Grouping species allows the analysis to provide a relatively uniform description of activities by vessel class and to report as much catch data as possible without violating NOAA Fisheries restrictions pertaining to release of confidential data .[5] In addition, seven geographic regions were defined to enhance the presentation of information on the linkages between groundfish harvesting and

[5] NOAA Fisheries and State of Alaska policies regarding the protection of confidential data require that fisheries operations data be aggregated to include information from at least four individual operations. Because of the limited activity of some types of vessels in some regions, disclosure of less aggregated species data would have violated this confidentiality limitation.

processing operations and coastal communities. These regional classes are presented in Table 3.9-3. Section 3.9.3 provides details on the socioeconomic relationship between the groundfish industry and communities and regions in Alaska, Washington, and Oregon.

Overview of Activities in Alaska Groundfish Fisheries

Economic conditions within the harvesting and processing sectors of the Alaska groundfish fisheries have undergone major changes over the past three decades. This section examines the historical context of economic conditions in the Alaska groundfish fisheries, as well as the possible agents of change. The description of historical trends is divided into two time periods. The period of 1977 to 1991 corresponds to the era of rapid development of domestic fishing and processing capacity following the enactment of the MSA. The years 1992-2001 follow the modification of the fisheries data collection system. All catch data reported after 1991 are based on the blend estimates of total catch which are used by NOAA Fisheries to monitor groundfish and prohibited species catch quotas during each fishing year. In addition, it is during this period that allocation issues among domestic fishery participants and the effects of the groundfish fisheries on the marine ecosystem received greater attention.

The availability and consistency of data limits the ability to analyze historical change in indicators of the economic condition of the Alaska groundfish fisheries, particularly during the years immediately following the implementation of the MSA. This analysis is also limited by the difficulty of delineating the cause-and-effect relationships between multiple factors and the resultant economic effects. As noted in Section 3.9.2.2, many factors substantially affect the economic status of the Alaska groundfish fisheries. Changes in markets, biological conditions and fishery management regulations can result in changes in the revenues and operating costs of firms participating in the fisheries as well as changes in fleet size and composition. Isolating the effects of a single factor is seldom possible, especially when data are presented for the groundfish fisheries as a whole. The effects of various factors are more easily discerned when the activities of individual catcher vessel and processor classes are described later in this section.

<u>1977 to 1991</u>

As discussed in Section 3.9.1, the MSA was designed to promote the development of a U.S. offshore fleet through an allocation system that favored domestic vessels over foreign vessels and joint venture operations. During the 1980s, the groundfish fisheries in the U.S. EEZ off Alaska changed from being primarily foreign fisheries to fully domestic fisheries. Foreign fishing ended in 1987, and JV processing operations peaked in the same year. In 1986, the transition to domestic processing began to accelerate, and by 1989 allocations to domestic processors exceeded allocations to joint ventures. The last JV processing operations occurred in 1990.

Much of the early development of domestic processing came in the form of U.S.-owned catcher processors and offshore motherships. Trawls, longlines, pots, and other types of fishing gear were used in the domestic groundfish fishery. Annual catch for virtually every gear group, area, and species increased dramatically from 1982 to 1990. However, vessels using trawl gear to harvest pollock in the BSAI area accounted for most of the total groundfish landings. Catch for offshore processing was the largest and fastest growing component of catch. The number of domestic catcher processors increased from only three in 1986 to 50 in 1991. By 1990, nearly 1.37 million mt of groundfish were processed offshore by domestic catcher processors and motherships, compared to 0.11 million mt in 1986. The catch processed by shore-based facilities increased from 61,500 mt in 1986 to 463,400 mt in 1991. The relative catch of these two types of operations varied by area and species (Kinoshita *et al.* 1993). In the BSAI the catch processed offshore exceeded that processed by inshore facilities for each species. The opposite was true in the GOA, with the exception of rockfish and flatfish.

The majority of the total groundfish catch was harvested by vessels with addresses listed in CFEC vessel registration or Federal permit data that indicated that they were based outside of Alaska. Much of the early development of domestic harvesting processing of groundfish resources came in the form of catcher processors and offshore motherships based in Seattle.[6] However, the percentage of catch taken by vessels registered by Alaska residents or corporations was greater when measured in terms of ex-vessel value rather than in terms of weight. This is because vessels registered by Alaska residents or corporations caught a larger proportion of higher priced species such as sablefish.

By 1991, the amount of groundfish handled by domestic processors was nearly 10 times greater than the amount of salmon, crab, halibut, and other species combined. Also, groundfish replaced salmon as the highest value commercial fishery off Alaska in 1991. The peak groundfish catch during that year occurred, in part, because blend estimates of catch and bycatch were not yet used by NOAA Fisheries to monitor most quotas. If they had been, several fisheries would have been closed earlier in the year (Hiatt *et al.* 2001).

<u>1992 to 2001</u>

Table 3.9-4 summarizes domestic harvesting and processing activity in the groundfish fisheries off Alaska from 1992 to 2001. More detailed information about each sector and region is contained in later subsections.

From 1992 through 2001, an average of 1,083 catcher vessels made landings of groundfish above threshold levels each year. In the same period, an average of 107 catcher processors and 68 motherships and inshore processors annually participated in the groundfish fisheries. The number of participants in the groundfish fisheries decreased substantially during the ten-year period. The cause of the decline is likely a combination of several factors, including the implementation of a vessel moratorium and license limitation program, quota allocations among participants in the groundfish fisheries, mandated vessel retirements under the AFA, and changes in global markets for groundfish products.

Between 1992 and 2001, processors received groundfish with an average annual ex-vessel value of $244 million. Total groundfish harvests ranged from a high of 2.3 million mt in 1992 to a low of 1.6 million mt in 1999. Pollock accounted for approximately 66 percent of total reported harvests during the ten-year period. About 86 percent of total reported groundfish harvests were in the BSAI.

For the domestic groundfish fisheries as a whole, 94 percent of the 2001 catch was made by vessels with addresses listed in CFEC vessel registration or Federal permit data that indicated that they were based outside of Alaska (Hiatt *et al.* 2002). The catches of Alaska and non-Alaska vessels were much closer to being equal in the GOA where Alaskan vessels accounted for the majority of the Pacific cod and sablefish catch.

An average of 580 thousand mt of product were produced from groundfish per year between 1992 and 2001. This equated to an average utilization rate (product tons divided by reported harvest tons) of 29 percent. The

[6] Most of the shoreside pollock processing capacity was built and owned by Japanese seafood companies.

estimated average annual wholesale value of production was $1.2 billion between 1992 and 2001. During this period, the groundfish fishing and processing industry generated an estimated yearly average of 4,700 FTE jobs in Alaska and 5,300 FTE jobs in the Washington inland waters (WAIW) region, with an estimated total average payment to labor of $589 million.

Overview of Other Indicators of Conditions in the Alaska Groundfish Fisheries

The preceding discussion examined historical conditions in the Alaska groundfish fisheries in terms of various quantitative measures of economic activity and output. This section provides an overview of three additional variables that are discussed in more qualitative terms: harvesting and processing capacity, average costs, and safety of human life at sea.

Harvesting and Processing Capacity

A detailed discussion of the issue of harvesting and processing capacity in the Alaska groundfish fisheries is provided in the qualitative analysis of overcapacity. A summary of portions of that analysis is presented here.

In simple terms, fishing capacity is the ability of a vessel or fleet of vessels to catch fish (NMFS 1999c). This ability is a function of such factors as the number of fishing vessels in the fleet; the size of each vessel; the technical efficiency of each vessel (determined by factors such as on-board gear and equipment, fishermen's knowledge and techniques, and the size of the crew); and the time spent fishing (National Fisheries Conservation Center undated). Loosely speaking, overcapacity in a fishery occurs when the ability to catch fish exceeds what is needed to harvest sustainable yields. This condition can lead to intense fishing pressure on stocks, poor economic performance within the fishing industry, and inefficient use of labor and capital.

The rapid expansion of U.S. participation in the Alaska groundfish fisheries during the 1980s and early 1990s led to excess capacity in a number of these fisheries. The NPFMC responded in 1992 by initiating a comprehensive rationalization program. In the years following the initiation of the program, NPFMC and NOAA Fisheries, whether intentionally or unintentionally, progressively limited the number of participants in the Alaska groundfish fisheries and the types of activities in which they can engage. Major regulatory actions that affected capacity in the groundfish fisheries included the following management programs.

The sablefish and halibut longline fishery IFQ program was approved by NPFMC in 1991 and implemented by NOAA Fisheries in 1995. Quota shares were allocated within separate management areas and for specific vessel size classes. Shares are marketable but can be sold or traded only within each management area, within the same vessel size category, and with restrictions on the total amount and type of quota held. In 2002, NPFMC amended the IFQ program to allow fishing villages in the GOA with fewer than 1,500 people to acquire quota shares for sablefish and halibut. The measure allows 42 villages to buy quota shares and lease them to resident fishermen.

The western Alaska CDQ program was created to provide fishermen who reside in western Alaska communities an opportunity to participate in the BSAI groundfish fisheries, to expand their participation in nearshore fisheries, and to help alleviate the poor economic conditions within these communities. Initially, the western Alaska CDQ program relied on an allocation of the annual pollock TAC in the Bering Sea. In

1993, NPFMC extended the community development quota to halibut and sablefish. The multi-species CDQ allocations, adding all remaining BSAI groundfish, prohibited species and crab, were implemented in 1998.

A moratorium on new harvesting vessels entering the groundfish fisheries was implemented in 1995. The moratorium reduced the possibility of significant increases in the number of large-capacity harvesting vessels actively participating in the groundfish fisheries.

Final implementing rules for NPFMC's groundfish North Pacific LLP were published in 1998, and the first licenses were issued in 2000. The LLP superceded the moratorium and further reduced the number of vessels eligible to participate in the groundfish fisheries. The LLP also established groundfish area and gear endorsements. Licenses under the LLP are generally transferable, but endorsements are not severable from the license. Licensed vessels can be replaced, but increases in the length of licensed vessels are limited in vessels under 125 ft and prohibited in larger vessels.

In 1998, Congress passed the AFA which, among other things, limited the number of harvesting and processing vessels that would be allowed to participate in the BSAI pollock fishery. Only harvesting and processing vessels that met specific requirements, based on their participation in the 1995-1997 fisheries, are eligible to harvest BSAI pollock. The AFA also established the authority and mechanisms by which the remaining pollock fleet can form fishing cooperatives. Within each cooperative, each member company is contractually allocated a percentage share of the total cooperative allocation based on its historical catch (or processing) levels. In practice, the cooperative system is similar to an IFQ system. However, the distribution of fishing privileges and the system for trading, selling or enforcing them is decided by the members of the separate cooperatives.

These measures have, at least in part, limited excess harvesting and processing capacity in the Alaska groundfish fisheries. As shown in Table 3.9-4, the number of participants in the groundfish fisheries has decreased substantially since 1992. Yet, as indicated by recent problem statements prepared by NPFMC, the measures have not been successful in eliminating excess capacity as one of the major management problems for these fisheries. A recent report by Felthoven *et al.* (2002) supports NPFMC's position that significant excess capacity remains in several Alaska groundfish fisheries. Under the current management regime, these fisheries are expected to continue to generate an important share of the total ex-vessel value of all domestic commercial fisheries. However, the use of the race for fish to allocate TACs and PSC limits and the high levels of excess harvesting and processing capacity in many of the groundfish fisheries are expected to significantly decrease the net benefits to the Nation from these fisheries.

Average Costs

The costs of operating a fishing boat include fuel, repairs and maintenance, wages of skipper and crew, protection and indemnity insurance, food and consumable supplies, bait, and ice. Because these expenses change with changes in the quantity of output produced they are referred to as variable costs. For some fishing vessels, fuel is the single largest variable cost. It is estimated that these costs represent approximately 10 to 15 percent of the variable cost (Pacific States Marine Fisheries Commission [PSMFC] 2003).

Crew members are paid on a share system, so labor costs depend on the quality and market value of the fish and the number of people receiving a portion of the proceeds. The share agreement can differ from boat to boat. Some fishermen receive a share of the profits, while others receive a share of the gross earnings of the boat. This traditional payment method produces strong economic incentives for maximizing catches and minimizing costs.

Repair and maintenance costs can change substantially from one year to the next. In a particularly bad year these expenses could account for 20 percent of variable costs (PSMFC 2003). Protection and indemnity insurance accounts for approximately 5 percent of variable costs. Unlike hull insurance, which most operators treat as a fixed cost, protection and indemnity insurance is a variable cost. Its price is primarily dependent on three factors: expected numbers of days at sea, number of crew, and the loss history of the vessel or company (PSMFC 2003). Food and consumables make up about 2 percent of an at-sea operation's total variable costs. This category includes food as well as galley supplies, cleaning products, linens, miscellaneous hardware, etc.(PSMFC 2003).

Major operating expenses for fish processing facilities include raw fish, labor, fuel, shipping, utilities, permits, and packaging supplies. Some processing facilities also purchase food additives. For example, pollock surimi additives such as sorbital, sugar and phosphates account for about 5 percent of the variable costs (PSMFC 2003). Shipping costs account for approximately 12 to 15 percent of variable costs. The majority of fish products are shipped via commercial carriers to intermediate or final destinations. Wage rates vary from one plant to another and among locations. While some floating processors pay minimum wage ($7.15 per hour), the average pay, when room and board is not provided, is about $7.50 per hour (Alaska Department of Labor and Workforce Development 2003). A few plants operate only for a short five to six week season and may pay $8 or $9 an hour. In addition to wages, some Alaska fish processing companies offer other benefits to employees, such as free lodging and meals and transportation to and from Alaska if employees fulfill their contractual obligations. The seafood processing industry in Alaska has become very competitive, and employee benefit costs are major expenses. Few corporations willingly settle for lower profits, and no one wants to shut down, so many seafood processing workers' wages and benefits have been cut in recent years.

Other significant operating costs for certain shore-based processors and fishing vessels are those associated with deployment of observers.[7] The fishing industry must bear these costs, which are about $355 per deployment day, not including food costs.

In addition to variable costs, the operators of fishing vessels and processing facilities must meet fixed costs, i.e., expenses that do not vary with level of production, such as the interest on the debt incurred in purchasing a boat, processing facility, license, or other fishing- or processing-related assets.

At present, there is insufficient data on operating costs to comprehensively assess economic conditions in the groundfish fisheries. The types of economic data that would be necessary include disaggregated cost and employment information from harvesting and processing firms. No data on the costs of production and little

---

[7] With some exceptions, observer regulations require vessels 125 ft or longer to carry an observer 100 percent of the time while fishing for groundfish; vessels 60-124 ft long to carry an observer during 30 percent of their fishing days in each calendar quarter of the year in which they fish more than 10 days; plants processing 1,000 or more metric tons in a month to have an observer in the plant each day they process groundfish; and those processing 500-1,000 mt to have observers 30 percent of the days.

data on employment levels are routinely collected.[8] Without information about costs, it is not possible to determine the profitability of harvesting and processing operations.

NOAA Fisheries and NPFMC have recognized the increasing need to collect economic data on a regular basis. To help meet this need, the Fisheries Economics Data Program was established as a cooperative data collection program by NOAA Fisheries and PSMFC with the assistance of NPFMC and Pacific Fishery Management Council. On-going economic data collection efforts by the program include a monthly survey of fuel docks at selected ports on the West Coast and in Alaska to create a marine fuel price index. Data are currently available for the period 1999-2002.

Safety of Human Life at Sea

The high risks faced by fishermen at sea and the effects of fishery regulations on those risks are recognized broadly. The MSA National Standard 10 highlights the issue of fishing vessel safety, stating that conservation and management measures must, to the extent practicable, promote the safety of human life at sea. The harsh sea and weather conditions in the Bering Sea and GOA make fishing in Alaska one of the most dangerous occupation in the U.S. (Barrett 2000). Lincoln and Conway (1999) of the National Institute of Occupational Safety and Health (NIOSH) estimate that, from 1991 to 1998, the occupational fatality rate in commercial fishing off Alaska was 116/100,000 (persons/full time equivalent jobs), or about 26 times the national average of 4.4/100,000.[9] Statistics indicate that 536 individuals suffered severe injuries in commercial fishing related incidents in Alaska during 1991-1997 (Lincoln *et al.* 2002), and 120 Alaska fishermen died between 1989 and 1999 (Cullenberg 2002). Over 90 percent of these deaths were due to drowning following vessel sinkings (Lincoln *et al.* 2002). Fatality rates were highest for the Bering Sea crab fisheries. Groundfish fatality rates, at about 46/100,000 were the lowest for the major fisheries identified by Lincoln and Conway. Even this relatively lower rate was about ten times the national average.[10]

Lincoln and Conway (1999) note, however, that during most of the 1990s commercial fishing in Alaska actually appeared to become safer. While annual vessel accident rates remained relatively stable, annual fatality per incident rates (case fatality rates) dropped. The result was an apparent decline in the annual occupational fatality rate. From 1991 to 1994, the case fatality rate averaged 17.5 percent a year; from 1995 to 1998 the rate averaged 7.25 percent a year. Lincoln and Conway (1999, p. 694) described their view of the source of the improvement in the following quotation:

> *"The impressive progress made during the 1990s in reducing mortality from incidents related to fishing in Alaska has occurred largely by reducing deaths after an event has occurred, primarily by keeping fishermen who have evacuated, capsized or sinking vessels*

[8] Most fishermen are considered self-employed and as a result are not included in Alaska Department of Labor and Workforce Development employment statistics.

[9] The rates in the NIOSH study are based on an estimate of 17,400 full time employees active in the fisheries. This estimate of the employment base was assumed constant over the time period. However, various factors may have affected this base, including reductions in the size of the halibut and sablefish fleets due to the introduction of individual quotas. These estimates must therefore be treated as rough guides.

[10] With an average fatality rate of approximately 28 fatalities per 100,000 FTE workers since 1990, the BSAI pollock fishery has enjoyed a relatively solid safety record for the past decade (Woodley 2002).

afloat and warm (using immersion suits and life rafts), and by being able to locate them readily, through electronic position indicating radio beacons."

There could be many causes for the lower number of deaths following vessel sinkings. Lincoln and Conway (1999) and van Amerongen (2002) point to provisions of the Commercial Fishing Industry Vessel Safety Act (CFIVSA) of 1988 that were implemented in the early 1990s. This law required the U.S. Coast Guard to issue new regulations for safety equipment and operating procedures for fishing, fish tender and fish processing vessels. It also increased casualty reporting requirements. As a result of this legislation vessels are better equipped with Emergency Position Indicating Radio Beacons (EPIRBs), life rafts, side-band radios, and survival suits. Moreover, emergency drill instructor training and mandatory monthly drills are required of all fishing vessels. Following the passage of the CFIVSA, vessels throughout Alaska have had the opportunity to obtain a Voluntary Dockside Examination (VDE) by the Coast Guard or Coast Guard Auxiliary (Medlicott 2002). If they pass the inspection they are issued a Vessel Safety Inspection Decal, valid for two years. Since a VDE is currently voluntary, the NPFMC initiated a regulation in 1998 that made the VDE or some other documentation of compliance with Coast Guard regulations mandatory for all vessels carrying observers (Cullenberg 2002).

In response to a surge in commercial fishing related deaths and vessel losses in 1999 (17 Alaska fishermen lost their lives in that year), the Seventeenth Coast Guard District increased the focus on commercial fishing vessel safety. One of the items developed was the "Ready for Sea" program (Page 2002). This is a list of the top ten safety items to which mariners should pay particular attention in order to mitigate known risks and help ensure a vessel's safe return to port. The checklist focuses on items that could prevent an incident and how to be prepared to respond if one does occur.

The Coast Guard receives support for maintaining fishing vessel safety from the North Pacific Fishing Vessel Owners' Association (NPFVOA), a non-profit, membership based organization. The NPFVOA and Coast Guard produced the Vessel Safety Manual in 1985 and collaborated on a core safety program and set of safety training videos. The core program consists of survival at sea training, first aid and CPR training, fire fighting, and stability training and the Safety at Sea video series includes four videos titled Safety Equipment and Survival Procedures, Fire Prevention and Control, Medical Emergencies at Sea, and Fishing Vessel Stability. After the passage of the CFIVSA, the NPFVOA developed a course to teach individuals how to conduct emergency drills. Since it was first organized, the NPFVOA has trained over 22,000 fishermen.

The IFQ program for the halibut and sablefish longline fishery and the establishment of cooperatives in the BSAI pollock fishery under the AFA have contributed to the improved safety record in the Alaska groundfish fisheries by slowing the pace of fishing. For example, the elimination of the race for fish in these fisheries provide captains with the opportunity to wait out a storm without negative economic consequences (van Amerongen 2002). A 1995 report from Marine Safety Reserve, a liability pool, noted a substantial decline in the longline vessel accident rate (injuries per fishing day) following implementation of the IFQ program (Buck 1995). Safety statistics compiled by the U.S. Coast Guard show that, as the IFQ program progressed, a substantial drop in search and rescue missions for the sablefish and halibut fisheries occurred (Hartley and Fina 2001a, Woodley 2002). Furthermore, a survey of sablefish fishermen revealed that more than 90 percent reported weather as an important factor in determining when to fish quota (Knapp and Hull 1996). Similar benefits in vessel safety have resulted from the operation of the AFA pollock cooperatives. While the slowing down of the BSAI pollock fishery and the flexibility offered by the quota systems has not had an impact upon fatality rates (the fatality rate has remained at zero since 1995), vessels from several of the Pollock

Conservation Cooperative companies have reported an approximately 50 percent reduction in processing-crew injuries (Woodley 2002).

Catcher Vessels

This section provides brief profiles of the nine classes of groundfish catcher vessels that participate in the groundfish fisheries off Alaska. As is the case with the profiles of the offshore and inshore processors that follow, the information on catcher vessels provided here is an abridged version of the detailed profiles in *Sector and regional Profiles of the North Pacific Groundfish Fisheries – 2001* (Northern Economics, Inc. and EDAW, Inc. 2001). Each catcher vessel profile reports generally the same types of information to ease comparisons among classes. The remainder of this introductory section describes the features that distinguish the various classes from each other and provides an overview of the catcher vessel activities from 1992-2001.

Catcher vessels harvest groundfish by using various gear types and deliver their catch to inshore processing plants or motherships. Catcher vessels can be divided into two general categories: trawl vessels and fixed gear vessels. This analysis creates five classes of trawl vessels based on participation patterns and vessel length. Four classes of fixed gear vessels are defined based on primary gears and vessel length. Each vessel with participation in the groundfish fisheries above threshold levels was assigned to one of these classes during a given year according to its fishing activities in that year and its size. The classes were developed specifically for use in this analysis to enhance the differences and similarities among the catcher vessels that participate in the groundfish fisheries.

Catcher vessels harvest a number of species, including both groundfish and non-groundfish. In an effort to provide a relatively uniform description of the activities of each of the nine types of catcher vessels and to report as much catch data as possible under NOAA Fisheries data confidentiality restrictions, this analysis aggregated the groundfish species into the four main groups (A-R-S-O, FLAT, PCOD and POLL) presented in Table 3.9-2. Further, catcher vessels operate in different regions of Alaska, and their owners and crew reside in communities located in or out of the state. The geographic regions that were identified for this analysis are presented in Table 3.9-3.

Table 3.9-5 provides a comparison of the relative level of activities of the different classes. Table 3.9-6 summarizes the operations of the nine catcher vessel classes in 2001.

The vessels in the first two trawl catcher vessel (TCV) classes (TCV Bering Sea pollock [BSP] ≥ 125 and TCV BSP 60-124) are all eligible to harvest the directed fishing allowance under Section (b)(1) of the American Fisheries Act and focus almost exclusively on BSP. The two classes differ in that the larger vessels can carry significantly more fish in their holds and are able to fish much farther from shore. In 2001, these two classes of catcher vessels accounted for more than half of the total catcher vessel ex-vessel value and payments to labor.

The third class of TCV (TCV Diversified-AFA) are also AFA-eligible, but they generate less gross revenue in the BSAI pollock fisheries than they do in other trawl fisheries, such as those occurring in the GOA. This class generally consisted of vessels between 60 and 124 ft in LOA, but in some years included one or two vessels longer than 124 ft. The fourth class of TCV (TCV Non-AFA) are not AFA-eligible and therefore do not have access to the lucrative BSAI pollock fisheries. Instead, these vessels focus their fishing effort in the GOA. These vessels are all greater than 60 ft long. The final class of trawl vessels (< 60) are all less than

60 ft in length and fish almost exclusively in the GOA. Most of these vessels also participate in Alaska salmon fisheries with purse seine gear. State regulations prohibit the use of vessels longer than 58 ft in salmon seine fisheries.

Pot catcher vessels (PCV) traditionally have focused on crab fisheries. Recently, these vessels have developed a secondary source of income between crab fishing seasons by using pot fishing techniques to harvest Pacific cod. Longline catcher vessels concentrate their fishing effort in sablefish and halibut IFQ fisheries. Although the groundfish harvests of Longline catcher vessels are substantially less than those of TCV, the value of their harvests are significant because of the relatively high ex-vessel value of sablefish. All vessels in the PCV and LCV classes are 60 ft or longer.

There are far more vessels in the class comprised of fixed gear catcher vessels from 33 to 59 ft in length (Fixed Gear Catch Vessels 33-59) than in any other class. Most of these vessels participate in groundfish fisheries to augment their earnings from Alaska salmon fisheries. However, because this class is so large it has the third highest ex-vessel value of groundfish among the catcher vessel classes. These vessels obtain most of their groundfish revenues from harvests of Pacific cod and high-value species in the A-R-S-O group, primarily sablefish and rockfish.

Fixed gear catcher vessels less than or equal to 32 ft in length (fixed gear catcher vessels ≤ 32) have limited activity in groundfish fisheries, as most of these vessels were constructed specifically to harvest salmon. They often harvest higher-value groundfish such as Pacific cod, rockfish and sablefish when not engaged in salmon fisheries. Vessel size restricts the effectiveness of the fixed gear catcher vessels ≤ 32 class in groundfish fisheries.

Overview of Catcher Vessel Activities

Table 3.9-6 summarizes the activities of catcher vessels in the Alaska groundfish fisheries during the 1992-2001 period. Major findings presented in the table are as follows:

- The number of catcher vessels in the groundfish fisheries declined from 1,374 in 1992 to 917 in 2001. However, the quantity of groundfish landed by catcher vessels and retained by processors remained relatively steady, fluctuating between a high of 970 thousand mt in 1997 and a low of 772 thousand mt in 1993. The harvest was stable in comparison to the number of participating vessels because most of the vessels that exited the fisheries were small fixed gear vessels (fixed gear catcher vessel 33-59 and fixed gear catcher vessel ≤ 32) that tend to harvest less fish. Furthermore, total groundfish catch depends less on the number of vessels than on the allowable harvest levels and allocations among fishery participants established by NOAA Fisheries and NPFMC.

- During the 1992-2001 period most of the catcher vessels were registered by individuals or companies in the southcentral Alaska and southeast Alaska regions. However, the number of vessels from these regions decreased, while the number of vessels from the WAIW region increased.

- In some years non-groundfish species were nearly as important as groundfish to catcher vessels as a whole in terms of ex-vessel value. Between 1992 and 2000, non-groundfish accounted for about half of the ex-vessel value of the landings of all catcher vessels.

- As a result of the high ex-vessel value of Pacific cod and species in the A-R-S-O complex, which includes sablefish and rockfish, the ex-vessel value of landings of these species approached or exceeded that of pollock in some years. In 1996, for example, pollock accounted for 47 percent of total ex-vessel value of groundfish landings, while the A-R-S-O group and Pacific cod accounted for 29 and 22 percent, respectively. However, pollock has accounted for most of the ex-vessel value of catcher vessels in recent years.

- Between 1992 and 2001, the BSAI accounted for 51 to 63 percent of the ex-vessel value of catcher vessel landings. It is in this area that large trawlers harvest pollock. The GOA is a major source of Pacific cod and A-R-S-O species.

- In 2001, the WAIW region accounted for about 40 percent of the total FTE groundfish employment on catcher vessels and approximately 60 percent of the total payments to labor. The difference is due to fact that most of the boats and employment came from smaller, Alaska-based vessels with generally lower groundfish revenues, while the larger vessels with higher groundfish revenues per crew were mainly based in Washington.

Drawing on information in *Sector and Regional Profiles of the North Pacific Groundfish Fisheries – 2001* (Northern Economics, Inc. and EDAW, Inc. 2001), the remainder of this subsection presents summary profiles of the nine catcher vessel classes. Each catcher vessel class profile provides a description of the class in terms of the size and number of vessels; an overview of participation by the class in groundfish and other Alaska fisheries; a more detailed look at the Alaska groundfish fisheries important to the class; estimates of employment and payments to labor in the Alaska groundfish fisheries; and patterns of vessel ownership.[11] Each profile also includes a table showing number of active vessels, vessel registration by region, groundfish landings retained, ex-vessel value of groundfish and non-groundfish retained, ex-vessel value of groundfish retained by species group, ex-vessel value of groundfish retained by FMP subarea, and groundfish employment and payments to labor by region.

<u>Bering Sea Pollock Trawl Catcher Vessels ≥ 125 ft in Length (Trawl Catcher Vessel BSP ≥ 125)</u>

Synopsis

Large vessels that are AFA-eligible and rely almost exclusively on pollock harvested in the Bering Sea. Nearly all of the catch of these vessels is delivered to Bering Sea pollock shoreplants (BSP-SPs) (Table 3.9-7).

Description of the Class

This catcher vessel class includes all vessels for which trawl catch accounts for more than 15 percent of total catch value, the value of BSP catch is greater than the value of the catch of all other species combined, vessel length is greater than or equal to 125 ft, and the total value of groundfish catch is greater than $5,000. All

[11] While it is known that many of the large inshore processing plants have full or part ownership of many of the catcher vessels that deliver to them, detailed information regarding ownership linkages within the fishing industry is absent. Vessel registration and permit information do not necessarily reveal the true ownership of vessels. Consequently, this analysis did not attempt to provide a detailed description of vessel ownership patterns.

of these vessels fishing after 1998 are AFA-eligible. In 2000, vessels in the TCV BSP ≥ 125 class had an average length of 153 ft, an average horsepower rating of about 2,475, an average gross tonnage of approximately 310 tons, and an average hold capacity of 13,500 cubic ft.

Participation in Groundfish Fisheries

The number of vessels in this class reached a peak of 36 in 1997. In 1999, the most recent year for which landings data for all non-groundfish species are available, about 93 percent of all ex-vessel value generated by the class came from groundfish fisheries. Some of these vessels also participate in the summer Pacific whiting fishery off the coasts of Oregon and Washington. During June and July, some vessels in this category may tender salmon or undergo maintenance if they are not engaged in the whiting fishery. The bimodal distribution of groundfish activity of this vessel class is a function of the two primary regulatory seasons for pollock—the roe season in the winter and spring and the non-roe season in the summer and fall. Because of the class's reliance on the pollock resource, the Bering Sea FMP subarea is clearly the most important fishing area. In recent years this area accounted for more than 98 percent of the total ex-vessel value of the groundfish landed by this vessel class. Nearly all of the groundfish was delivered to BSP-SPs.

Groundfish Landings by Species

Pollock is clearly the most important fishery for the class, accounting for nearly all of the retained groundfish landings and ex-vessel value. Pacific cod has been the second most important species in terms of volume and value since 1988. From 1992 to 2001, the volume of groundfish retained for the class varied between 206 thousand mt and 383 thousand mt. In the same period, groundfish ex-vessel value ranged from a high of $100 million in 1997 to a low of $35 million in 1993.[12]

Employment, Payments to Labor, and Ownership

Normally, a vessel in the TCV BSP ≥ 125 class carries four to five crew members (including the skipper) when fishing for pollock and other groundfish. In addition to the fishing crew, one or more people must be responsible for accounting, correspondence, record keeping, and other business requirements. The vessel owner may fill this role or hire a person or firm to complete these tasks. Payments to labor for this vessel class have varied widely as a result of fluctuations in ex-vessel value. In 2001, Washington residents or companies registered all vessels in this class except one. The one exception was a vessel registered by a resident of the Other regions.

Bering Sea Pollock Trawl Catcher Vessels 60 to 124 ft in Length (Trawl Catcher Vessel BSP 60-124)

Synopsis

These are large- or medium-sized vessels that are AFA-eligible and rely almost exclusively on pollock harvested in the Bering Sea. Many of the vessels deliver their catch to motherships or catcher processors (Table 3.9-8).

[12] After the enactment of the American Fisheries Act in 1998, ex-vessel prices may have been more closely tied to the quality of fish delivered, particularly for roe-bearing pollock harvested in the A Season. Higher A Season prices were noted in payments to TCV from motherships.

Description of the Class

This catcher vessel class includes all vessels for which trawl catch accounts for more than 15 percent of total catch value, the value of BSP catch is greater than the value of the catch of all other species combined, vessel length is 60 ft to 124 ft, and the total value of groundfish catch is greater than $5000. All of these vessels fishing after 1998 are AFA-eligible.

Vessels in this class are similar to vessels in the TCV BSP ≥ 125 class. The key difference between the two classes is vessel size. Because of their relatively small fish-hold sizes, many of the vessels in this class cannot carry enough pollock to be cost-effective in the high-volume, shore-based pollock fishery. Therefore, many vessels deliver their pollock to motherships or to catcher processors. In 2000, over 42 percent of the total value of deliveries in the TCV BSP 60-124 class was generated by at-sea deliveries. In that year vessels in the TCV BSP 60-124 class had an average length of 113 ft, an average horsepower rating of about 1,330, and an average hold capacity of 7,763 cubic ft.

Participation in Groundfish Fisheries

The number of vessels in this class has fluctuated, reaching a peak of 63 in 1995 and declining to a low of 42 in 1999. The vessels in this class focus their fishing effort in the BSAI pollock fishery. The primary pollock fishing periods extend from mid-January through the end of April and from August through November, with variations due to regulatory changes. Some of these vessels also participate in the summer Pacific whiting fishery off the coasts of Oregon and Washington. During June and July, some vessels in this category may tender salmon or undergo maintenance if they are not engaged in the whiting fishery. In 1999, the most recent year for which complete landings data for non-groundfish species are available, about 88 percent of all ex-vessel value generated by the class came from groundfish fisheries. Because of reliance on pollock, the Bering Sea FMP subarea is the most important fishing area for the class and accounted for about 97 percent of the total ex-vessel value of groundfish retained in 2001. In 2000, roughly 56 percent of the ex-vessel value was generated from deliveries to Bering Sea pollock-shoreplants, while motherships accounted for 40 percent of the class's groundfish revenues.

Groundfish Landings by Species

In 2000, pollock accounted for 94 percent of harvest volume and 87 percent of total ex-vessel value. From 1992 to 2001, the volume of groundfish retained for the class varied between 254 thousand mt and 424 thousand mt. In the same period, groundfish ex-vessel value ranged from a high of $95 million in 1992 to a low of $43 million in 1998.

Employment, Payments to Labor, and Ownership

Four- to five-person crews, including the skipper, are typical on vessels in the TCV BSP 60-124 class, although it is likely that the AFA will result in a reduction in crew size for some vessels. Since 1992, the estimated FTE groundfish employment for this class has fluctuated widely, from a low of 128 in 1999 to a high of 290 in 2001. Estimated payments to labor have also varied widely as a result of fluctuations in ex-vessel value. In 2001, vessels registered in WAIW accounted for about two-thirds of the vessels in this class, and Oregon residents or companies registered about 22 percent of the fleet. In recent years, a few vessels have been registered by individuals or companies in Kodiak.

Diversified AFA-Eligible Trawl Catcher Vessels Greater than or Equal to 60 ft in Length (Trawl Catcher Vessel Div. AFA)

Synopsis

These are medium-sized vessels that are AFA-eligible but participate in the GOA pollock fishery and BSAI and GOA Pacific cod fisheries as well as the Bering Sea pollock fishery (Table 3.9-9).

Description of the Class

This catcher vessel class includes all vessels that are AFA-eligible for which trawl catch accounts for more than 15 percent of total catch value, the value of Bering Sea pollock catch is less than value of catch of all other species combined, vessel length is equal to or greater than 60 ft, and the total value of groundfish catch is greater than $5,000.

Vessels in the TCV Div. AFA class are more diversified in fishing effort than vessels in the TCV BSP ≥ 125 and TCV BSP 60-124 classes, but they are also eligible under AFA to participate in the BSAI pollock fisheries. In 2000, vessels in the TCV Div. AFA class had an average length of 92 ft, an average horsepower rating of about 995, an average gross tonnage of approximately 170 tons, and an average hold capacity of 4,866 cubic ft.

Participation in Groundfish Fisheries

The number of vessels in this class varied between 19 and 34 during the 1992-2001 period. In 1999, the most recent year for which complete landings data for non-groundfish species are available, about 93 percent of all ex-vessel value generated by the class came from groundfish fisheries. In addition to Bering Sea pollock, vessels in the TCV Div. AFA class have significant participation in the GOA pollock fisheries and the Pacific cod fisheries in both the BSAI and GOA. Some vessels in the class also participate in the Pacific whiting fishery off the coasts of Oregon and Washington. In recent years, GOA fisheries were more important for this class than BSAI fisheries in terms of ex-vessel value of groundfish retained. In 2000, roughly 46 percent of the ex-vessel value was generated from deliveries to Kodiak shoreplants, while 36 percent of the ex-vessel value was from Bering Sea processing facilities.

Groundfish Landings by Species

Pollock is the single most important species for the TCV Div. AFA class in terms of harvest volume and ex-vessel value. Pacific cod is the second most important species. Overall, ex-vessel value peaked in 1992 as the groundfish fisheries changed from joint venture fisheries to domestic processing operations. In 1993, gross revenues dropped significantly due primarily to lower ex-vessel prices rather than smaller harvests. From 1992 to 2001, the volume of groundfish retained for the class varied between 48 thousand mt and 111 thousand mt. In the same period, ex-vessel value ranged from a high of $33 million in 1992 to a low of $12 million in 1996.

Employment, Payments to Labor, and Ownership

Four person crews, including the skipper, are typical on vessels in the TCV Div. AFA class. Payments to labor have varied widely as a result of fluctuations in ex-vessel value. In 2001, vessels registered in Washington accounted for 45 percent of the vessels in this class, while individuals or companies in Oregon accounted for 20 percent of the vessels. The percentage of vessels registered by Kodiak residents or companies has declined over the years, but this region still accounted for one-fifth of the fleet in 2001.

<u>Non-AFA Trawl Catcher Vessels Greater than or Equal to 60 ft in Length (Trawl Catcher Vessel Non-AFA)</u>

Synopsis

These are medium-sized vessels that participate in the GOA groundfish fisheries and may also participate in halibut IFQ fisheries using longline gear (Table 3.9-10).

Description of the Class

This class includes all vessels that are not AFA-eligible for which trawl catch accounts for more than 15 percent of total catch value, the value of Bering Sea pollock catch is less than the value of catch of all other species combined, vessel length is greater than or equal to 60 ft., and the total value of groundfish catch is greater than $5,000. In 2000, vessels in the TCV Non-AFA class had an average length of 83 ft, an average horsepower rating of about 660, an average gross tonnage of approximately 140 tons, and an average hold capacity of 3,550 cubic ft.

Participation in Groundfish Fisheries

Participation peaked at 48 vessels in 1992, and then dropped back to a more stable level between 32 and 40 vessels. The annual cycle of operations of vessels in the TCV Non-AFA class differs from that of AFA-eligible TCV s. Differences include the reliance of the TCV Non-AFA fleet on the GOA groundfish fishery and the participation of several vessels in this class in the halibut IFQ fisheries using longline gear. Because these vessels are longer than 60 ft, they are ineligible to participate in Alaska commercial salmon fisheries with seine gear. In 1999, the most recent year for which complete landings data for non-groundfish species are available, about 84 percent of all ex-vessel value generated by the class came from groundfish fisheries. The central GOA has been the most important FMP subarea for the class. The importance of the Bering Sea peaked in 1997. After that year, vessels in the TCV Non-AFA class were unable to fish for BSAI pollock as a result of enactment of the AFA. However, the non-pollock harvest restrictions on AFA trawl vessels may encourage non-AFA trawl vessels to increase their participation in the BSAI Pacific cod fishery. In 2000, deliveries to Kodiak shoreplants accounted for 74 percent of gross revenues, while deliveries to Alaska Peninsula and Aleutian Islands shoreplants (APAI-SP) accounted for 11 percent.

Groundfish Landings by Species

As with AFA eligible TCV s, pollock is the primary species in terms of retained tonnage for vessels in the TCV Non-AFA class. However, the ex-vessel value of Pacific cod exceeded that of pollock in every year except 1998 and 2001. From 1992 to 2001, the volume of groundfish retained for the class varied between

33,000 and 55,000 mt. In the same period, ex-vessel value ranged from a high of $22 million in 1997 to a low of $9 million in 1994.

Employment, Payments to Labor, and Ownership

Vessels in the TCV non-AFA class typically carry a crew of four, including the skipper. One crew member usually functions as the engineer in addition to filling a position on deck. One person may function as the cook, or that role may be shared among crew members. Payments to labor have varied widely as a result of fluctuations in ex-vessel value. A fairly stable ownership pattern by Alaska residents or companies is evident for vessels in this class. Between 11 and 15 of the vessels were registered to individuals or companies in Kodiak between 1992 and 2001. Other Alaska residents or companies were the registered owners of another three to eight vessels. Individuals or companies in Washington and Oregon were the registered owners of most of the remaining vessels.

<u>Trawl Catcher Vessels Less than 60 ft in Length (Trawl Catcher Vessel < 60)</u>

Synopsis

These are small trawlers that participate in the GOA groundfish fisheries and may also participate in salmon fisheries using purse seine gear (Table 3.9-11).

Description of the Class

This catcher vessel class includes all vessels for which trawl catch accounts for more than 15 percent of total catch value, vessel length is less than 60 ft, and the total value of groundfish catch is greater than $2,500. The TCV < 60 fleet is treated as a distinct class because of differences between these vessels and larger TCVs. In particular, vessels in the TCV < 60 class are allowed to participate in the State of Alaska commercial seine fisheries for salmon. Alaska's limited entry program for salmon fisheries established a 58-foot length limit for seine vessels entering these fisheries after 1976. Many TCVs less than 60 ft in length were built to be salmon purse seine vessels, while others were designed to function as both trawlers and seiners.

Vessels in the TCV < 60 class are distinct from fixed gear vessels greater than 32 ft and less than 60 ft because of their ability and propensity to use trawl gear. Vessels in the TCV < 60 class have larger engines, more electronics, larger fish holds, and the necessary deck gear and nets to operate in the trawl fisheries. Similar-sized fixed gear vessels that participate in commercial salmon fisheries with purse seine gear have not made the necessary investment to participate in the trawl fisheries.

Participation in Groundfish Fisheries

The number of vessels in this class increased steadily from 1989 through 1993. This increase coincided with the development of domestic shore-based fisheries in the western GOA and central GOA FMP subareas of the GOA, where most of these vessels participate. From 1994 through 2001, the number of vessels in the TCV < 60 class remained between 44 and 61. Vessels in the TCV < 60 class participate in multiple fisheries and generally take full advantage of locally available fishery resources. These resources can differ significantly across different fishery management areas. Salmon harvesting is important to the economic viability of most vessels in this class. A significant percentage of the vessels also participate in the sablefish and halibut longline IFQ fisheries. In 1999, the most recent year for which complete landings data for non-groundfish species are available, about 55 percent of all ex-vessel value generated by the class came from groundfish fisheries. The decline in non-groundfish revenues after 1995 was primarily the result of a drop in salmon landings. The western GOA and central GOA are by far the most important fishing areas for the class, accounting for about 90 percent of the ex-vessel value in 2001. Vessels in the TCV < 60 class are increasingly relying on APAI-SPs. In 2000, they received 82 percent of their gross revenues from these plants, up from 70 percent in 1998. Processors in Kodiak are becoming less important to the TCV < 60 class, accounting for 34 percent of the ex-vessel value in 1995 and 6 percent in 2000.

Groundfish Landings by Species

Vessels in the TCV < 60 class focus their effort on Pacific cod in the western GOA and central GOA FMP areas of the GOA. Pollock is also an important trawl species, while sablefish (a component of the A-R-S-O species aggregation) harvested with longline gear makes a substantial contribution to the gross revenues of the class. From 1992 to 2001, the volume of groundfish retained for the class varied between 19,800 and 39,800 mt. In the same period, ex-vessel value ranged from a high of $14 million in 1997 to a low of $7 million in 1993.

Employment, Payments to Labor, and Ownership

The crew size on vessels in the TCV < 60 class typically ranges from three to four, including the skipper, depending on the fishery. Usually these crew members are employed in other fisheries as well. Since 1992, total estimated groundfish employment in the TCV < 60 class has varied between 91 and 129. About 75 percent of the vessels were registered by Alaska residents or companies in 2001, and the remainder were registered predominantly by individuals or companies in Washington. Individuals or companies in the Alaska Peninsula and Aleutian Islands region have consistently had the highest number of vessels in this class during the past decade, with most based in King Cove and Sand Point.

<u>Pot Catcher Vessels (PCV)</u>

Synopsis

These are medium-sized vessels that rely mostly on crab fisheries but also participate in Pacific cod fisheries primarily in the Bering Sea and central GOA (Table 3.9-12).

Description of the Class

This catcher vessel class includes all vessels that are not TCVs for which the value of pot catch is greater than15 percent of total catch value, vessel length is greater than or equal to 60 ft, and the total value of groundfish catch is greater than $5000. The vast majority of vessels in this class focus on crab fisheries and participate in groundfish fisheries only as a secondary activity. This class is distinct from other fixed gear vessels because all vessels in the class have crab endorsements under the BSAI groundfish and crab fisheries LLP, primarily use pots rather than longline or jig gear, and are longer than 60 ft. These differences in vessel size, gear type, and relevant regulations result in operational and financial differences between PCVs and other fixed gear catcher vessels. However, many PCVs have substantial landings with longline gear. In 2000, vessels in the PCV class had an average length of 105 ft, an average horsepower rating of about 825, an average gross tonnage of approximately 185 tons, and an average hold capacity of 7,475 cubic ft.

Participation in Groundfish Fisheries

The number of PCVs that have made more than incidental landings of groundfish varied widely between 1992 and 2001. During the early part of this period, many vessels experimenting with pot fishing for Pacific cod could not make enough money to justify continued participation. In 1995, harvests in the opilio tanner crab fishery, which had become the mainstay of the crab fleet, reached the lowest levels in a decade, and crab fishers sought other fisheries to generate needed revenues. The number of PCVs with substantial groundfish landings jumped to 101. Between 1995 and 2000, participation first declined as opilio harvests increased but then sharply increased to 158. In 1999, the most recent year for which complete landings data for non-groundfish species are available, about 13 percent of all ex-vessel value generated by the class came from groundfish fisheries. The crab fishery is the mainstay of the PCV class. The Pacific cod fishery is a way to keep crew members employed for longer periods and possibly make additional marginal contributions to the financial bottom line. The Bering Sea FMP subarea is the most important fishing area for the PCV class, followed by the central GOA. Bering Sea shoreplants are the largest buyers of groundfish harvests of PCVs, accounting for approximately 40 percent of gross revenues. Processors in Kodiak account for about 30 percent of PCV ex-vessel value.

Groundfish Landings by Species

Pacific cod has been the most important groundfish species for this class in terms of harvest volume and total ex-vessel value, and pollock has been the least important groundfish species. The A-R-S-O aggregation also accounts for a relatively large share of ex-vessel value, reflecting the fact that between 10 and 17 vessels in this class have participated in the high-value sablefish fisheries over the years. From 1992 to 2001, the volume of groundfish retained for the class varied between 7,000 and 27,000 mt. In the same period, ex-vessel value ranged from a high of $21 million in 2000 to a low of $4 million in 1993.

Employment, Payments to Labor, and Ownership

Pot vessels harvesting groundfish have an average of four to five crew members, including the skipper. Since 1992, total estimated FTE groundfish employment in the PCV class has varied between 72 in 1993 to 329 in 2000. During the 1992-2001 period, about half of the vessels in this category were registered by Alaska residents or companies, on average. However, in recent years the percentage of vessels registered by Washington residents or companies has substantially increased. Among the regions in Alaska, Kodiak has generally had the most vessel owners in this class.

<u>Longline Catcher Vessels Greater than or Equal to 60 ft in Length</u>

Synopsis

These are medium-sized vessels that target halibut and higher-priced groundfish such as sablefish and rockfish mainly in the eastern and central GOA (Table 3.9-13).

Description of the Class

This catcher vessel class includes all vessels that are not TCVs or PCVs for which vessel length is greater than or equal to 60 ft and the total value of groundfish catch is greater than $2,000, excluding halibut and state water sablefish. A large majority of the vessels in this class operate solely with longline fixed gear, focusing on halibut and relatively high-value groundfish such as sablefish and rockfish. Their operating parameters are influenced primarily by regulations for fixed gear fisheries targeting these species. The reliance of LCVs on groundfish fisheries sets them apart from smaller fixed gear catcher vessels, which are much more likely to operate in Alaska salmon fisheries with multiple gear types. The use of 60 ft as the minimum length for vessels in this class reflects the fact that regulations for State of Alaska salmon fisheries limit participating vessels to 58 ft. Thus, by definition vessels in the LCV class are generally precluded from operating in Alaska salmon fisheries. The LCVs reliance on longline gear sets them apart from the other large fixed gear vessels that use pots and have crab endorsements under the Crab LLP. In 2000, vessels in the LCV class had an average length of 72 ft, an average horsepower rating of about 395, an average gross tonnage of approximately 90 tons, and an average hold capacity of 4,688 cubic ft.

Participation in Groundfish Fisheries

The number of LCVs increased from 89 in 1988 to 121 in 1994. The general decline in the number of vessels in this class since 1994 may be the outcome of the IFQ program. In 1999, the most recent year for which complete landings data for non-groundfish species are available, about 34 percent of all ex-vessel value generated by the class came from groundfish fisheries. The eastern GOA and central GOA FMP subareas are the most important fishing areas for the LCV class. In 2000, LCVs received 37 percent of their gross revenues from processors in southcentral Alaska and 31 percent from processors in southeast Alaska. The relative importance of processors in Kodiak increased from 10 percent of the ex-vessel value in 1999 to 19 percent in 2000.

Groundfish Landings by Species

A-R-S-O were the most often landed groundfish species for the LCV class during the 1992-2001 period, whereas pollock was the least. From 1992 to 2001, the volume of groundfish retained for the class varied between 4,200 and 18,400 mt. In the same period, ex-vessel value ranged from a high of $39 million in 1997 to a low of $8 million in 1993. Low prices in 1998 and 1999, due to primarily the Asian economic crisis, had a major negative impact on gross revenues.

Employment, Payments to Labor, and Ownership

The LCV class is one of the most labor-intensive of the groundfish catcher vessel classes due to the need to handle each fish and piece of fishing gear individually. Longline catcher vessels typically carry between three and six deckhands and a skipper who also works the deck, although the number of crew members has decreased since 1995 with implementation of the IFQ system. The actual number of deckhands on LCVs generally depends on the fishery and the experience and productivity of the captain and crew. Total estimated FTE employment in groundfish fisheries in the LCV class declined from its high in 1995 (215 FTE) to 169 FTE in 2000. Labor payments per FTE position varied considerably over the 1992-2001 period. Prior to implementation of IFQs in 1995, FTE labor payments were relatively low, but they increased to a peak at $79,213 in 1997. In 1998 and 1999, payments declined due primarily to low prices resulting from the Asian economic crisis. In 2001, about half of the vessels in this category were registered by Alaska residents or companies, and the remainder were registered mainly by Washington residents or companies. Southeast and southcentral Alaska have had the largest number of registered vessel owners in this class among the Alaska regions since the late 1980s. The number of registered owners in southeast Alaska has been stable over the years compared to the number of owners from other Alaska regions. The percentage of registered owners in southcentral Alaska declined from 27 in 1994 (the year before IFQs) to 9 in 1999. Post-IFQ changes in other regions do not appear to be as significant.

Fixed Gear Catcher Vessels Greater than 32 and Less than 60 ft in Length

Synopsis

These are small vessels that focus on salmon, halibut, and higher-priced groundfish using a mix of gear types mainly in the eastern and central GOA (Table 3.9-14).

Description of the Class

This catcher vessel class includes all vessels that are not TCVs for which vessel length is 33 to 59 ft, and the total value of groundfish catch is greater than $2000. The larger size of these vessels in comparison to vessels in the smaller fixed gear class results in greater capacity and fishing efficiency. Consequently, this class accounts for a large portion of the total harvest of fixed gear vessels. The vessels in this class employ a mix of gear types, with smaller vessels typically using longline and jig gear, and larger vessels typically employing longline and pot gear. This class was established because these vessels were typically designed for, and participate in, a greater number of fisheries than smaller fixed gear vessels do, and vessels in this class use more gear types than larger fixed gear vessels use. The length of these vessels (< 60 ft) also means they can participate in almost all Alaskan salmon fisheries with the notable exception of fisheries in Bristol Bay. In 2000, vessels in the fixed gear catcher vessel 33-59 class had an average length of 47 ft, an average horsepower rating of about 313, an average gross tonnage of approximately 36 tons, and an average hold capacity of 2,395 cubic ft.

Participation in Groundfish Fisheries

From 1994 through 2001, the number of vessels in the fixed gear catcher vessel 33-59 class fluctuated between 514 and 860. The significant decline in vessel numbers after 1994 is assumed to be a result of the implementation of IFQs in sablefish and halibut fisheries. The activities of this vessel class have focused on salmon, halibut, and groundfish. Groundfish harvests decline significantly when these vessels switch to harvesting salmon and halibut. In 1999, the most recent year for which complete landings data for non-groundfish species are available, about 29 percent of all ex-vessel value generated by the class came from groundfish fisheries. From 1992 to 2001, the eastern GOA and central GOA FMP subareas accounted for almost all of the value of groundfish retained by this class. Processors in southeast Alaska accounted for approximately 45 percent of the ex-vessel value generated by the fixed gear catcher vessel 33-59 class. Processors in Kodiak and southcentral Alaska both contributed about 20 percent of the total ex-vessel value of the class. The relative importance of Kodiak processors increased following implementation of IFQs in 1995.

Groundfish Landings by Species

Landing volumes were significantly greater for A-R-S-O than for the other species during the entire 1992-2001 period, and pollock and flatfish had the lowest landings. High-value sablefish has been the most important species. Pacific cod has been the second most important species in terms of volume, but is a much smaller component in terms of ex-vessel value. From 1992 to 2001, the volume of groundfish retained for the class varied between 15,000 and 27,000 mt. In the same period, ex-vessel value ranged from a high of $48 million in 2000 to a low of $30 million in 1998.

Employment, Payments to Labor, and Ownership

This analysis assumed an average crew size of 3.5, including the skipper, for this type of vessel. The actual number of crew depends on a number of factors such as the type of gear, the presence of automatic baiting machines, the size of the vessel, and the amount of sablefish IFQ shares owned by the skipper and crew. Since 1992, total estimated FTE employment in groundfish fisheries in the fixed gear catcher vessel 33-59 class has varied between 1,119 and 724. In 2001, about 81 percent of these vessels were registered by Alaska residents or companies, and most of the remainder were from Washington. Individuals or companies in southeast Alaska have had the largest number of vessels in this class among the Alaska regions since the late 1980s. The data reveal that there has been a marked decline in participation of vessels from southcentral and southeast Alaska, while participation by other Alaska regions has remained relatively stable or increased. The regional differences may be due to the opportunistic nature of participation by small boats in groundfish and other fisheries. Residents of southcentral and southeast Alaska have relatively more non-fishing income-generating opportunities than residents of Kodiak and the Alaska Peninsula. If the likelihood of big pay-offs in fishing decline, those individuals that can are more likely to engage in non-fishing occupations. Similar declines are not apparent in Washington and Oregon because it is more likely registered vessel owners in these regions are full-time fishers. Estimated payments per FTE position have varied within a relatively narrow band since 1993, with the exception of 1998, when gross revenues and payments to labor fell due to the Asian economic crisis.

<u>Fixed Gear Catcher Vessels Less than or Equal to 32 ft in Length</u>

Synopsis

These are small vessels that focus on salmon, halibut, and high-value groundfish using a mix of gear types primarily in the central GOA (Table 3.9-15).

Description of the Class

This catcher vessel class includes all vessels that are not TCVs for which vessel length is less than or equal to 32 ft. and the total value of groundfish catch is greater than $1000. These vessels constitute a distinct class because of specific differences when compared to larger fixed gear catcher vessels. A length of 32 ft is the maximum for the Bristol Bay salmon drift gillnet fishery, and vessels in this fishery typically are built to this size limit. A large number of vessels of this size have been built for the Bristol Bay fishery and other salmon fisheries in Alaska. Similar size restrictions do not apply to other salmon management areas in the state. Vessels in this class typically were designed for salmon fisheries. The vessels may use a mix of longline, jig, and sometimes pot gear to harvest halibut and groundfish before or after the salmon season. In 2000, vessels in the fixed gear catcher vessel ≤ 32 class had an average length of 30 ft, an average horsepower rating of about 330, an average gross tonnage of approximately 14 tons, and an average hold capacity of 1,193 cubic ft.

Participation in Groundfish Fisheries

The number of vessels in the fixed gear catcher vessel ≤ 32 class decreased significantly in 1995, at least partly as a result of implementation of the halibut and sablefish IFQ system. Groundfish catches are important to the financial health of vessels in the fixed gear catcher vessel ≤ 32 class, but non-groundfish species generally account for the majority of the total earnings for the fleet. In 1999, the most recent year for which complete landings data for non-groundfish species are available, about 19 percent of all ex-vessel value generated by the class came from groundfish fisheries. The central GOA FMP subarea is the most important fishing area for this class. In recent years, this area has accounted for at least half of the total value of groundfish retained by this fixed gear catcher vessel class. In 1994, Kodiak shoreplants accounted for just 6 percent of the ex-vessel value for the class while southcentral Alaska processing facilities accounted for 50 percent. By 2000, gross revenues from Kodiak plants were 61 percent of the class total, while southcentral Alaska plants accounted for 16 percent. This change has come about because of the increasing importance of the Pacific cod fishery to vessels in the fixed gear catcher vessel ≤ 32 class.

Groundfish Landings by Species

Landing volumes were significantly greater for A-R-S-O (primarily sablefish) and Pacific cod than for other species during the entire 1992-2001 period. Pollock and flatfish were the least important species. Between 1992 and 2001, the volume of groundfish retained for the class varied between 700 and 1,200 mt. In the same period, ex-vessel value ranged from a high of $1.5 million in 1993 to a low of $0.7 million in 1995.

Employment, Payments to Labor, and Ownership

This analysis assumed an average crew size of three, including the skipper, for this type of vessel. Another 0.5 position was added to the average to account for vessel support staff. The actual number of crew depends primarily on the size of the vessel. Since 1992, total estimated FTE groundfish employment in the fixed gear catcher vessel ≤ 32 class has varied between 146 and 77. In 2001, about 84 percent of the vessels in this category were registered by Alaska residents or companies, and the remainder were from Washington or Other regions.

Catcher Processors

This section provides brief profiles of the five classes of groundfish catcher processor vessels that participate in the groundfish fisheries off Alaska. In general, catcher processors are integrated operations that harvest fish using various gear types and process them on board. The information provided in this analysis is an abridged version of the detailed sector profiles in *Sector and regional Profiles of the North Pacific Groundfish Fisheries—2001* (Northern Economics, Inc. and EDAW, Inc. 2001). Each of the catcher processor profiles report generally the same types of information to ease comparisons among classes. The remainder of this introductory section provides an overview of the catcher processor activities from 1992-2001 and describes the unique features that distinguish the various classes from each other.

Five different catcher processor classes were defined for this analysis based on predominant product or gear type. These classes, which are mutually exclusive, are as follows:

- Surimi trawl catcher processors: These factory trawlers have the necessary processing equipment to produce surimi from pollock and other groundfish. They are generally the largest of all catcher processors.

- Fillet trawl catcher processors: These factory trawlers have the processing equipment to produce fillets from pollock, Pacific cod, and other groundfish. They are generally smaller than surimi trawl catcher processors and are not surimi-capable according to past production records.

- Head-and-gut trawl catcher processors: These factory trawlers do not process more than incidental amounts of fillets. Most of the vessels are limited to producing headed and gutted products or kirimi. In general, they do not focus their efforts on pollock, opting instead for flatfish, Pacific cod, rockfish, and Atka mackerel. Surimi trawl catcher processors are the smallest of the trawl catcher processors.

- Pot catcher processors: These vessels have been used primarily in the crab fisheries of the North Pacific, but increasingly they are participating in Pacific cod fisheries. They generally use pot gear but may also use longline gear. They produce whole or headed and gutted groundfish products, some of which may be frozen in brine rather than blast frozen.

- Longline catcher processors: These vessels, also known as freezer longliners, use longline gear rather than trawls or pots and focus their effort on Pacific cod. Most longline catcher processors are limited to headed and gutted products. They are typically smaller than surimi trawl catcher processors.

Table 3.9-16 summarizes the operations of the five catcher processor classes in 2001. The table provides a comparison of the relative level of activities of the different classes. Of the 89 catcher processors, 39 were trawl catcher processors and 50 used longlines or pots. The 12 surimi trawl catcher processor vessels had the highest total catch of all catcher processors and generated about 41 percent of the catcher processor total gross product value and payments to labor and 34 percent of the total FTE groundfish employment.

Overview of Catcher Processor Activities

Table 3.9-17 summarizes domestic catcher processor activity in the Alaska groundfish fisheries during the 1992-2001 period. The number of active vessels peaked at 136 in 1992 and declined to 88 by 1999. One likely reason for this decline was the inshore/offshore allocations of pollock and Pacific cod. In addition, the decline after 1998 was directly related to the AFA, which mandated the removal of nine trawl catcher processors from the fishery.

From 1992-2001, catcher processors harvested an average of 1,203 thousand mt of groundfish per year. This annual harvest generated an average of 326 thousand mt of product, with an estimated wholesale value of $672 million. The average ton of product had a value of about $2,000. Pollock accounted for about 60 percent of all groundfish harvested by catcher processors, with about 89 percent of all catcher processor harvests coming from the BSAI. Over the ten-year period, catcher processors improved their average product utilization rate from about 24 percent in 1992 to around 30 percent in 2001.

Catcher processors are estimated to have generated an average annual groundfish employment of 4,487 FTE positions between 1992 and 2001, and annual payments to labor averaged $263 million. The vast majority of catcher processors are registered or operated by Washington-based individuals or corporations, and the WAIW region accounted for approximately 93 percent of total catcher processor groundfish employment and income in 2001. Data on crew complements are reported weekly to NOAA Fisheries by offshore processors (catcher processors and motherships). Therefore, employment estimates of offshore processors are more reliable than estimates generated for inshore processors, which are based on production to labor ratios derived from survey data collected in the early 1990s.

Drawing on information in *Sector and regional Profiles of the North Pacific Groundfish Fisheries – 2001* (Northern Economics, Inc. and EDAW, Inc. 2001), the remainder of this subsection presents summary profiles of the five catcher processor classes. The profile of each catcher processor class includes information on the size and number of vessels; fishing and processing operations; and employment and income linked to regions in Alaska, Washington and Oregon. A summary table provides data on number of active vessels, groundfish catch, groundfish catch by species group; groundfish catch by FMP subarea, quantity and value of the processed products made with groundfish catch, and groundfish employment and payments to labor by region.

<u>Surimi Trawl Catcher Processors</u>

Synopsis

These are large factory trawlers focusing almost exclusively on surimi production in the BSAI pollock fisheries (Table 3.9-18).

Description of the Class

This class is distinct from other trawl catcher processors because all surimi trawl catcher processors have the capacity to produce surimi. Consequently, they are typically the largest catcher processors in the North Pacific. Catcher processors in this class have an average length of 308 ft, an average horsepower rating of about 6,500, an average gross tonnage of approximately 445 tons and an average hold capacity of 50,500 cubic ft. These vessels are capable of harvesting 400 mt or more of fish daily and producing 100 mt or more of frozen surimi or fillets per day. They typically have a full processing deck below the main deck, plus a lower deck of freezer holds. The size of these vessels enables them to operate in the Bering Sea during poor weather. However, they now operate in a pollock cooperative under AFA, which, along with the resulting quasi-property rights, should allow them to modify operations in terms of when they fish and what they process to account for changing weather, markets, and management restrictions.

Participation in Groundfish Fisheries

The number of surimi catcher processors has decreased by about 40 percent since 1992. A combination of excess capacity in pollock surimi production, reduced quotas for the offshore sector, and the decommissioning of vessels under the AFA reduced the number of surimi catcher processors to 12 in 2001. The operational characteristics and activities of these vessels in waters off Alaska are largely determined by the pollock fishing seasons. Their Alaska operations are restricted under the AFA to the Bering Sea and

Aleutian Islands regulatory areas. Surimi catcher processors focus almost exclusively on pollock, although some have produced surimi from yellowfin sole.

Groundfish Landings by Species

Surimi catcher processors focus almost exclusively on pollock, although some have produced surimi from yellowfin sole. In 2001, pollock accounted for nearly all of the total tons of groundfish harvested and wholesale production value of these vessels.

Employment, Payments to Labor, and Ownership

An annual average of 1,641 FTE positions were generated by this vessel class during the 1992-2001 period, and estimated yearly payments to labor averaged $104 million. The registered owners of shoreplants vessels all list addresses in WAIW. While the employment aboard surimi catcher processors is assigned to the regions where the vessels are registered, employment of Alaska residents in this vessel class has increased substantially since the beginning of the western Alaska CDQ program, as discussed in Section 3.9.4.

Fillet Trawl Catcher Processors

Synopsis

These are large factory trawlers focusing mainly on fillet production in the BSAI pollock fisheries (Table 3.9-19).

Description of the Class

These trawl catcher processors produce fillets as their primary product from harvests in the BSAI pollock fisheries. The large size of these vessels also provides room for equipment to produce fishmeal, minced product, and other product forms. Pollock is the primary species harvested by this vessel class, but Pacific cod are also targeted. Their operational characteristics and activities in waters off Alaska are largely determined by the fishing seasons for these species. Fillet catcher processors have been defined as a distinct class because these vessels do not have the capability to produce surimi, and because of their focus on higher value but more labor-intensive fillet production. Catcher processors in this class have an average length of 250 ft, an average horsepower rating of about 4,550, an average gross tonnage of approximately 490 tons and an average hold capacity of 40,425 cubic ft.

Participation in Groundfish Fisheries

The size of the fillet catcher processor fleet has decreased to less than one-fifth of its peak of 22 in 1993. The elimination of excess fishing capacity under the AFA and declining quotas for the offshore sector resulting from inshore/offshore allocations were two factors that contributed to this decline. Competition from surimi catcher processors with the capacity to switch between surimi and fillets depending on the market for pollock products may be another reason for the smaller number of fillet catcher processors. Fishing season regulations in the BSAI groundfish FMPs allow shoreplants vessels to operate from mid-January through March or April, and from July through October. Because of AFA the remaining vessels in this class can be more selective as to when in the pollock fishing seasons they fish. The Bering Sea is clearly the focus of shoreplants vessels, with the Aleutian Islands accounting for about 10 percent total value prior to it closure to pollock fishing in 1999. Vessels in the shoreplants class have not had significant GOA participation since the implementation of inshore/offshore allocations.

Groundfish Landings by Species

All of the fillet catcher processors reported harvesting the major groundfish species groups (pollock, Pacific cod, flatfish, and the A-R-S-O group) for the 1992-2001 period, although some species were bycatch. In 2001, pollock accounted for 95 percent of the total tons of groundfish harvested.

Employment, Payments to Labor, and Ownership

The average crew size is less for fillet catcher processors than for surimi catcher processors, but larger than for other catcher processor classes. Before the AFA was enacted in 1998, the class generated an average of 1,325 FTE positions per year, but from 1999-2001, fillet catcher processors produced less than 400 FTE positions. Virtually all fillet catcher processors are registered by WAIW entities.

Head-and-Gut Trawl Catcher Processors

Synopsis

These are large and medium-sized factory trawlers that primarily produce headed and gutted products from Pacific cod, flatfish, Atka mackerel, and rockfish caught in the BSAI and GOA fisheries (Table 3.9-20).

Description of the Class

This subsection describes the characteristics and activities of trawl catcher processors that primarily produce headed and gutted products from the BSAI and GOA groundfish fisheries. Flatfish is the primary target species for this vessel class, and components of the A-R-S-O species aggregation (primarily Atka mackerel and rockfish) and Pacific cod are important secondary targets. This class was established because 1) it is the only trawl catcher processor group that does not focus on pollock; 2) vessels in this class are smaller than surimi catcher processors or fillet catcher processors; and 3) head-and-gut catcher processors primarily produce one product form—headed and gutted products. Loadline regulations (which establish standards for seafood processing on vessels), space constraints, and other factors make the production of surimi and fillets infeasible for head-and-gut catcher processors.

This focus on trawl fisheries other than pollock results in spatial and temporal differences in the operating patterns of head-and-gut catcher processors compared to surimi catcher processors or fillet catcher processors. Head-and-gut catcher processors have an average length of 166 ft, an average horsepower rating of about 2,100, an average gross tonnage of approximately 345 tons and an average hold capacity of 16,650 cubic ft.

Participation in Groundfish Fisheries

The number of head-and-gut catcher processors decreased from 32 in 1995 to 23 in 2001. These vessels target a number of species and operate for longer periods than the surimi catcher processors or fillet catcher processors. Whereas the surimi catcher processors and fillet catcher processors operate almost solely in the BSAI, head-and-gut catcher processors operate in both the BSAI and GOA. The target fisheries of head-and-gut catcher processors are usually limited by prohibited species catch limits for halibut or market constraints. Only rarely are these vessels able to catch the entire TAC of the target fisheries available to them. The Bering Sea is clearly the focus of these vessels, but a substantial number also fish in the Aleutian Islands, western GOA, and central GOA. Relatively few head-and-gut catcher processors fish in the eastern GOA.

Groundfish Landings by Species

Flatfish species—yellowfin sole and rock sole, in particular—are the primary targets of the head-and-gut catcher processor fleet. These vessels almost never target pollock because headed and gutted pollock sells for less than the cost of production. Species in the A-R-S-O species aggregation have also been very important to the class, particularly Atka mackerel and various rockfish species. In 2001, FLAT and A-R-S-O accounted for about 80 percent of the total tons of groundfish harvested. The recent increase in price of Pacific cod products due to reduced Atlantic cod harvests from the Barents Sea and an improving Asian economy should result in higher gross product values for this class. However, the closure of some of the best fishing grounds for the major target species to protect Bering Sea crab and Steller sea lions has adversely affected the cost structure of the head-and-gut catcher processors. In addition, headed and gutted fish harvested by Japanese and Korean vessels from Russian waters is increasing competition in the marketplace.

Employment, Payments to Labor, and Ownership

The smaller vessel size and limited product forms in the head-and-gut catcher processor class result in much smaller crews compared to surimi catcher processors or fillet catcher processors. The average crew size of about 34 persons is about one-third of the average employment on a surimi catcher processor and less than half of the average crew of a fillet catcher processor. A typical crew might include a captain, a mate, two engineers (one each for the vessel and processing equipment), a cook/housekeeper, two to three crew members dedicated to the deck, a processing foreman and assistant, and about 25 processing workers. On some vessels two or three crew members may split their time between processing and deck work. Any variation in crew size usually is the result of a change in the number of processing workers employed. An annual average of 1,022 FTE positions were generated by this vessel class during the 1992-2001 period, and estimated yearly payments to labor averaged $55 million. As with registered owners of surimi catcher processors and fillet catcher processors, most head-and-gut catcher processor registered owners are located in Washington. Only one head-and-gut catcher processor is currently registered by an Alaskan.

Pot Catcher Processors

Synopsis

These are large and medium-sized vessels that focus on crab fisheries in the Bering Sea but also produce headed and gutted products principally from Pacific cod harvested in the Bering Sea and GOA fisheries (Table 3.9-21).

Description of the Class

The vessels in this class of catcher processors use predominantly pot gear to harvest BSAI and GOA groundfish resources. Virtually all vessels in the pot catcher processor class also fish and process crab in the BSAI. In fact, the crab fisheries in the Bering Sea are the primary fisheries for the class and groundfish harvest and production are typically secondary activities. Because of the focus on crab, operating patterns are much different than for other catcher processors. When harvesting groundfish the pot catcher processor class principally targets Pacific cod and other species that can be captured in sufficient numbers with pot gear to generate adequate revenues. The operating characteristics and activities of this class are the result of both crab and groundfish regulations and the use of pot gear. Vessels in the pot catcher processor class have an average length of 149 ft, an average horsepower rating of about 1,466, an average gross tonnage of approximately 470 tons and an average hold capacity of 15,705 cubic ft.

Participation in Groundfish Fisheries

Pot catcher processors are crab boats that are also capable of processing groundfish. When these vessels are not targeting crab, Pacific cod becomes the primary target. Headed and gutted products are the primary finished products from the pot catcher processor class. During the 1992-2000 period, these products accounted for 88 percent of the wholesale production value for this class. The number of pot catcher processors that process groundfish varied over the past 9 years, reaching a peak of 14 vessels in 1992 and a minimum of 2 vessels in 1993. The success of these vessels in crab fisheries during any given year influences the number of vessels participating in the groundfish fisheries. In recent years, relatively low crab harvests and historically high prices of Pacific cod have made the groundfish fisheries more attractive for pot catcher processors. The Bering Sea FMP subarea is clearly the focus of these vessels.

Groundfish Landings by Species

While participating in groundfish fisheries, pot catcher processors focus on Pacific cod. Other species processed by this class are harvested incidentally. In 2001, Pacific cod accounted for 94 percent of the total tons of groundfish harvested.

Employment, Payments to Labor, and Ownership

This class typically uses a personnel structure similar to that of a catcher vessel. Although pot catcher processors require personnel with some expertise in processing activities, it does not usually hire persons who strictly process, as is the case for other catcher processor operations. Rather, crew members are usually capable of undertaking both fishing and processing tasks, as well as normal ship operational duties. The average pot catcher processor crew size is about 11. Since 1992, annual groundfish employment in the pot catcher processor class has averaged about 36 FTE positions. The relatively small number of FTE positions reflects the fact that pot catcher processors have spent relatively little time participating in the groundfish fisheries. As with registered owners of head-and-gut catcher processors, surimi catcher processors and fillet catcher processors, registered owners of most pot catcher processor are located in Washington. One pot catcher processor has been registered by an individual or company Kodiak since 1995.

Longline Catcher Processors

Synopsis

These are large and medium-sized vessels that primarily produce headed and gutted products from Pacific cod and other high-value species harvested in the Bering Sea and GOA fisheries (Table 3.9-22).

Description of the Class

Vessels in this class are restricted to producing headed and gutted products for reasons similar to those described for head-and-gut catcher processors—loadline regulations plus a lack of space to accommodate additional crew and equipment. Pacific cod is the primary target species, with sablefish and Greenland turbot as important secondary targets. The longline catcher processor class evolved because regulations applying to this gear type provide more fishing days than are available to trawlers. These vessels are able to produce relatively high-value products that compensate for the relatively low catch volumes associated with longline gear. Vessels in the longline catcher processors class have an average length of 135 ft, an average horsepower rating of about 1,275, an average gross tonnage of approximately 385 tons and an average hold capacity of 13,500 cubic ft.

Participation in Groundfish Fisheries

The number of longline catcher processors decreased from a peak of 56 in 1992 to 39 in 1999. In 2001, 43 longline catcher processors participated in the groundfish fisheries. Most of the product of longline catcher processors is marketed overseas, with price determining where product is sold. During the 1992-2000 period, headed and gutted products accounted for about 96 percent of the wholesale production value of the fleet. The longline catcher processor fleet generally begins fishing for Pacific cod on January 1 and continues to April or May. This species is fished again from September 15 to November or December. Most vessels in this class undergo maintenance and repair in the summer months, although several vessels process and custom freeze salmon during this period. The BSAI is by far the most important FMP subarea for the longline catcher processor class.

Groundfish Landings by Species

In 2001, Pacific cod accounted for 79 percent of the total tons of groundfish harvested. The A-R-S-O species complex (primarily sablefish) and flatfish (primarily Greenland turbot) are also important species in terms of volume. Sculpins, which are included in the A-R-S-O species aggregation, are a major component of bycatch of longline catcher processors.

Employment, Payments to Labor, and Ownership

The main employment positions on a longline catcher processor include processing crew, fishing crew, and officers. Large vessels are required to have more licensed officers than are small ones. On smaller vessels, specialized personnel such as the engineer or cook may also have additional crew duties, the processing crew and fishing crew may not be as distinct from one another as they are on larger vessels, and fishing effort must be reduced during processing. A vessel of average size typically has a crew of 16, consisting of six fishers, six processors, a skipper, a cook, an engineer, and an observer. The longline catcher processor class is the most diverse of all the processor classes in terms of ownership. In 2001, 28 percent of owners resided in Alaska or regions other than WAIW and Oregon coast region. Within Alaska, ownership is distributed across all four regions, with 16 of the 23 vessels owned by residents of southcentral or southeast Alaska.

Inshore Plants and Motherships

In addition to catcher processors, the groundfish processing sector includes shore-based plants, several FLPs that are moored or anchored near shore in protected bays and harbors, and motherships. Motherships are grouped with inshore processors because they do not catch their own fish and depend on deliveries from catcher vessels. This analysis includes plants engaged in primary processing of groundfish. It does not include plants engaged in secondary manufacturing, such as converting surimi into analog products (imitation crab), or further processing of other groundfish products into ready-to-cook meals or products. These secondary processors are described in Section 3.9.1.

Seven processor classes were defined for this analysis, primarily based on the regional location of the facilities. The Bering Sea pollock shoreplants are defined as a separate class because of the large scale of their groundfish operations compared to other processors. The seven classes, which are mutually exclusive, are as follows:

- Bering Sea pollock shoreplants (BSP-SP): Includes the four major shore-based BSAI pollock processors in Dutch Harbor/Unalaska and Akutan. Also includes two FLPs—*Arctic Enterprise and Northern Victor*—that have had substantial pollock history and function from a single location in state waters off Unalaska and Akutan Islands.

- Alaska Peninsula and Aleutian Islands shoreplants (APAI-SP): Includes all shoreplants in the Aleutians East Borough and in the Aleutians West Census Area, excluding all Bering Sea pollock shoreplants. In general, these plants are much smaller than Bering Sea pollock shoreplants, do not have the same level of focus on BSAI pollock, and in some cases produce more salmon than groundfish. These plants are treated separately from the Bering Sea pollock shoreplants because of these operational differences.

- Kodiak shoreplants (K-SP): Includes all shoreplants in the Kodiak archipelago. Many of these plants focus on groundfish but also process some salmon and halibut. Others focus on salmon and halibut but also process some groundfish.

- Southcentral Alaska shoreplants (SC-SP): Includes all shoreplants in the Kenai Peninsula Borough, the Municipality of Anchorage, the Matanuska-Susitna Borough, and the Valdez-Cordova Census Area. In general, these processors focus on salmon and halibut but also process some groundfish.

- Southeast Alaska shoreplants (SE-SP): Includes all shoreplants in southeast Alaska from Yakutat to Ketchikan. In general, these processors focus on salmon and halibut but also process some groundfish, primarily higher priced species such as rockfish and sablefish.

- Floating Inshore Processors: Includes all floating inshore plants other than *Arctic Enterprise* and *Northern Victor* (which are grouped with Bering Sea pollock shoreplants).

- Motherships: Includes all motherships operating in the EEZ of the BSAI and GOA. Currently there are only three active motherships. This class does not include FLPs that operate exclusively in state waters.

Table 3.9-23 summarizes activities of inshore processors and motherships by class for 2001. The table provides a comparison of the relative level of activities of the different classes. Overall, 59 facilities contributed to the inshore and mothership processing total in that year. The six Bering Sea pollock shoreplants were the most substantial contributors, producing 61 percent of the inshore processor wholesale product value and total payments to labor and 68 percent of the total FTE groundfish employment. Motherships accounted for 11 percent of the total product value, and shore-based processors in Kodiak generated 11 percent of the total value of this portion of the groundfish processing sector. Shore plants in southcentral Alaska and southeast Alaska contributed only about one percent of the total catch by volume, but because of their focus on high-value species, they generated about 8 percent of the total value.

Overview of Inshore Processor and Mothership Activities

Table 3.9-24 summarizes the activities of inshore processors and motherships in groundfish fisheries during the 1992-2001 period. Inshore processors and motherships profiled in this document rely heavily, but not exclusively on groundfish. In 1999, the most recent year for which complete landings data for non-groundfish species are available, about 31 percent of the total ex-vessel value of landings came from groundfish fisheries. While it appears that groundfish are relatively more important in 2000, the non-groundfish numbers shown for 2000 are preliminary and do not include halibut.

Pollock accounted for about 80 percent of all the groundfish retained and processed by inshore processors and motherships between 1992 and 2001. Pacific cod accounted for about 13 percent. Flatfish and species in the A-R-S-O aggregation accounted for about 4 percent each. Approximately 79 percent of all harvests delivered to inshore processors and motherships came from the BSAI. Between 1992 and 2001, inshore processors and motherships generated an average of 258 thousand mt of product per year, with a wholesale value of $573 million. Inshore processors and motherships improved their product utilization rate from 28 percent in 1992 to 37 percent in 2001.

Inshore processors and motherships were estimated to have generated annual groundfish employment averaging 3,861 FTE positions between 1992 and 2001 and annual payments to labor averaging $225 million. Most of the inshore processors are registered by individuals or companies in the WAIW region. However, because the shoreplants are physically located in Alaska, nearly all FTE groundfish employment and payments to labor have been assigned to Alaska coastal communities. Groundfish employment and payments to labor generated by motherships have been assigned to WAIW, as individuals or companies in WAIW generally own these vessels. Additional employment and payments to labor have been assigned to WAIW to account for home office staff who are assumed to reside in the same region as the plant owners.

Groundfish employment estimates for inshore plants are based on information gathered in surveys of processors conducted by Northern Economics, Inc. (1990 and 1994). The information gathered in the surveys indicated the number of employee hours necessary to generate one ton of product for each product and species. More reliable data on groundfish employment for inshore processors are not available. While the State of Alaska, Department of Labor and Workforce Development regularly collects employment data from processing facilities, the information is aggregated with processing employment in crab and salmon fisheries. If this data were used, groundfish employment would be significantly overestimated.

Drawing on information in *Sector and regional Profiles of the North Pacific Groundfish Fisheries – 2001* (Northern Economics, Inc. and EDAW, Inc. 2001), the remainder of this subsection presents summary profiles of the seven processor classes. Each inshore processor/mothership profile describes the facilities in the class and number of participants; the relative dependence on groundfish compared to non-groundfish species such as salmon, crab, halibut, and herring; fishing and processing operations; relationships with different catcher vessel classes; and employment and labor income associated with the groundfish fisheries. Payments to labor and employment are linked to regions in Alaska and the Pacific Northwest. Table 3.9-24 also summarizes statistics on the number of processing facilities, groundfish catch of catcher vessels that deliver to the facilities, ex-vessel value of groundfish and non-groundfish retained,[13] groundfish catch by species group, groundfish catch by FMP subarea, ex-vessel value paid to catcher vessels by type, and groundfish employment and payments to labor by region.

Bering Sea Pollock Shore Plants (BSP-SP)

Synopsis

These are AFA-eligible plants that operate year-round, processing almost all species harvested in the BSAI, and western GOA. Pollock is the most important species processed at these plants in terms of both volume and value (Table 3.9-25).

Description of the Class

This class includes the major onshore plants at Unalaska/Dutch Harbor and Akutan, and the two large floating pollock processors anchored near shore in Beaver Inlet of Unalaska Island or, more recently, in Akutan. These AFA-eligible, shore-based and nearshore plants are the primary markets for groundfish catcher vessels operating in the BSAI, particularly those harvesting pollock. The plants operate year-round, processing almost all species harvested in the BSAI and western GOA. Pollock is the most important species processed at these plants in terms of both volume and value. Pacific cod is the next most important groundfish species, while flatfish and sablefish are substantially less important. These plants also process large amounts of crab and halibut harvested in the BSAI.

BSP-SPs are a distinct processor class for three reasons: their geographic proximity to each other and the major fishing grounds of the BSAI; the magnitude of the pollock processing at these facilities; and their status as AFA-eligible plants. The nearshore processing ships, *Arctic Enterprise* and *Northern Victor*, are included in this class because they are more similar to shoreplants than to offshore motherships or floating inshore operations, are included in the inshore allocations of pollock, and are treated under AFA as if they were shoreplants.

[13] Ex-vessel value is equal to the amount of fish retained for processing multiplied by the ex-vessel (dockside) price. This value is equal to the payments made by processors for raw fish.

Participation in Groundfish Fisheries

During the 1992-2001 period, there were six BSP-SPs—at Dutch Harbor, one at Akutan, and two FLPs near Unalaska Island or in Akutan Bay. While all BSP-SPs have the capacity to produce fillets, only three have a long history of fillet production. The other three produce larger quantities of surimi and tend to produce headed and gutted or salted products rather than fillets. BSP-SPs are the only inshore processors that generate more ex-vessel value in groundfish fisheries than in non-groundfish fisheries. In 1999, the most recent year for which complete landings data for non-groundfish species are available, approximately 58 percent of the ex-vessel value paid to catcher vessels was from groundfish species. Crab is by far the most important non-groundfish product, accounting for 93 percent of the non-groundfish ex-vessel value in 1999. The plants all process substantial quantities of pollock and Pacific cod. In 2001, pollock accounted for 96 percent of the total tons of groundfish caught. In that year, the Bering Sea FMP subarea accounted for nearly all of the groundfish processed by plants in the BSP-SP class.

Payments to Catcher Vessels and Gross Product Value

Historically, BSP-SPs have worked closely with larger Trawl catcher vessels, especially vessels in the two Trawl catcher vessel BSP classes. On average, vessels in these two classes accounted for roughly 86 percent of the ex-vessel value of groundfish purchases made by Bering Sea pollock-shoreplants from 1992 through 2000. During the 1992-2000 period, surimi accounted for about half of the total wholesale value, and fillets, roe, and meal accounted for the remaining half.

Employment, Payments to Labor, and Ownership

Employment at BSP-SPs fluctuates markedly by season and the type of product being processed, even if the products are derived from the same species. At one BSP-SP, for example, groundfish employment during pollock roe season is 66 percent higher than it is during non-roe pollock processing. The registered addresses of the owners of all six BSP-SPs are in WAIW. A review of the ownership of these facilities was conducted in a previous analysis that examined processing limits for AFA-eligible entities (Northern Economics, Inc. 2000). The study indicated that Japanese companies have ownership shares of at least 50 percent in three of the BSP-SPs. The study also indicated that two of the other facilities are owned by a single U.S. corporation. This company also owns several trawl and pot catcher processors as well as a fleet of Trawl catcher vessels.

<u>Alaska Peninsula and Aleutian Islands Shoreplants (APAI-SP)</u>

Synopsis

These are typically multi-species plants that process salmon, crab, halibut and groundfish such as Pacific cod and pollock harvested mainly in the western GOA (Table 3.9-26).

Description of the Class

These plants process groundfish resources from the BSAI and GOA. The shoreplants on the Alaska Peninsula are the oldest in the region, some dating back to the 1800s, while the plant at Adak, the site of a former U.S. Naval facility, has only been operating for a few years. The facilities in the Pribilof Islands are also relatively recent entrants into groundfish processing. The plants in King Cove and Sand Point are AFA-qualified and process pollock. The class also includes several non-AFA plants in Unalaska/Dutch Harbor for which Pacific cod and crab are of particular importance. Some plants in the APAI-SPs class are limited in the volume they can handle and their ability to process certain species or product forms. APAI-SPs historically have relied mainly on non-groundfish species, particularly salmon. As halibut, sablefish, and crab fisheries developed, they were incorporated into the regional salmon processing pattern. Today, APAI-SPs are typically multi-species plants, with salmon still serving as the "foundation" species. The plants in the region differ in terms of their relative dependence on salmon, groundfish and crab.

Participation in Groundfish Fisheries

In 1999, the most recent year for which complete landings data for non-groundfish species are available, approximately 17 percent of the total ex-vessel value was from groundfish species. Crab is the most important species for APAI-SPs, accounting for about 54 percent of the ex-vessel value paid to catcher vessels in 1999. During the 1992-2000 period, groundfish fillets accounted for about 45 percent of the total wholesale value, while headed and gutted products accounted for 13 percent. In 2001, pollock and Pacific cod accounted for about 95 percent of the total tons of groundfish caught. A majority of the fish used by APAI-SPs facilities came from the western GOA FMP subarea, although in some years a significant amount of the fish processed was caught in the Aleutian Islands subarea.

Payments to Catcher Vessels and Gross Product Value

APAI-SPs historically have worked with a variety of catcher vessels. From 1992 through 2001, Trawl catcher vessels were the most common types of catcher vessels receiving payments from APAI-SPs, with vessels in the Trawl catcher vessel < 60 class receiving the largest share of the ex-vessel value. Wholesale value per ton of round weight deliveries increased dramatically in 1999—from $634 per ton to $920 per ton. These changes are due primarily to changes in Pacific cod processing. At least two new facilities focusing on Pacific cod have come online and product prices have increased to levels well above prices reported by processors in the BSP-SP class.

Employment, Payments to Labor, and Ownership

During the 1992-2001 period, these plants generated an average of about 363 FTE positions per year and an estimated $17 million in annual income. As with shoreplants in other regions, groundfish employment in this class fluctuates markedly by season and the type of product being generated. These seasonal product fluctuations do not affect all components of a plant's work force. There is typically a year round core of 30 to 50 administrative, management, and maintenance staff at each plant, and even during "down" periods a few production workers are required to handle processing odds and ends. For some processing activities the number of persons required is independent of the amount of fish processed (Impact Assessment Inc. [IAI] 1998). For example, fish meal processing may be so automated that it requires a fixed number of persons, regardless of the volume processed (IAI 1994). The plants in the region are registered to companies based in Washington or Alaska.

Kodiak Shoreplants (K-SP)

Synopsis

These are diversified processing facilities that receive nearly of all their fish from the central GOA (Table 3.9-27).

Description of the Class

The groundfish processing plants in Kodiak differ from those in southcentral and southeast Alaska by their capacity to handle larger volumes of groundfish and more product forms. It should also be noted that several of the plants on Kodiak are registered to entities that are AFA-eligible, but none of the plants themselves participate in AFA cooperatives. According to IAI (1998), K-SPs have existed since the 19th century. Initially, plants in Kodiak mainly canned salmon and herring, with some operations reportedly processing frozen halibut. In the 1950s, processing operations expanded to include king crab. Crab processing operations reached a peak in the late 1960s. As these operations began to decline, some processors moved from Kodiak to Dutch Harbor and other ports in order to be closer to Bering Sea king crab fisheries. However, a second boom in king crab stocks near Kodiak Island resulted in the construction of additional plants and expansion of existing ones. After king crab harvests peaked in 1980, K-SPs made a major effort to diversify their operations to include shrimp and groundfish. Processing facilities that did not already process salmon and herring began to do so.

Today, in addition to salmon, K-SPs also depend on pollock, Pacific cod, flatfish, and some other species of groundfish. By processing groundfish, plants can operate for longer periods of the year, thereby providing some stability to the work force. In addition, the groundfish market allows vessels to operate over a longer period, provides them with additional income, and enhances the vessel-processor relationship.

Participation in Groundfish Fisheries

Fourteen Kodiak facilities were active in groundfish through 1994, dropping to 10 by 1996. In 1999, the most recent year for which complete landings data for non-groundfish species are available, approximately 46 percent of the total ex-vessel value was from groundfish species. Salmon and halibut are also important species for K-SPs, together accounting for 49 percent of the total ex-vessel value paid to catcher vessels. In 2001, pollock and Pacific cod accounted for 69 percent of the total tons of groundfish caught. K-SPs receive nearly of all their fish from the central GOA FMP subarea.

Payments to Catcher Vessels and Gross Product Value

In 2000, vessels in the Trawl catcher vessel Div. AFA and Trawl catcher vessel Non-AFA classes accounted for 49 percent of deliveries by value, with vessels in the fixed gear catcher vessel 33-59 class accounting for about 24 percent of delivery value. The size and composition of the fleet delivering fish varies among plants. One plant may cater to a large number of small longline and pot gear vessels, with an occasional delivery from small trawlers, while another plant's fleet may consist of large trawlers. Most vessels that deliver to K-SPs are multi-purpose vessels that change fisheries to meet current market and fishing circumstances. The size of a processor's fleet depends on the season and what species the vessels are targeting. According to IAI (1998), a plant may have a fleet of eight to 16 vessels delivering groundfish and crab. A plant processing pollock usually has a fleet of four to ten trawlers fishing for it. Most plants also have six to ten fixed gear vessels delivering Pacific cod and/or tanner crab. In addition to taking deliveries from their regular fleet, processors will accept deliveries from other vessels if they have the processing capacity. The majority of vessels harvesting groundfish for K-SPs are Kodiak-based vessels. Vessels from Newport, Oregon or Seattle augment the local trawl and longline fleets. In 2000, fillets accounted for slightly more than half of the total wholesale value, while headed and gutted products accounted for 22 percent.

Employment, Payments to Labor, and Ownership

During the 1992-2001 period, these plants generated an average of about 609 FTE positions per year and an estimated $32 million in annual income. The percentage of plants on Kodiak registered to companies in Washington has shown an upward trend. Seventy percent were registered by Washington companies in 2001.

Southcentral Alaska Shoreplants (SC-SP)

Synopsis

These processors rely mostly on salmon but also process sablefish and other groundfish species harvested mainly in the central GOA and eastern GOA (Table 3.9-28).

Description of the Class

The southcentral region includes boroughs and census areas that border the marine waters of the GOA (east of Kodiak), Cook Inlet, and PWS, including the Kenai Peninsula Borough, the PWS census area, the Municipality of Anchorage, and the Matanuska-Susitna Borough. Most of the processing plants in this region were established to process salmon. They later expanded into groundfish processing to increase annual revenues and help cover fixed costs. However, processors in southcentral and southeast Alaska process much less groundfish than processors in the three classes discussed previously (APAI-SPs, BSP-SPs, and K-SPs).

Participation in Groundfish Fisheries

Southcentral shoreplants are located in Anchorage and several communities on the Kenai Peninsula (including Homer, Kenai, Nikiski, Ninilchik, Seward, and Soldotna) and in the PWS Census Area (including Cordova, Valdez, and Whittier). In 1999, the most recent year for which complete landings data for non-groundfish species are available, approximately 21 percent of the total ex-vessel value was from groundfish species. Salmon is the most important species for SC-SPs, accounting for 58 percent of the total ex-vessel value paid to catcher vessels in 1999. Between 1992 and 2001, most SC-SPs reported processing flatfish, Pacific cod and species in the A-R-S-O complex, primarily sablefish. In 2001, species in the A-R-S-O complex accounted for 65 percent of the total tons of groundfish harvested and 88 percent of the wholesale production value. In recent years, two to five processors participating in the groundfish fisheries have not processed pollock. The central GOA FMP subarea is the most important source of groundfish for this processor class. A significant quantity also came from the eastern GOA FMP subarea.

Payments to Catcher Vessels and Gross Product Value

SC-SPs work primarily with vessels in the fixed gear catcher vessel 33 ft to 59 ft and LCV classes reflecting their focus on higher priced groundfish such as sablefish. Between 1992 and 2000, fish delivered by these vessels accounted for more than 85 percent of the ex-vessel value of groundfish. The total value of production varied between $23 million and $40 million. In 2000, headed and gutted products accounted for 85 percent of the total wholesale value from groundfish.

Employment, Payments to Labor, and Ownership

During the 1992-2001 period, these plants generated an average of about 109 FTE positions per year and an estimated $12 million in annual income. In 2001, registered ownership of southcentral Alaska shoreplants was evenly divided between companies in southcentral Alaska and Washington.

Southeast Alaska Shoreplants (SE-SP)

Synopsis

These processors depend primarily on salmon but also process sablefish and other groundfish species harvested mainly in the eastern GOA (Table 3.9-29).

Description of the Class

The southeast Alaska region extends from Yakutat to Metlakatla. This processor class is similar to the SC-SPs class, as most SE-SPs began as salmon processing facilities and later expanded into groundfish, particularly higher priced species such as sablefish and rockfish. Groundfish stocks in the region are not nearly as large as those in areas to the west. In addition, the sheltered nature of many of the fishing grounds, most of which are in state waters, has fostered a fleet composed primarily of relatively small vessels that do not use trawl gear. Local vessels catch Pacific cod and rockfish by longline and pot. SE-SPs are not designed to process the large groundfish landings of trawl vessels. It is difficult for them to compete with the BSAI Pacific cod fishery or with those processors that already process pollock.

Participation in Groundfish Fisheries

Communities with active processors include Hoonah, Juneau, Ketchikan, Petersburg, Pelican, Sitka, Wrangell, and Yakutat. According to IAI (1998), all SE-SPs process multiple species. Groundfish are important to components of the local fishing fleet but are of secondary importance to most processors. In 1999, the most recent year for which complete landings data for non-groundfish species are available, approximately 20 percent of the total ex-vessel value was from groundfish species. Salmon is the most important species for SE-SPs, accounting for 31 percent of the total ex-vessel value paid to catcher vessels in 1999, while halibut accounted for 25 percent of the ex-vessel value. Between 1992 and 2001, most SE-SPs reported processing flatfish, Pacific cod, and species in the A-R-S-O complex. In 2001, species in the A-R-S-O complex (primarily sablefish) accounted for 94 percent of the total tons of groundfish harvested and nearly all of the wholesale production value. The eastern GOA FMP subarea has historically been the most important source of fish processed by SE-SPs.

Payments to Catcher Vessels and Gross Product Value

Most groundfish catcher vessels delivering to SE-SPs are multi-species harvesters. According to IAI (1998), vessels of 40 to 58 ft in length are probably the most productive vessels in the fleet. Most SE-SPs do not have formal contracts with the vessels that deliver to them. Some processors indicated that they had a "core group" of vessels, which constituted about 40 percent of their total delivery fleet. The vessels in the core group consistently delivered to a single processor, whereas the other vessels tended to shift from processor to processor. The sablefish fleet is smaller than the halibut fleet, which, in turn, is smaller than the dungeness crab fleet. Nearly all of the fish processed by SE-SPs is caught in state waters. Fixed gear catcher vessels, especially those 33 to 59 ft in length, accounted for most of the total ex-vessel value paid by SE-SPs to groundfish catcher vessels. Longline catcher vessels were the next most important catcher vessel type.

In 2000, headed and gutted products accounted for 95 percent of the total wholesale value. SE-SPs also produce frozen fillets. When possible, the plants serve the markets for high-price products, such as the seasonal market for fresh Pacific cod in Korea or the domestic market for fresh rockfish. The total value of production varied between $27 million and $42 million.

Employment, Payments to Labor and Ownership

During the 1992-2001 period, these plants generated an average of about 44 FTE positions per year and an estimated $13 million in labor payments. According to IAI (1998), some processors in this class have year-round operations while others operate seasonally. All of the plants have the largest workforce in the summer when salmon is processed. During the off-season a minimal number of people are employed for maintenance and administration. Even the year-round plants have relatively few processing line employees working full-time after the salmon season. Local residents provide most of the labor required to process halibut, sablefish, and species harvested in the winter fisheries. This periodic dependence on local labor distinguishes SE-SPs from processing operations in western Alaska, which almost exclusively employ individuals from outside the region. The summer salmon harvest is the only time in which it is economical for SE-SPs to bring in outside workers. Even then, a few plants can meet their summer labor needs with temporary employees from the local community. When more than one processor operates in the same community there is competition for the available local labor. Those processors with year-round operations usually have an advantage, as they can offer more stable jobs. In addition, processors will offer workers who stay employed with them higher wages in order to maintain a stable workforce.

In 2001, the proportion of SE-SPs registered to companies in Alaska peaked at 53 percent. According to IAI (1998), SE-SPs tend to have been in operation longer than plants other regions. Both third-generation, family-owned plants and facilities owned by multi-state corporations are present in the southeast region.

Motherships

Synopsis

These are large vessels that serve as offshore processors in the Bering Sea pollock fishery (Table 3.9-30).

Description of the Class

Motherships do not catch fish but act as mobile processors. Catcher vessels offload their catch to a mothership for processing, and the mothership, in turn, offloads finished product to trampers (cargo vessels) for transport to foreign or domestic markets. Motherships are among the largest vessels in Alaska's fishing industry. They have an average length of 427 ft, an average horsepower rating of about 5,250, an average gross tonnage of approximately 500 tons and an average hold capacity is 72,770 cubic ft.

The delivery of catch to motherships is performed on the high seas. Catcher vessels can offload without mooring to a mothership by transferring full cod ends to a stern ramp on the mothership. The large size of motherships provides them with considerable processing capacity. Some vessels are reportedly capable of producing 200 mt of finished frozen surimi per day. After the fish are processed, the product is usually stored in freezer holds until offloaded to tramp steamers, which convey the product to Asian markets. Buyers often place inspectors aboard the motherships to monitor product quality. A relatively small amount of groundfish products is offloaded at Unalaska/Dutch Harbor or Seattle. Delivering product to the latter port is an economical option at the end of a season.

Participation in Groundfish Fisheries

In 2001, there were three motherships participating in the groundfish fisheries. In addition to participating in the Bering Sea groundfish fishery, these vessels participate in the whiting fishery off the coasts of Oregon and Washington during the summer. In 2001, pollock accounted for nearly all of the groundfish harvested and wholesale production value.

Payments to Catcher Vessels and Gross Product Value

Motherships participating in the groundfish fisheries rely almost exclusively on vessels in the Trawl catcher vessel BSP 60 to 124 class for their supplies of fish. In 2001, these catcher vessels were all AFA-eligible. According to IAI (1998), motherships typically rely on a mix of company-owned and independent catcher vessels to supply their processing lines. In the past, independent vessels were usually not formally contracted by a particular mothership, but implementation of the AFA may have resulted in the introduction of formal contracts. Motherships usually provide basic services to those catcher vessels that regularly supply them with fish. The operating schedules for motherships coincide with those of their catcher trawlers. The Alaska groundfish fisheries occur from mid-January through April and from late August through October. The motherships are in port or participating in the whiting fishery in May, June, and July, and typically undergo maintenance and repair from November through early January.

The large size of motherships enables them to produce a wide range of products. In 2000, surimi accounted for 74 percent of the total wholesale value and roe products accounted for about 20 percent.

Employment, Payments to Labor, and Ownership

During the 1992-2001 period, motherships generated an average of about 395 FTE positions per year and an estimated $25 million in annual income. According to IAI (1998), the largest mothership employs between 190 and 200 persons during the peak season. The number of core staff, including the captain and crew, engineers, and other personnel necessary for at-sea operations, varies by vessel size, but it is less variable than the number of processing crew. The number of processing crew increases dramatically during peak fishing seasons—vessels reportedly employed 45 to 60 percent more people during the peak pollock seasons. Seattle is the point of hire for both salaried and non-salaried (hourly wage) employees. Most of the latter list one of the Pacific Northwest states as their place of residence, but some are not U.S. residents. Nearly all non-salaried employees sign a formal contract before starting work (IAI 1998). All motherships participating in the BSAI and GOA groundfish fisheries are registered to companies in Washington.

Floating Inshore Processors (FLP)

Synopsis

These are floating facilities that operate in sheltered waters and process mainly non-groundfish species but process some groundfish, especially Pacific cod (Table 3.9-31).

Description of the Class

FLPs are similar to motherships because they have the ability to change their locations in which they operate in order to maximize opportunities for delivery and efficiency. However, unlike motherships, most FLPs were designed to process crab and salmon and typically do not have stern ramps which would allow delivery of trawl cod ends in open waters. Instead FLP vessels take deliveries "over the side" employing pumps or brailers—large net bags that are filled with crab or fish on the delivery vessel and moved to the processor using a crane. The use of brailers or pumps requires that the delivery vessels be alongside the process while delivering. Typically, delivery vessels and floaters are separated only by large rubber bumpers. The necessity to take deliveries from vessels alongside means that FLPs must operate in sheltered waters. In fact, many processors in this class establish semi-permanent moorages with shore-based infrastructures, such as docks, gangways and fresh-water supplies. Processors in the FLP class have an average length of 215 ft, an average horsepower rating of about 1,580, an average gross tonnage of approximately 400 tons and an average hold capacity of 72,950 cubic ft. Several FLPs are barges and not self-propelled. FLPs occasionally operate with auxiliary barges operating alongside that process fish meal.

Participation in Groundfish Fisheries

Groundfish is typically a relatively small part of FLPs' annual round of activities. In 1999, the most recent year for which complete landings data for non-groundfish species are available, approximately 3 percent of the total ex-vessel value was from groundfish species. The groundfish that is processed is most often Pacific cod, which is either headed and gutted or filleted, depending primarily on the equipment on board the vessel. For many FLP vessels, participation in groundfish fisheries is largely dependent on the prospect of a lucrative season in the opilio crab fisheries. If operators believe that the guideline harvest level for opilio is high enough to justify sending the processor north from Puget Sound (where most of the vessels are based), then the FLPs will likely stay on to participate in the groundfish fisheries. Other FLP vessels focus more on salmon than on crab.

Payments to Catcher Vessels and Gross Product Value

Among all processors, the FLP class exhibits the least consistency in terms of the type of vessels from which they take deliveries. However, the fixed gear catcher vessel 33-59 class has typically been the most important for FLPs. On average during the 1992 to 2000 period, catcher vessels in this class have provided nearly 41 percent of the raw product received by FLPs in terms of value.

Between 1992 and 2001, most FLP vessels reported processing flatfish, Pacific cod and species in the A-R-S-O complex. In 2001, species in Pacific cod accounted for 89 percent of the total tons of groundfish harvested and nearly all of the wholesale production value.

Employment, Payments to Labor, and Ownership

Between 1992-2001, FLP vessels averaged about $3 million in estimated annual payments to labor from groundfish. Two of the three active FLP vessels were owned by individuals registered to companies in Washington in 2001.

3.9.3 Regional Socioeconomic Profiles

3.9.3.1 Regulatory Context

The socioeconomic analysis provided in this section is driven by requirements of the NEPA, the MSA, AND EO 12898. Under NEPA, 'economic' and 'social' effects are specific environmental consequences to be examined (40 CFR § 1508.8). This section contains an overview of the standard socioeconomic variables typically found in an EIS, including a summary of population, income and employment data for each region.

This section is also guided, in part, by National Standard 8 under the MSA. National Standard 8 is part of a set of standards that apply to all FMPs and regulations promulgated to implement such plans. Specifically, National Standard 8 states that:

> *Conservation and management measures shall, consistent with the conservation requirements of this [Magnuson-Stevens] Act (including the prevention of overfishing and rebuilding of overfished stocks), take into account the importance of fishery resources to fishing communities in order to (A) provide for the sustained participation of such communities and (B) to the extent practicable, minimize adverse economic impacts on such communities (Sec. 301(a)(8)).*

The MSA defines a 'fishing community' as "...a community which is substantially dependent on or substantially engaged in the harvest or processing of fishery resources to meet social and economic needs, and includes fishing vessel owners, operators, and crew, and United States fish processors that are based in such community" (Sec. 3 [16]). NOAA Fisheries further specifies in the National Standard guidelines that a fishing community is "...a social or economic group whose members reside in a specific location and share a common dependency on commercial, recreational, or subsistence fishing or on directly related fisheries dependent services and industries (for example, boatyards, ice suppliers, tackle shops)" (63 FR 24235, May 1, 1998). 'Sustained participation' is defined by NOAA Fisheries as "...continued access to the fishery within the constraints of the condition of the resource" (63 FR 24235, May 1, 1998). Consistent with National Standard 8, this section first identifies affected regions and communities and then describes and assesses the nature and magnitude of their dependence on and engagement in the groundfish fisheries of the North Pacific.

Beyond NEPA and MSA requirements, social and community analysis needs to take into account Executive Order 12898 (59 FR 7629 [1994]), which requires federal agencies to address environmental justice concerns by identifying "disproportionately high and adverse human health and environmental effects...on minority populations and low-income populations." Existing conditions information needed for subsequent assessment of environmental justice concerns, such as demographic data on minority and low-income populations specific to the relevant groundfish communities, is presented in its own section (Section 3.9.6) for ease of review.

3.9.3.2 Regions and Communities Involved in the North Pacific Groundfish Fishery

In support of the community impact analysis of the various management alternatives under consideration, this section provides a description of the existing regional and community context of the North Pacific groundfish fishery. First, an overview is provided of the fishery as a whole. Next, socioeconomic profiles of six geographic areas with ties to the North Pacific groundfish fishery are provided: four in Alaska, one in Washington, and one in Oregon. The regions were defined based on logical socioeconomic and geographic units. Internal consistency with respect to type of engagement or dependence upon the groundfish fishery was more important in defining the regions than attempting to make them comparable for non-groundfish-related criteria. The regional definitions are consistent with those used in recent groundfish FMP-related analyses, such as the previous 2001 Draft Alaska Groundfish Fisheries Draft Programmatic SEIS (NMFS 2001a), as well as the more recent Steller Sea Lion Protection Measures Final SEIS (NMFS 2001b), and the detailed sector and community profiles on the NPFMC website (NPFMC 2002d). The regions and their constituent jurisdictions or geographies are listed in Table 3.9-32 and shown on Figures 3.9-6 and 3.9-7. Figure 3.9-8 shows the adjacent FMP areas and subareas.

These regional profiles examine the engagement with, and dependence upon, the fishery from a human geography perspective. The regional profiles are designed to be used in combination with the sector information presented in Section 3.9.2 to provide a rounded perspective on the socioeconomic aspects of the fishery. The sector profiles provide descriptions of the groups engaged in the fishery and their activities; the regional profiles describe how those groups and activities fit into a regional socioeconomic context. The regional descriptions in this section complement the more detailed sector and regional descriptions presented in the Sector and Regional Profiles of the North Pacific Groundfish Fisheries (NPFMC 2002d) to provide a more comprehensive treatment of the socioeconomic aspects of the fishery.

Quantitative data used in these regional descriptions are derived from the same data sources used in the sector descriptions that appear in Section 3.9.2. Specific data sources, and their limitations, are described in those sections. The geographic reach of the areas of Alaska, Washington, and Oregon potentially related to the North Pacific groundfish fishery—and likely to experience socioeconomic impacts due to the proposed management alternatives—is enormous. At the same time, these areas encompass many communities with few or no direct ties to the fishery itself. The profiles focus primarily on the regional rather than the community level of analysis, but limited community level information is provided for regionally important groundfish communities where strong historical ties to the groundfish fishery are known to exist and where such information is considered important to understand the specific community context of the fishery. Many more communities are home to at least some very small portion of the far-flung groundfish catcher vessel fleet. A number of other communities are the sites of relatively modest volumes of groundfish processing activity or are attempting to initiate local processing.

Overview of the North Pacific Groundfish Fishery by Region

This subsection presents comparative information on population, employment and income, processing, processing ownership, and catcher vessel ownership and activity across the regions. In subsequent sections, each region is broken out separately, with a broad regional overview following a common format. The intent is to provide the reader with enough information to place the region in terms of its level of participation in the fishery in a comparative context alongside the other regions, as well as to understand the relative level of importance of pollock and Pacific cod vis-á-vis other groundfish fisheries within each region. The topics introduced in this section are presented in the same order as in the individual profiles themselves. The four Alaskan regional profiles closely parallel each other in presentation, but the two Pacific Northwest regional presentations vary somewhat due to the quite different types of engagement in (or dependence on) the Alaskan groundfish fishery.

Fisheries data have been provided in full time series format (1992-2001) where appropriate. The earliest year for which comparable data are available across processing and harvesting sectors is 1992 and 2001 represents the most recent full year for which data are available. Where single year "snapshot" data are more appropriate to the discussion than time series information, data for 1999, 2000, and 2001 are provided. Data from 1999 are presented as this represents the last full year prior to the implementation of the more sweeping Steller sea lion-related protection management measures. Data from 2000 are presented as a transition year, and interpretation of 2000 data in terms of understanding the impacts of Steller sea lion protection measures is problematic for several reasons, not the least of which is that management conditions changed dramatically during the year itself, so that the year as a whole represents neither pre- nor post-Steller sea lion RPA conditions. Data from 2001 are included as these represent the most current full year data available.[14,15]

The population of the regions varies considerably. Within Alaska, the Alaska Peninsula and Aleutian Islands region had a population of approximately 6,000 in 2000; the Kodiak Island region had approximately 14,000 residents; and the southcentral and southeast Alaska regions had populations of about 367,000 and 75,000, respectively. In the Pacific Northwest, the Washington inland waters region had about 3.9 million residents and the Oregon coast region had a population of about 105,000. Beyond overall population, the types of communities within the regions also vary considerably. The Alaska regions contain the largest community in the state. Anchorage, that, along with its surrounding area, contains nearly half of the state's population,

---

[14]It should be noted that the 1999-2000 period was a time of structural change for a good part of the groundfish fishery independent of Steller sea lion protection management related issues. The most obvious of these changes were those associated with the AFA which, among other things, reduced the offshore catcher-processor fleet, shifted quota from offshore to inshore, and facilitated the formation of co-ops for offshore catcher processors in 1999 and for inshore and mothership catcher vessels in 2000. A comprehensive discussion of the social impacts of the AFA is beyond the scope of this document, but is provided in the NPFMC's report to Congress. It is sufficient to note that inclusion of 1999 as a base year for this analysis does not portray a socioeconomic context in static equilibrium and it is not realistic to assume that all other things are being held equal.

[15]As a methodological note, it should also be stated that while historic time series data in this document are similar to those found in the previous version of the 2001 Draft Alaska Groundfish Programmatic SEIS, they are not identical. The reason for this variation is discussed in some detail elsewhere (NPFMC 2002d), but in general results largely from a refinement of data resulting from an improved ability to focus on directed catch (and exclude bycatch). It is the target fisheries that will be subject to the more direct impacts of proposed management alternatives. While consistency with previous documents might be valuable in an abstract sense, it is not particularly important in a practical (pragmatic) sense for the present task. For the purposes of the regional and community impact discussions, the precision of individual numbers is much less important than the accuracy of the nature, direction and magnitude of trends in existing conditions, and the direction and magnitude of change resulting from the proposed alternatives.

as well as very small relatively isolated traditional communities. Within the Pacific Northwest, the regions include the greater Seattle metropolitan area as well as relatively small coastal fishing communities.

The population structure of the regions also varies considerably. As shown in the individual regional profiles, the fishery has an impact on the male-female population balance for some of the Alaskan communities that are the focus of intensive groundfish processing. This is due to the fact that processing workers come to these communities for various lengths of time, and there are many more males than females in this workforce. This type of direct impact on population structure attributable to groundfish is seen in few communities, but these tend to be the communities with the highest level of groundfish-related processing activities. Within Alaska, particularly in the Aleutian and Kodiak Island regions, there is also a relationship between percent of Alaska Native population and commercial fisheries development, with communities that have developed as large commercial fishing communities becoming less Native in composition over time compared to other communities in the region. There are many variables involved, but for a few of the communities noted, the relationship is quite straightforward. These differences in the male/female and Native/non-Native population segments are, to a degree, indicative of the relative degree of isolation or integration of the directly fishery-related population with the social and economic structures of rest of the community. Again, this varies considerably from place to place and is not apparent in the Alaska southcentral and southeast regions in the same way it is in the more western regions.

Employment and Income. Employment and income (payments to labor) information presented for each region provides a look at types and levels of economic engagement with the groundfish fishery. Detailed employment and income figures for each region may be found in the community profiles on the NPFMC website (NPFMC 2002d). Information on employment in the processing sector provides insight on the level of employment in the communities that is directly attributable to groundfish fishery activity.

The working assumptions with regard to community employment calculations in groundfish processing are relatively crude, due to the limits of the information available. Employees of shoreplants are counted as part of the labor force for the community in which the shoreplant itself is located, while those of the more mobile processors are counted as part of the labor force of the community of vessel owner's address as listed in CFEC vessel registration files or NOAA Fisheries federal permit data, as described in Section 3.9.2.

With these assumptions, during 2001 primary or direct Alaska groundfish processing employment ranged from none in the Oregon coast region to more than 3,500 persons in the Alaska Peninsula/Aleutian Islands region and nearly 3,800 persons in the Washington inland waters region.

Interpretation of these data in terms of engagement with the community is less straightforward for some regions than for others. For some, processing plants tend to be industrial enclaves that are somewhat separate from the rest of the community, while for others there is no apparent differentiation between the processing workforce and the rest of the regional or local labor pool. For the Washington inland waters region, Alaskan groundfish processing work is at sea, so in some respects it does not take place 'in' a community at all. In all cases, however, processing employment tends to be seasonal in nature.

A further complication for attribution of socioeconomic impacts to a regional base is the fact that many workers in many sectors perform groundfish-related work in a region or community other than the locations where they have other socioeconomic ties. It is not uncommon for fishery-related workers to spend little money in their work region and to send pay 'home' to another community or region (and, further, legal residence may or may not be consistent with what people think of as ‘home’ or what may be considered ‘home’ in terms of where economic benefits ultimately accrue). In this sense, regional employment is indicative of the volume of economic activity, if not a specific level of labor activity directly comparable to other industries. The importance of this flow varies from region to region and from sector to sector, but is most apparent for the communities that are most heavily engaged in the processing aspect of the groundfish fishery.

The CDQ region is a particular or specific example of this type of flow, where a number of catcher processor firms based in the Washington inland waters region have seen significant investment by CDQ groups in recent years, but where registrations and permits have largely been retained by individuals or entities based in Washington. This CDQ ownership interest (along with targeted hiring efforts by some firms as well as other aspects of the CDQ program itself) has resulted in increased levels of Alaska resident employment (and revenue and income for Alaska based entities and individuals) associated with the groundfish fishery. As the growing CDQ based engagement in this sector has not typically resulted in transfers of permits or registrations between regions, or has resulted from aspects of the CDQ program that are unique within the fishery, this activity is not well captured by the economic models and is therefore discussed in detail in its own section (Section 3.9.4).

Tax and Revenue. Tax and revenue information is presented for each Alaska region to provide a perspective on the role of the groundfish fishery in the underpinning of the local economy. Data are from the Alaska Department of Revenue, Alaska Department of Community and Economic Development (ADCED), and local sources, as appropriate.

Information on the local tax structure of each relevant community is provided, and the communities and regions vary in the way that direct revenue is collected on fishery-related transactions that occur in the regions. For communities (and boroughs) in the more western Alaska regions, a local fish tax is often a significant source of local revenue. For other regions, direct revenue benefits are more closely tied to the state fish tax. Information is provided for each region on shared taxes and the role of state shared fish tax in relation to these other taxes. Again, there is considerable variability from region to region. Also apparent is the regional differentiation in the importance of the relatively new fishery resource landing tax. This source of revenue comes from the offshore sectors of the fishery, and is designed to capture some of the economic benefits of offshore activity for adjacent coastal Alaska regions. This tax is far more important to the revenue structure of the Alaska Peninsula/Aleutian Islands region than for any other region.

Inshore Processing. Inshore groundfish processing information is presented for each region to facilitate analysis of the volume and value of the groundfish that are landed in a region. The information is broken out by species, and historical information is provided on utilization rate, product value, and value per ton. When examined on a region-by-region basis, these data point out that the groundfish fishery varies widely from one region to another. For example, in 2001, for the Alaska Peninsula/Aleutian Islands region, local groundfish processing activity is relatively focused on pollock, while in the southeast Alaska region, the fishery is focused much more on the non-pollock, non-cod, non-flatfish, other (A-R-S-O) species. Therefore, there are sharp differences in value per ton (about six times greater in the southeast Alaska region) and in volume (greater in the Alaska Peninsula/Aleutian Islands region, which accounts for about 88 percent of the total volume for the state). These differences correspond with differences in a number of other factors, including the extent to which a local labor force is used in processing and the degree to which a local fleet is harvesting the resource (both measures are high in the southeast Alaska region, but low in the Alaska Peninsula/Aleutian Islands region).

Overall, this information is useful in looking at where fishery resources come ashore, and can be used as a rough indicator of the economic activity generated in processing communities. The relative amount of economic benefit to regions and specific communities varies considerably from place to place, as processing entities are integrated with communities in different ways in different places, and patterns of ownership influence the flow of economic benefits.

Processor Ownership. In part to portray the flow of economic benefits in general and to help characterize them on a regional basis in particular, ownership information is presented for processing entities by region. Caution must be taken in interpreting this information, however, as assignment of entities to regions is based on ownership address information, and this is known to be less than precise in a number of cases due to different criteria for assigning addresses. Also, for entities with ownership interest divided among entities residing in two or more regions, the entire operation was counted for the region with the majority of the ownership interest (and therefore caution must be exercised in the use of this information and this known shortcoming taken into account in interpretation of results). This information presented by region, by sector, and by groundfish species includes all processing sectors, both fixed processors in communities and mobile, at-sea processors (motherships and various catcher processor sectors). The data in this section facilitate consideration of how resource utilization is linked to ownership patterns and how those ownership patterns play out among regions.

For example, the Alaska Peninsula/Aleutian Islands region has the greatest volume and value processed inshore among all the regions, but ownership of shore processing facilities in this region is highly concentrated among individuals and firms located in the Washington inland waters region. The large mobile processors that work the Bering Sea have varying catch and processing locations and at least some ties to adjacent Alaska regions (through CDQ group ownership interest, for example), but ownership again clearly shows predominant ties to the Pacific Northwest. Combining all types of processors (inshore, mothership, and offshore), processors owned by Washington inland waters region residents accounted for 97 percent of total reported tons and 95 percent estimated wholesale value of all North Pacific groundfish processed in 2001.

Catcher Vessel Ownership and Activity. Information on catcher vessel ownership patterns is presented to demonstrate the links between resource harvesting and specific regions. As for catcher processors, region of ownership is based on the vessel owner's address as listed in CFEC vessel registration files or NOAA Fisheries federal permit data, so some caution in the interpretation of this information is warranted. It is not unusual for vessels to have complex ownership structures involving more than one entity in more than one region, or for some of the vessels from the Pacific Northwest that spend a great deal of time in Alaska ports to hire at least few crew members from those ports, but the region of ownership provides a rough indicator of the direction or nature of ownership ties when patterns are viewed at the sector or vessel class level.

Data are presented on the number and types of vessels in the regionally owned fleet and the employment and payments to labor that result from catcher vessel resource activities. Resources from FMP subregions adjacent to the Alaska Peninsula/Aleutian Islands, Kodiak, and other Alaska regions are not uniformly harvested by catcher vessels from those regions. Different regions have varying combinations of local harvesting activity, local processing activity, and ownership of both harvesting and processing entities, and all of these have implications for the role of the groundfish fishery in the local socioeconomic context. For example, in terms of groundfish harvest value and volume, Alaska Peninsula/Aleutian Islands features a mostly non-residential fleet, except for some of the smaller vessel classes. While the highest volume and value of groundfish resources harvest occur near this region, the catcher vessels accounting for most of this activity are from elsewhere (primarily the Washington inland waters and Oregon coast regions).

As discussed in the individual region profiles, the higher the catcher vessel harvest volume in a given area, the less local the fleet tends to be. Put another way, the more important the region is to the overall groundfish fishery, the lower the proportion of total catch is likely to be harvested by the local fleet in that region, although recent CDQ partnership arrangements may serve to ameliorate this historical disjunction.

Information on total groundfish harvest by FMP area for each region is provided to allow consideration of distribution of effort by the fleets of the individual regions in different groundfish management areas. In other words, this information facilitates gauging the relative importance of groundfish from each management area to the catcher vessel fleets based in each region. regions vary widely in how local the catch effort is by the local fleet. For example, catcher vessels in the southeast Alaska region have a very high concentration of effort in the eastern GOA FMP area, while efforts of catcher vessels based in Kodiak are more wide-ranging. More detailed regional harvest information for Pacific cod and pollock, the two most economically important groundfish species overall, is also provided by FMP. Total regional groundfish harvest is also broken out by species so that relative dependency on species by area can be assessed. In this way, relative dependence on alternative measure impacted resources can be examined, at least in general terms.

Harvest Diversity. Recently produced extended sector and regional profiles (NPFMC 2002d) include a treatment of diversity in the catcher vessel fleet, and discusses a brief treatment of the annual cycle for groundfish catcher vessels and information on how groundfish fit into that cycle both in terms of timing and value. Information is also presented on how groundfish has fit into overall catcher vessel effort for groundfish catcher vessels over the last several years so that the relative role of groundfish can be seen over time. This information is abstracted for this document, and clearly shows that the relative importance illustrates marked differences between regions.

For each of the regions a section on community rankings by catcher vessel ownership is provided. While most of the rest of the data are regional in nature, the top communities (to the 95th percentile) for vessel ownership are listed to provide a sense of subregional distribution of engagement with the groundfish fishery from the harvest perspective. (Analogous volume information for processing cannot be shown due to confidentiality restrictions, but the top three communities for processing volume/value for each region are identified but not ranked).

Processor Diversity. Diversity information similar to that presented for catcher vessels is also available for processors (NPFMC 2002d) for each of the regions to allow at least a general-level consideration of the relative importance of groundfish, and that information is abstracted in this document. For the larger Bering Sea pollock inshore plants, for example, groundfish accounted for more than 60 percent of total ex-vessel value over the period 1995-1997, while in the southeast Alaska region, analogous value ranged from 10 to 35 percent over the period 1991-1998. The estimates provided also indicate the amount of groundfish and non-groundfish processed at all regional processors that take deliveries of at least some quantity of groundfish.[16] This document only describes changes in patterns of processor diversity to a limited degree, as they are more clearly associated with local community effects.

Subsistence. Each Alaska region profile contains a brief summary of subsistence resource use for selected communities with known ties to the groundfish fishery. The basic data used for this description were taken from the ADF&G subsistence database. The management of the consumptive use of subsistence resources in Alaska is complex, and is summarized elsewhere (NPFMC 2002d). Groundfish comprise up to 9 percent of total subsistence resources consumed in some communities. Level of Steller sea lion take for subsistence purposes in Alaska coastal communities is mentioned in each of the regional profiles, but is described in more detail in Section 3.9.5 as well as in other existing documentation (NPFMC 2002d). Section 3.9.5 also provides more detail on existing conditions related to a number of other subsistence topics.

Tables 3.9-33 through 3.9-38 present information on participation in the groundfish fishery by region for processing and catcher vessel sectors. Parallel tables are presented for each of the individual regions and provide time series information on most of these same indicators. Confidentiality has been preserved for vessels and processors with few members in any particular class or sector by using a normative value for operations within a particular class that are then adjusted regionally so that regional subtotals will match the actual regional total.

Answers to several "big picture" questions are summarized in the individual regional profiles (and more detailed description is available in the companion community profiles document [NPFMC 2002d]). These include the following questions:

How have fishing communities in Alaska been affected by the growth of the domestic groundfish fishery?

- On a regional basis, and specifically with respect to the high volume, formerly foreign fleet fisheries, the primary regions that have been affected are the Alaska Peninsula and Aleutian Islands region and the Kodiak Island region.

- Within the Alaska Peninsula and Aleutian Islands region, the growth of the domestic groundfish fishery has caused profound changes in the communities of Unalaska and Akutan. In Unalaska in recent years, it has provided the mainstay of the fisheries-based portion of the economy and generally reversed the local economic decline that followed the crash of the King crab fishery. Both inshore and offshore sectors have contributed to the local tax base and the economic climate that has fostered the development of a significant support services sector. In Akutan, the groundfish fishery, primarily in the form of a large groundfish oriented shore plant, has transformed the community from a small primarily Native community to a much larger, predominantly non-Native community. The implications of this change should be interpreted with caution, however, as the processor (through an enclave type of development) and the rest of the community remain separate in a number of different ways. Lesser changes have been seen in Sand Point and King Cove, although both have experienced a significant growth in local groundfish processing in recent years. Sand Point's residential catcher vessel fleet has benefitted disproportionately from the development of the

[16] A summary analysis of processors within the four Alaskan regions defined in this study revealed that shore based processors that took deliveries of at least some amount of groundfish accounted for approximately 77 percent of all non-groundfish processed at all shore based processors within those regions.

groundfish fishery in comparison to other communities in the region, but at the same time, other fishery changes have had the effect of shifting some groundfish processing away from the community. Communities within the Aleutians East Borough with no direct involvement in the groundfish fishery have also benefitted from the borough's fish tax. Other CDQ communities in the region have benefitted in yet other ways.

- Within the Kodiak Island region, the City of Kodiak has been the prime beneficiary of the development of the groundfish fishery. It has served as an important buffer for variation in other fisheries, especially after the decline of the locally important shrimp and crab fisheries, as well as the Bering Sea crab fisheries.

- The Alaska southcentral and southeast regions have not seen the level of changes experienced by communities in the Alaska Peninsula/Aleutian Islands region and the Kodiak Island region. The fishing communities in these regions tend to be quite diversified, although groundfish is an important component of this mix for some communities.

- It should also be noted that the development of the domestic groundfish fishery has also been important for regions and communities outside of Alaska, particularly for the Oregon (primarily Newport) catcher vessel sector, and the Washington (primarily Seattle) distant water fleet (catcher vessels, motherships and catcher processors) and regionally based processing and support entities active in the Alaskan groundfish fishery.

How have historic changes in fisheries management affected fishing communities?

- Beyond the overall development of the domestic fishery, a number of fisheries management changes have had significant impacts on the regions and communities.

- With the JV era, expertise in the groundfish fishery was gained, and the foundation was laid for more complete domestic development of the fishery.

- Concerns regarding overcapitalization of the fishery and growth of the offshore sector in the late 1980s led to management actions based on avoiding preclusion of different sectors. This, in turn, had a number of impacts in both Alaskan and Pacific Northwest regions. Inshore/Offshore allocative splits changed the fishery in both the GOA and Bering Sea.

- Implementation of IFQ-based management for sablefish profoundly changed that part of the groundfish fishery.

- License limitation served to cap entries into the fishery, but did not stabilize ownership patterns.

- The evolution of the CDQ program has served to involve entire regions in the groundfish fishery that were not directly involved in the groundfish fishery prior to the implementation of the program.

- The AFA changed the nature of quota allocations between and among sectors. Co-ops were recently formed both offshore (1999) and onshore (2000), and fishery participants are still adapting to the new context. Significant capital was removed (i.e., vessels retired) from the offshore fleet, the race for fish was essentially eliminated, and new types of operational relationships were formed between processors and their harvesting fleets. Ownership structures changed, with increased American ownership overall, and a specific trend of note has been increased investments in the fishery by CDQ groups. In terms of regional or community-based impacts, the beneficial economic impacts of the reduction of the race for fish have accrued to most participants, but perhaps especially to the Washington inland waters region, due to the ownership patterns and basic operational structure of the sector. Some adverse support sector impacts have been felt in Unalaska due to lessening of seasonal peak demands. In general, not enough time has passed since the full implementation of the provisions of AFA for all likely impacts to have become manifest.

- Management measures directed toward Steller sea lion protection have made a significant impact on the fishery. Some of the more restrictive measures were imposed in 2000, and a full suite of alternative measures were analyzed by NOAA Fisheries in 2001. Given the recency of these developments and the interactive nature of Steller sea lion-related management changes with other management initiatives, impacts are still unfolding, and are expected to vary significantly from community to community and region to region.

These issues are important to an understanding of the cumulative nature of the impacts of commercial groundfish fisheries development on the relevant communities and regions, as well as to developing an understanding of the present context or an “existing conditions” baseline against which the impact of the various management alternatives will be assessed. It is also important to note that among the analytic challenges in providing a baseline is the fact that some aspects of the industry cannot be 'held equal,' although they are clearly important.

First, in trying to isolate community impacts by looking at the intersection of communities and sector entities, the picture is complicated by entities that have a presence in multiple areas, such as both the BSAI and GOA areas, that may experience different types of impacts. Second, some entities have a presence in two or more different sectors (catcher vessels, catcher processors, and shore processing), such that impacts that may be seen as accruing to one sector may be influenced by other sector changes. Third, entities in the groundfish fishery differ markedly in the degree to which they participate in and depend on other fisheries. This, of course, helps to determine the magnitude of impacts, or the consequences of impacts, experienced by the individual entities and communities. Other types of factors that confound the analysis in fundamental ways are aspects of the fisheries context that are outside of the control of the entities engaged in the fishery. As mentioned above, AFA-related consequences have recently changed the fishery in a number of ways at approximately the same time that Steller sea lion Regulatory Flexibility Act (RPA) impacts were being realized. Also, Area M salmon changes have had interactive impacts on a number of alternative measure-influenced entities and communities.

In summary, the Alaska groundfish fisheries are taking place in a dynamic socioeconomic context, one that has proven particularly volatile in the past few years. This volatility has resulted at least in some part from changes within the groundfish fishery itself, as well as with respect to other fisheries that, in turn, have fostered interactive or synergistic impacts to the groundfish fishery context. These factors resulted in a status quo that is by no means a set of static conditions. As a result, there are known limitations on the degree to which causality of recent sector and community changes can be assigned to past individual management actions, and this serves to limit the confidence with which projected future changes can be assigned to the proposed alternatives, or that likely changes can be quantified with assurance of accuracy. As a result, the descriptions in this section (and the subsequent impact analysis) are best viewed as indicative of the type, direction and magnitude of changes seen and expected in the groundfish fishery rather than a precise quantification of the socioeconomic parameters of the fishery. A brief overview of the effects of past/present actions and events on regions and communities is summarized in Table 3.9-126.

Alaska Peninsula and Aleutian Islands Region

Overview. The Alaska Peninsula/Aleutian Islands region, shown in Figure 3.9-9, is in several ways the center of the Alaska groundfish fishery in general and the Bering Sea pollock fishery in particular. The adjacent FMP area features the greatest groundfish harvest, and it sees significant activity from both onshore and offshore fishery sectors. In 2001, the region accounted for about 88 percent by volume and 79 percent by value of all groundfish processed in Alaska. During 1992 and 2000, this region accounted for more than four times the volume of groundfish processed inshore than in the other Alaska regions combined. This volume includes 89 percent of the pollock, 68 percent of the Pacific cod, 42 percent of the flatfish, and 31 percent of the A-R-S-O processed.

The relative dependence of regional communities on the groundfish fishery varies greatly. While four of Alaska's top five groundfish landing ports are in this region, some other communities in the region have little, if any, direct involvement with the fishery. Extended profiles of the regionally important groundfish communities of Unalaska/Dutch Harbor, Akutan, King Cove, and Sand Point are available elsewhere (NPFMC 2002d). No groundfish data are yet available for False Pass, but it is known that substantial processing investment has been made in the community, and that at least some groundfish was locally processed during 2001. Groundfish has not been a major focus of processing in St. Paul in recent years, but groundfish do appear in the processing reports for 2000.[17] Additionally Adak, a former military community, has become a significant regional processor of groundfish in the recent past. Although production figures are confidential, it is common knowledge that although no groundfish were landed in the community prior to 1998, it has since become a significant and growing purchaser of groundfish, particularly cod, within the region. This community is quite different in sociocultural terms from the other communities of the region, given its recent development as an industrial site on a converted military base rather than within or adjacent to a traditional community.

It is also important to note that within this region the Aleutians East Borough encompasses the communities of Akutan, Cold Bay, False Pass, King Cove, Nelson Lagoon, and Sand Point. Given that changes in tax revenue resulting from changes in groundfish landing patterns in one community within the borough are directly linked to expenditures in other communities in the borough (for example, a decline in fish tax revenue in King Cove paid to the Borough would impact Nelson Lagoon if it were large enough to necessitate reductions in school expenditures), the borough structure would serve to distribute impacts to communities in a different way than seen in the rest of the region that has no such structure.

This region, then, is one of strong contrasts with respect to involvement with commercial fisheries in general, and the groundfish fishery in particular. In terms of the structural links to the groundfish fishery, for the purposes of socioeconomic characterization, there are four main categories of communities within the region

[17] It is worth noting that Chignik - although not geographically in the region is lumped analytically in regional totals for the fishery - has run some groundfish as well, but like St. Paul this is clearly not the main focus of local processing. Brief information on the Chignik groundfish fleet is provided in recently produced groundfish community profiles (NPFMC 2002d).

that have links to harvesting or onshore and offshore processing sectors of the Bering Sea groundfish fishery. These are characterized as follows:

- Communities with well-developed socioeconomic ties to both onshore and offshore sectors. This category consists of one community: Unalaska/Dutch Harbor. This community has been the number one fishing port in the United States in terms of volume of catch landed since 1992, and held the number one rank in value of catch landed from 1988 through 1999, slipping to number two in 2000 and 2001. Groundfish (especially pollock) is a central part of the community's fishery-based economy. The community has also seen the development of a significant support service sector in recent years, and this support service sector provides services for a number of sectors engaged in the Bering Sea pollock fishery, including shoreplants, floating processors, catcher vessels, and catcher processors. It is also the shipping hub of the Bering Sea. In line with National Standard 8 under the MSA, Unalaska is both highly "dependent" upon and "engaged" in the fishery. This is particularly true when a sense of scale is applied, and the importance of the fishery in relation to the overall size of the community, both in economic and social terms.

- Communities with large shoreplants that are also CDQ communities. This category consists of one community: Akutan. Akutan is quite different from Unalaska in that it is the host community to a single rather than to multiple shoreplants, and the geo-social relationship between the plant and the community is of quite a different nature than those found in Unalaska.

- Communities that are not CDQ communities, have shoreplants that process groundfish, but that have no direct ties to the offshore sector. These are the communities of King Cove and Sand Point. These communities as a pair also differ from Unalaska and Akutan in that they historically have had a resident fishing fleet that provides more than a negligible amount of product to the local plant. Sand Point differs from Unalaska, Akutan, and King Cove in that they did not qualify as a site for an AFA catcher vessel co-op. Like each of the other communities listed, Sand Point does have an AFA-qualified plant.

- Communities that are CDQ communities without a large shore groundfish processing presence. This includes Atka, Nikolski, St. George, St. Paul, Nelson Lagoon, and False Pass. These communities are not discussed in this section, as CDQ issues are presented in Section 3.9.4 of this document.

The major groundfish communities in the region display quite different histories and this, in turn, continues to influence community socioeconomic structure.

Site of a traditional Aleut village since long before contact times, Unalaska became a Russian trading port for the fur seal industry in 1768. Trade in otter skins was the major economic activity until the turn of the last century. Unalaska has extensive historical links to the groundfish fisheries, with at least some cod fishing and processing taking place for decades.

The pre-World War II American period in Unalaska was characterized by a series of booms and busts. Processing of salmon and herring was established in the early 1900s, although major fisheries based on herring were not established until the late 1920s. The economy was depressed after the WW II, until interest in the fishing industry was renewed in the late 1950s; the present crab fishery was established in the early 1960s. Since that time, the level of activity associated with commercial fishing and fish processing has both increased and diversified, and is now the basis of the local economy. Large multi-species groundfish shore processing plants in the community include Alyeska, Unisea, and Westward. Royal Aleutian is a large crab processor, and Icicle brings significant processing capacity to the community in the form of mobile processing facilities.

In contrast, the contemporary community of Akutan began in 1878 as a fur storage and trading port for the Western Fur & Trading Company. The company's agent established a commercial cod fishing and processing business that quickly attracted nearby Aleuts to the community, and a church and a school were built that same year. World War II affected Akutan by displacing Alaska Native residents, and they were not allowed to return until 1944. In 1948 the first catcher processor was sent to Akutan, and eventually Akutan became established as a premier port for floating processors. Today a large processing plant west of the village proper processes significant quantities of groundfish as well as crab. The processing plant supplies the community with substantial economic benefit, but large-scale commercial fishing activity is largely not integrated with the daily life of the community. The Trident plant is the principal facility in the Akutan port and, historically, a number of smaller, mobile processing vessels have operated seasonally out of the port of Akutan. Akutan does not have a vessel harbor or an airport in the community. Beyond the limited services provided by the plant, no opportunity exists in Akutan to provide a support base for the other major commercial fisheries. Hence, alternative economic opportunities of any kind are extremely limited.

King Cove is historically a commercial fishing community. For decades, King Cove has had processing facilities as part of the community as well as resident commercial fishing fleets that deliver to local seafood processors with longstanding relationships. Local fishermen traditionally have fished for all major species, including groundfish, herring, crab and salmon, with crab and salmon predominant. King Cove was founded in 1911 when Pacific American Fisheries built a salmon cannery on the site. During this time they also acquired a salmon saltery at Thin Point near King Cove. The original settlers were Scandinavian, other European, and Aleut fishermen. Much of the Aleut population came from Belkofski for employment in the local cannery. However, in 1965 when Alaska outlawed salmon traps in Alaska waters, it signified the end of Pacific American Fisheries. Currently Peter Pan Seafoods Inc. controls Alaska's largest production facility in King Cove. Salmon is the primary species harvested and processed. The canned salmon output of King Cove in a single season actually exceeds the annual canned production of the entire country of Canada, but change is occurring. Canned salmon markets have declined over time relative to other product forms and groundfish has gained importance in recent years, with the plant qualifying as an AFA facility.

Sand Point, like King Cove, has had processing facilities as part of the community for decades and resident commercial fishing fleets that deliver to local seafood processors with long-standing relationships. Sand Point was founded in 1898 by a San Francisco fishing company as a trading post and cod fishing station. The cod fishing station employed schooners from its home in San Francisco. It served as a repair and supply center for gold mining during the early 1900s, but fish processing became the dominant activity in the 1930s. World War II affected Sand Point little compared with other communities in the area. The U.S. military built an airport that remains to this day. Aleutian Cold Storage built a halibut plant in 1946. Today it is home to the largest fishing fleet in the Aleutian Chain. Trident operates the current processing plant, processing cod, black cod (sablefish), halibut, pollock, salmon and other assorted bottomfish. Peter Pan Seafoods Inc. operates a support station in Sand Point for their processing plant in King Cove.

Population. The Alaska Peninsula/Aleutian Islands region has the smallest population (6,008 in 2000) of the four Alaska regions characterized. The regional population has declined in recent years with the closure of the military installation at Adak, formerly the largest community in the region. Now Unalaska (population 4,283 in 2000) is the largest community in the region, and has ranked first among domestic ports in volume of landings since 1992 and was first in value of landings from 1988 to 1999.[18] Of the other four communities with more than 200 residents in 2000, three (Akutan [population 713], King Cove [population 792], and Sand Point [population 842, the second largest community in the region]) are substantially involved with the groundfish fishery and are the sites of large processing facilities. These communities have a disproportionately male population, consistent with a predominantly male workforce at the seafood plants that, in turn, comprises a significant proportion of the total community population. Although they vary between plants and communities, processor workforces tend to be made up of short-term residents housed in industrial-enclave-type settings.

Employment and Income. Alaska Peninsula/Aleutian Islands communities have a wide range of employment opportunities and income levels. These opportunities are closely related to the commercial fishery in general, and the groundfish fishery in particular. Communities with sizeable seafood processing operations (Akutan, King Cove, Sand Point, and Unalaska) have typically had very low official unemployment rates.[19] Processing workers tend to be in the community because of the employment opportunity, tend to leave when employment terminates, and comprise a significant portion of the population. Among civilian employment sectors, manufacturing, typically associated with seafood processing in this region, has dominated employment. In 1999, 2,958 persons were employed in manufacturing, almost five times as many as in the next most important sector, state and local government. Regional personal income and earnings from manufacturing exceeded earnings of all other sectors combined in 1999.

Tax and Revenue. Commercial fisheries-related taxes are important to the region in absolute and relative terms. Akutan, King Cove, Sand Point, and Unalaska all have local raw fish taxes, and the first three are also subject to a borough raw fish landing tax. Fisheries-related shared taxes accounted for 99.7 percent of all the shared taxes and fees coming to the region from the state in 1999, and total fisheries-related tax revenues exceeded $7 million. The offshore processing component paid more than $2 million in Fisheries Resource Landing tax in 1999. This tax is considerably more important in the Alaska Peninsula/Aleutian Islands region, in both absolute and relative terms, than for any other Alaska region.

Inshore Processing. In the Alaska Peninsula/Aleutian Islands region in 2001, pollock comprised more than 93 percent of the groundfish volume processed, Pacific cod 5 percent, and A-R-S-O and flatfish 1 percent each. This pattern by species varies considerably from those of other Alaska regions. With 674,000 total reported metric tons of groundfish processed and 268,000 metric tons of total groundfish final product in 2001, the Alaska Peninsula/Aleutian Islands region dominates the other regions in inshore processing. With a 2001 total product value of $491 million and a value of $727 per metric ton, this region has the highest total

[18]In 2000, Unalaska dropped to second in value of landings behind New Bedford, Massachusetts (where the value of landings totaled $146 million [versus $125 million in Unalaska] on a much lower volume [89 versus 700 million pounds] than landed in Unalaska). At least a portion of the relative drop in Unalaska in 2000 can be attributed to declines in the crab fisheries.

[19]Preliminary 2000 census unemployment data show very high unemployment rates in some communities that typically have reported virtually no unemployment (e.g., Akutan). While still being analyzed, from initial review it is apparent that at the time the 2000 census was taken large numbers of processing workers were present in the community but the plants were temporarily idle between seasons, an anomaly that resulted in very large numbers of persons reported as 'not working.' For practical purposes, this means that 2000 census data on employment/unemployment are not useful for at least some communities, pending further review. This is discussed in more detail in Section 3.9.6.

value (reflecting enormous volume processed) and the lowest value per ton (reflecting disproportionate dependence on pollock). In 2001, pollock accounted for 88 percent of processed product value, Pacific cod 10 percent, A-R-S-O less than 2 percent, and flatfish about one-tenth of one percent. Within this region, shoreplants are divided into two subsectors for the purposes of this analysis, as noted in Section 3.9.2: the BSP-SPs and the APAI-SP, based on distinctive operational profiles. The BSP-SPs include three large shore processors in Unalaska, one large shore processor in Akutan, and, as of 2002, one floating processor in Beaver Inlet on Unalaska Island, and one floating processor in Akutan Bay. These same plants have operated every year during the 1992 and 2000 period (although one of the floaters has moved from Beaver Inlet to Akutan Bay during this time). The APAI-SP category is comprised of all other groundfish plants in the region (Aleutians East Borough and the Aleutians West Census Area) exclusive of the six Bering Sea plants (and including the plants in Sand Point and King Cove, among others). The Bering Sea plants dominate processing in the region (and, indeed, the state) in terms of volume of groundfish processed. The number of smaller plants in the region has varied from 5 to 8 per year from 1992 to 2000. In 2000, eight APAI-SP (i.e., the regional non-Bering Sea pollock sector plants) reported processing groundfish in Adak (1), Chignik (1), Unalaska/Dutch Harbor (3), King Cove (1), Sand Point (1), and St. Paul (1).

Processor Ownership. Though the center of both onshore and offshore groundfish processing activity, the Alaska Peninsula/Aleutian Islands region has by far the least ownership of groundfish processing entities of any Alaska region. None of the largest shoreplants are owned by resident entities, and the number of smaller regionally-owned inshore plants varied between zero and six per year over the period 1992-2001. To the extent that economic benefits flow to the location of ownership, most of these benefits leave the region. In terms of reported tons in 2001, groundfish processed by inshore plants owned by residents of the region was equal to less than three-tenths of one percent of the total groundfish processed at plants located in the region. Offshore processing in the region displays the same pattern. Regionally owned shoreplants had a wholesale product value of approximately $1.56 million in 2001, while the analogous figure for motherships was $0. Catcher processors have been well below $1 million for all years data can be disclosed.

Catcher Vessel Ownership and Activity. Groundfish catcher vessel ownership is lower in the Alaska Peninsula/Aleutian Islands region than in any other region. In recent years, none of the AFA Trawl catcher vessels (which supply a very large proportion of the groundfish processed in the region) have been locally owned. Ownership is clustered in two vessel classes (TCVs 60 ft and fixed gear catcher vessels 33 ft to 59 ft) that tend to work the nearshore fisheries in the GOA. Vessel ownership within the region is strongly clustered in Sand Point and King Cove, with a secondary cluster in Unalaska. Sand Point residents owned 49 percent of the regionally owned groundfish vessels that, in turn, accounted for 59 percent of the total regionally owned vessel value landed during the period 1992 to 2000. King Cove residents owned 24 percent of the vessels that, in turn, accounted for 23 percent of the regionally owned vessel landings value over this same period. Analogous figures for Unalaska were 21 percent of regional vessels and 14 percent of regionally owned vessel landings value, respectively. No other community accounted for more than 3 percent of regional vessels or one percent of regional value landed by regionally owned vessels. In 2001, these vessels employed 327 persons, with $2.6 million in payments to labor in groundfish. In 2001, 90 percent of the retained harvest value from these vessels came from the western GOA FMP area. About 34 percent retained harvest volume was Pacific cod, and 64 percent was pollock. For that same year, Pacific cod accounted for 66 percent of total groundfish value, and pollock 33 percent.

Harvest Diversity. For groundfish catcher vessels owned by regional residents, groundfish has accounted for roughly half of the ex-vessel value for major fisheries since 1996, a substantial increase over the early

1990s. These vessels are primarily dependent on the groundfish and salmon fisheries, as each of these two fisheries is economically more important by a factor of four or more than any other fishery. About 7 out of 10 vessels participated in the salmon fishery, about one-third in the halibut fishery, and about one-quarter in crab or other fisheries (NPFMC 2002d).

Processing Diversity. For the smaller groundfish processing plants in the region, groundfish roughly accounted for between 10 and 25 percent of ex-vessel value of landings during 1991-1998, with a general increase over this period. In 1998, groundfish accounted for 23 percent of value, while salmon and crab accounted for 30 and 44 percent, respectively. For the larger BSP-SP, groundfish has accounted for more than 50 percent of ex-vessel value of landings from 1991-1998, and well over 60 percent of value for 1995-1997. At these larger plants in 1998, crab accounted for roughly the same proportion of total value as in the smaller APAI-SP, and groundfish alone accounted for roughly the same value as groundfish and salmon combined in the smaller plants (NPFMC 2002d).

Subsistence. Akutan, King Cove, Sand Point, and Unalaska have a subsistence resource consumption ranging from about 200 pounds per capita to more than 450 pounds per capita. Of this total, groundfish specifically ranges from 4 to 9 percent of the total. Subsistence use of Steller sea lions is not well documented, but is heaviest in southwest Alaska and is historically concentrated among relatively few communities (Atka, Akutan, St. George, St. Paul, and Unalaska). Such use has decreased significantly since 1992, and is discussed in more detail in Section 3.9.5.

Tables 3.9-39 through 3.9-44 summarize information on the Alaska Peninsula/Aleutian Islands regional engagement with the groundfish fishery through 2001.

Kodiak Island Region

Overview. The Kodiak Island region encompasses the Kodiak Island Borough, which includes Kodiak Island, other parts of the Kodiak archipelago, and a portion of the Alaska Peninsula, as shown in Figure 3.9-10. Linkages between this region and the groundfish fishery are predominantly associated with the City of Kodiak and its suburbs. Kodiak is the dominant GOA fishing community for groundfish, and is important for salmon, halibut, and other species. In 2001, the region accounted for about 10 percent of the volume and about 13 percent of the value of the total groundfish processed in Alaska. The region accounted for almost 16 percent of the volume of groundfish processed inshore in all regions of the state (1992 to 2000). This volume included 11 percent of the pollock, 28 percent of the Pacific cod, 54 percent of the flatfish, and 30 percent of the A-R-S-O category of groundfish processed. Within this region, the City of Kodiak is the location of virtually all of the direct links with the commercial groundfish fishery. (Processing data does show that groundfish are also run at Atilak, but this is a relatively specialized operation and very small relative to the aggregated operations associated with the City of Kodiak.) An extended community profile of Kodiak is available elsewhere (NPFMC 2002d).

Traditional communities existed in the area in precontact times, but commercial fish processing in the Kodiak region began on the Karluk spit in 1882. Not long after that, canneries were established in the community of Kodiak. While the quantity and form of shore processing plants in Kodiak have changed, this sector remains an influential component of the fishing industry that is, in turn, fundamental to the community and its economy. Shore processing facilities in the Kodiak region concentrated primarily on salmon and herring prior to 1950, although there was a cold storage facility at Port Williams where halibut was frequently landed. The product produced at these facilities was most often canned fish. Cannery operations expanded in the 1950s and 1960s to accommodate king crab processing. Thirty-two processors processed 90 million pounds of crab in 1966. Declining harvest levels, however, prompted several shoreplants to move their operations during the late 1960s and early 1970s to Unalaska/Dutch Harbor in the Aleutian Islands, closer to the larger supply of Bering Sea-Aleutian Island king crab. When king crab stocks started to crash in the late 1960s, some of the remaining Kodiak plants sought to diversify. At least one plant added facilities to separate the previously dominant crab line and the main plant was then converted into a shrimp plant. Many of the plants maintained halibut production lines while they were processing crab, shrimp, and salmon. By the late 1970s a few K-SPs, according to one plant manager, started experimenting with groundfish resources "because there wasn't much crab to do." However, the majority of the groundfish caught prior to 1988 was processed aboard foreign vessels, first by wholly foreign operations, and then by joint ventures where American boats delivered to floating foreign processors. Plant and dock expansions fostered the ability of local plants to further utilize groundfish resources. The first surimi production in Alaska took place in Kodiak in 1985. According to the City of Kodiak, Kodiak is currently home port to 770 commercial fishing vessels, making it the state's largest fishing port. The development or evolution of the Kodiak harvesting fleet has essentially paralleled that of the processors to which they deliver (along with the development of a fleet component that in part or in whole participates in BSAI fisheries).

Population. In 2000, the Kodiak Island region had a population total of 14,256. The City of Kodiak has become the hub community of the region, at present comprising just less than 50 percent of the total Kodiak Island Borough population. Furthermore, a significant part of the region's population lives very near Kodiak in unincorporated areas of the Kodiak Island Borough. When these areas are taken into account, at present approximately 85 percent of the Kodiak Island Borough population lives in and around the City of Kodiak. In terms of ethnicity, the city is about 13 percent Native, while organized communities outside the city are predominantly Native (68 to 94 percent). The predominant minority in the city and its surroundings is Asian and Pacific Islanders, followed by Natives and Blacks. The predominant minority in other (unorganized) regional communities is Caucasian, with few other minorities present.

Employment and Income. The economies of the Kodiak Island region communities are all dependent to some degree on fishing and, for the City of Kodiak, groundfish are an important component of this dependence. In 1999, regional service sector employment outpaced manufacturing, but manufacturing provides more income than any other sector. The fishing sector provides an important base for the retail and government sectors, which follow it in relative size. The military sector is also significant, and is actually second in income and earnings, primarily because of a local Coast Guard base, the largest in the country. The City of Kodiak can be distinguished from other regional communities in several ways. Whereas the city has relatively low rates of unemployment and poverty, other communities have higher rates. In terms of income measures, the city ranks highest.

Tax and Revenue. The City of Kodiak and the Kodiak Island Borough are the primary taxing entities in the region. City or community services outside the city are quite limited, or are supplied by the Kodiak Island Borough or privately. The Kodiak Island Borough levies a property tax of 9.25 mills, a 5 percent accommodations tax, and a 0.925 percent severance tax on natural resources. Other communities levy limited taxes. The Kodiak Island region is also dependent on income from State of Alaska fisheries taxes. The region's share of the fisheries business tax and fishery resource landing tax amounted to $1,330,856 in 1999.

Inshore Processing. In recent years, groundfish has made up over 70 percent by weight of the fish processed in the Kodiak Island region. In 2001, pollock comprised about 43 percent of the groundfish by volume. Pacific cod made up about 29 percent, A-R-S-O about 13 percent, and flatfish about 17 percent. In terms of value, the pattern is somewhat different. Pollock accounted for 40 percent of product value in 2001, Pacific cod 35 percent, A-R-S-O 17 percent, and flatfish 7 percent. While the volume of groundfish processed in the region is much less than in the Alaska Peninsula/Aleutian Islands region, value per ton of final product was higher. Groundfish has recently comprised 40 to 45 percent of the total value of fish processed in the Kodiak Island region. Since 1995, one plant has operated at Alitak and the rest of the region's plants reporting groundfish processing (11 in 1999 and 10 in 2000) have operated in Kodiak itself.

Processing Ownership. Although Kodiak residents own both onshore and offshore processing facilities, onshore plants that process pollock and Pacific cod are owned predominantly by entities outside the region (1995 to present). Kodiak Island region residents are active in the ownership of offshore processing vessels for groundfish other than pollock. Residents historically have owned three to six offshore processing facilities, with the lower numbers in earlier years. In 2001, catcher processors owned by regional residents had a wholesale product value of $23.6 million, and shoreplants had an analogous figure of $2.8 million. No motherships were owned by regional residents.

Catcher Vessel Ownership and Activity. The Kodiak Island regionally owned fleet is very diverse. Some vessel classes, especially the larger trawl vessels, have displayed remarkable stability over time. Smaller trawlers have become fewer. Fixed gear vessels have increased in number. Most of the fleet's fishing activity is in the central GOA, and product is delivered to K-SPs. Regional vessel ownership is heavily concentrated in the City of Kodiak, whose residents over the period of 1992 through 2000 owned 87 percent of all regionally owned vessels, and these vessels, in turn, accounted for 95 percent of regionally owned vessels' landings value over this same period. No other community was home to 6 percent or more of the regionally owned vessels, or accounted for more than 2 percent of the total value of the landings of regionally owned vessels over the 1992 and 2000 period. Since 1991, catcher vessels owned by Kodiak Island region residents have harvested a significant amount of fish in the Bering Sea as well. In 2001, the central GOA accounted for 57 percent of ex-vessel value, and the Bering Sea accounted for 27 percent. The Aleutian Islands, western GOA, and eastern GOA areas accounted for 2, 8, and 4 percent, respectively. Pacific cod accounted for 25 percent by volume and 45 percent by value of retained groundfish harvest, while pollock accounted for 60 percent of volume and 29 percent by value in 2001.

Harvest Diversity. In terms of the 'annual round' for groundfish catcher vessels owned by residents of the Kodiak Island region, groundfish and other species tend to complement each other. Groundfish have accounted for less than half of the total ex-vessel value accruing to these vessels in recent years. Halibut, crab, and salmon are also important fisheries to these vessels. More than 50 percent of the groundfish catcher vessels participate in the halibut fishery, and more than 33 percent participate in the salmon fishery (NPFMC 2002d).

Processing Diversity. Groundfish have accounted for roughly 30 to 47 percent of ex-vessel value for all onshore processing plants in the Kodiak Island region from 1991 to 1999, with a general increase in value over this period. This increased to about 61 percent for 2000 (with the qualification that halibut numbers were not included in the 2000 totals, so that the significance of this increase is suspect). Groundfish are economically more important than any other species or species group. Salmon are second in importance, in some years being close to (or as recently as 1995 exceeding) groundfish in value. Halibut, while relatively more important for the Kodiak Island region than for the Alaska Peninsula/Aleutian Islands region, generally accounts for less than 20 percent of the ex-vessel value of fish delivered to shoreplants in the Kodiak Island region (NPFMC 2002d).

Subsistence. Kodiak is the single regionally important groundfish community. Residents of the City of Kodiak are reported to harvest and consume about 151 pounds of subsistence resource per capita, of which 72 percent is fish. However, groundfish comprise only about 8 percent of the total (12 pounds per capita). Subsistence use of Steller sea lions is not well documented, but has historically been important in the Kodiak Island region, particularly for the communities of Old Harbor and Akhiok. Such use has decreased since 1992 (see Section 3.9.5).

Tables 3.9-45 through 3.9-50 summarize information on the Kodiak Island regional engagement with the groundfish fishery through 2001.

Southcentral Alaska Region

Overview. The southcentral Alaska region, shown in Figure 3.9-11, spans the most heavily populated area of the state. In the southcentral Alaska region, participation in the groundfish fishery varies considerably from other Alaska regions, and the region is little involved with the Bering Sea pollock fishery in particular. In 2001, the region accounted for less than one percent of the volume and 3.8 percent of the value of all groundfish processed in Alaska. While accounting for less than 1 percent of the pollock, 2 percent of the flatfish, and 5 percent of the Pacific cod processed inshore in Alaska regions over the period of 1992 through 2000, the southcentral Alaska region did account for 19 percent of the A-R-S-O species group. The region also differs from the others by virtue of its connection of communities and ports by a road system and this, in turn, influences the nature of engagement with the groundfish fishery. Homer and Seward serve as the primary ports for groundfish trucked on the Alaska road system. During 1991 through 1999, groundfish were processed in 11 regional communities, with (in alphabetical order) Cordova, Nikiski and Seward accounting for the majority of processing. Like other regions, the recent situation is somewhat fluid, as Steller sea lion protection measures may have already had significant effects on the groundfish (and especially pollock) fisheries that exist in the region.

The important groundfish communities of southcentral Alaska have a very different socioeconomic context than those of the previous regions profiled. Cordova, arguably southcentral's most fishery-dependent community, has its origins in transportation as well as fishing. One of the first producing oil fields in Alaska was discovered at Katalla, 47 miles southeast of Cordova, in 1902. Cordova became the railroad terminus and ocean shipping port for copper ore from the Kennecott Mine up the Copper River. The Bonanza-Kennecott Mines operated until 1938 and yielded over $200 million in copper, silver and gold. By 1938, however, the ore supply had diminished, the price of copper dropped and the mines and railway closed down. The Katalla oil field produced until 1933, when it was destroyed by fire. The commercial fishing foundation of the local economy dates back to the 1800s. In 1893, commercial fishing had expanded from the Copper River to include PWS. Between 1889 and 1917, canneries opened in locations including Shepherd Point, Eyak Village, Valdez, Port Nellie, Port San Juan, Drier Bay and Canoe Pass. World War I stimulated the development of the fishing industry, though it decreased after the war. Chinese immigrant labor became prevalent in the canneries. By 1924, seven canneries existed in the PWS with two in the Cordova area. Herring fishing began in 1913, and harvesting of commercial razor clams began in 1916 and lasted until the 1964 earthquake. Dungeness crab harvesting began in the 1930s, followed by catching Tanner crab in the late 1960s. Shrimp fishing, longlining of rockfish, sablefish, and lingcod occurred intermittently in the late 1970s, and salmon seining and gillnetting followed thereafter.

The Homer area has been the site of traditional communities since long before contact times. In 1895 the USGS arrived to study coal and gold resources, and soon thereafter local beach mining operations began. In 1899, Cook Inlet Coal Fields Company built a town and dock on the Homer Spit, a coal mine at Homer's Bluff Point, and a 7-mile-long railroad that carried the coal to the end of Homer Spit. Various coal mining operations continued until World War I, and settlers continued to trickle into the area, some to homestead in the 1930s and 1940s, others to work in the canneries built to process Cook Inlet fish. Coal provided fuel for homes, and there are still an estimated 400 million tons of coal deposits in the vicinity of Homer. The City government was incorporated in March 1964. After the Good Friday earthquake in 1964, the Homer Spit sunk approximately 4 to 6 ft, and several buildings had to be relocated. Today, sport fishing for halibut and salmon contributes significantly to the economy along with the commercial fisheries. A total of 541 area residents hold commercial fishing permits. In 2000, the estimated gross fishing earnings of residents neared $27 million. The fish dock is equipped with cold storage facilities, ice manufacturing and a vacuum fish-loading system. A sawmill processes borough timber, and wood chips are exported from Homer to Japan. Tourism is also an important component of the local economy (ADCED 2002).

Nikiski, now important as a landing/processing/shipping location for the groundfish fishery does not have the type of historical ties to commercial fisheries seen in a number of the other communities. Nikiski is located on the Kenai Peninsula, nine miles north of the city of Kenai. Although Russian fur traders first arrived in 1741, it was not until 1791 that Kenai became the second permanent settlement established by the Russians in Alaska, when a fortified post called Fort Saint Nicholas was built near the community. In 1848, the first Alaska gold discovery was made on the Russian River. In 1869, the U.S. Army established Kenai and in 1899, a Post Office was authorized. The area was homesteaded in the 1940s, and grew from the mid-1950s, when oil exploration led to the first major discovery in the area, the Swanson River oil reserves, 20 miles northeast of Kenai (discovered in 1957). In 1959, natural gas was found in the Kalifornsky beach area 6 miles south of the city of Kenai. By 1964, oil-related industries located within the vicinity included Unocal, Phillips 66, Chevron and Tesoro. Extensive exploration offshore in upper Cook Inlet has established Cook Inlet's middle ground layers containing one of the major oil and gas fields in the world. Today, the main economy is based on the oil industry and derivative products. The industrial complex of Unocal Chemicals produces ammonia and urea for fertilizer, Phillips Petroleum operates a liquid natural gas plant, and Tesoro has a refinery in Nikiski. Fifteen drilling offshore platforms are in the Cook Inlet around Kenai's waters, all equipped with underwater pipelines bringing the crude oil to the shipping docks on either side of the Cook Inlet and from there directly onto tankers. While petroleum activity dominates, federal and state agencies, commercial and recreational fishing, fish processing and tourism are also important parts of the economy of the community.

Non-Native settlers began arriving in Seward in the 1890s. Seward became an incorporated city in 1912. The Alaska Railroad was constructed between 1915 and 1923, and Seward developed as the ocean terminus and supply center. By 1960, Seward was the largest community on the Kenai Peninsula. Tsunamis generated after the 1964 earthquake destroyed the railroad terminal and killed several residents. As an ice-free harbor, Seward has become an important supply center for Interior Alaska. At the southern terminus of the Alaska Railroad, Seward has been a transportation hub for decades. The economy also includes tourism, commercial fishing, ship services and repairs, oil and gas development, a coal export facility, a state prison and the University of Alaska's Institute of Marine Services.

Population. At 366,984 persons in 2000, the southcentral Alaska region is the largest of the four Alaska regions, and it includes Anchorage (population 260,155), as well as small rural communities. Many fishing enterprises and organizations as well as government agencies have offices in Anchorage, and the community is the home of the NPFMC. The southcentral Alaska region groundfish communities tend to be largely non-Native. The high male-to-female ratio often present in small to moderate-sized communities with relatively large processing capacity (such as Alaska Peninsula/Aleutian Islands communities) is not present in this region. This circumstance reflects both a smaller scale of processing operations and a more resident workforce.

Employment and Income. The economies of the southcentral Alaska region groundfish communities tend to be more diversified than those of the Alaska Peninsula/Aleutian Islands or Kodiak Island regions. In part, this greater diversification is a function of road-connectedness and associated access to a large population base, as well as the presence of other developable resources. Groundfish are of lesser importance for employment and income to the region in absolute and relative terms than for either the Alaska Peninsula/Aleutian Islands or Kodiak Island regions. In comparison with the manufacturing sector, in 1999 ten sectors in this region had greater employment and income (the service sector alone had 12 times the number of jobs and 8 times the income of manufacturing).

Tax and Revenue. None of the southcentral Alaska region groundfish processing communities have a local or borough fish tax. At $1,521,569 in fiscal year 1999, 73.3 percent of the region's shared taxes and fees were fisheries-related. This is a higher amount than the Kodiak Island region received (although derived to a lesser extent from groundfish).

Inshore Processing. The groundfish processed in the southcentral Alaska region in 1999 accounted for less than two percent of the groundfish processed inshore in all Alaska regions. The A-R-S-O species group accounted for 43 percent of the volume reported over the period 1991-1998, and Pacific cod, pollock, and flatfish accounted for 35, 17, and 5 percent of the total, respectively. Pollock landings were highly variable. The groundfish value per mt ($3,380 in 2001) for the southcentral Alaska region was almost five times higher than in the Alaska Peninsula/Aleutian Islands region. However, the total product value, $23 million in 2001, was approximately 21 times lower than in the Alaska Peninsula/Aleutian Islands region. The differences between the regions can be accounted for by relative importance of comparatively high-value, low-volume groundfish species. In 2001, A-R-S-O accounted for 52 percent of the volume and 82 percent of the product value for all groundfish processed in the region, while Pacific cod accounted for 18 percent of volume and 10 percent of value. Pollock comprised 25 percent of the volume and 9 percent of value of regional processing, with flatfish accounting for 4 percent of volume and far less than one percent of value. Furthermore, the A-R-S-O species group varies internally among regions, with Atka mackerel (lower value) concentrated to the west, and rockfish (higher value) becoming more important to the east. Processing is also different in the aggregate, as shown by the much higher utilization rates in the southcentral Alaska region (more than 61 percent in 1999) compared to the Alaska Peninsula/Aleutian Islands and Kodiak Island regions (35 and 27 percent in 1999, respectively).[20] In 2000, 17 regional plants reported processing groundfish in Anchorage (2), Cordova (3), Homer (5), Kenai (4), Ninilchik (1), and Seward (2).

---

[20]It should be noted, however, that utilization rates are changing (increasing) significantly in the more western regions due, in large part, to recent changes associated with AFA provisions, so this gap will likely narrow somewhat.

Processor Ownership. Groundfish processor ownership by southcentral Alaska region residents is concentrated in the shore plant sector, with secondary focus on head and gut trawl and longline catcher processor sectors. More processing entities are owned by southcentral Alaska region residents than by residents of any other Alaska region. For these processors during 1991-1999, A-R-S-O and flatfish far outdistanced Pacific cod in volume for most years. Although variable, Pacific cod, in turn, represented a higher-volume fishery year to year than pollock. In 2001, 18,000 tons with a wholesale value of $25 million were reported for regionally owned processors. Of the total value, $20 million came from shoreplants and $5 million from catcher processors. There were no motherships owned by regional residents.

Catcher Vessel Ownership and Activity. More groundfish catcher vessels are owned by southcentral Alaska region residents than by residents of either the Alaska Peninsula/Aleutian Islands or Kodiak Island regions. Fixed gear catcher vessels predominate, and since 1995, five or fewer trawl vessels have been locally owned. In the fixed gear vessel class, smaller vessel classes predominate by a large margin. This pattern is due, in part, to the relatively small scale of fisheries (and processing capacity) in the southcentral Alaska region, the diversified nature of the fisheries pursued, and the presence of relatively sheltered waters. Ownership of vessels is spread through numerous communities in the region, but (in order of importance) Homer, Anchorage, Cordova, and Seward combined accounted for 63 percent of the total number of regionally owned vessels between 1992 and 2000, and these vessels, in turn, accounted for 73 percent of the ex-vessel value accrued by regionally owned vessels over this same period. Homer accounted for 26 percent of regional value and 32 percent of regional vessels, Anchorage for 19 percent of value and 14 percent of vessels, Cordova for 15 percent of value and 9 percent of vessels, and Seward for 13 percent of value and 8 percent of vessels. No other community accounted for more than 5 percent of value for regionally owned vessels, nor more than 8 percent vessels themselves for the 1992 through 2000 period. Locally owned vessels harvested groundfish in all five Alaska FMP areas, but relatively little effort is directed at the Aleutian Island eastern GOA areas (4 and 6 percent of value of total groundfish retained harvest for these vessels for each of these areas). In 2001, 67 percent of value came from the central GOA, 14 percent came from the western GOA and 10 percent come from the Bering Sea. In 2001, for retained harvest, 49 percent of volume and 44 percent of value came from Pacific cod, while A-R-S-O accounted for 11 percent of volume and 47 percent of value. Pollock, while comprising 32 percent of total groundfish volume only accounted for 6 percent of total value; flatfish was 7 percent of volume and 3 percent of value for that same year.

Harvest Diversity. In recent years, groundfish has accounted for roughly 25 percent of ex-vessel value for groundfish catcher vessels owned by southcentral Alaska region residents. In 1998, halibut was the most important species, accounting for about one-third of total ex-vessel value. Groundfish and salmon account for roughly 25 percent and crab about 15 percent of the total ex-vessel value. Fully 75 percent of all groundfish vessels fished halibut, and 6 out of every 10 fished salmon (NPFMC 2002d).

Processing Diversity. Groundfish has accounted for roughly 10 to 35 percent of ex-vessel value at all southcentral Alaska region inshore plants over the period from 1991 to 1998. In 1998, ex-vessel value was slightly less for groundfish than for halibut (29 and 31 percent, respectively), and quite a bit less important than for salmon (40 percent of ex-vessel value). Virtually no crab is processed at these plants (NPFMC 2002d).

Subsistence. Until May 2000, Homer, Kenai, and Seward were not classified as subsistence communities. Older data suggest that residents of Homer and Kenai consumed between 84 and 94 pounds of subsistence resources per capita per year and zero or less than one pound of subsistence groundfish. No information exists for Seward. Anchorage is not classified as a subsistence community. For Cordova, groundfish are reported as approximately 4 percent (7 pounds per capita) of the total subsistence consumption (179 pounds per person per year). Subsistence use of Steller sea lions in the region is not well documented, but has historically been important for the community of Tatitlek. No other southcentral community is noted to have a regular pattern of harvest for Steller sea lions (see Section 3.9.5).

Tables 3.9-51 through 3.9-56 summarize information on the southcentral Alaska regional engagement with the groundfish fishery through 2001.

Southeast Alaska Region

Overview. The southeast Alaska region, shown in Figure 3.9-12, encompasses a wide range of communities from Yakutat to Ketchikan and Prince of Wales Island. In 2001, the southeast Alaska region accounted for only 0.8 percent by volume and 4.4 percent by value of the groundfish landed and processed in Alaska. In this regard it is much more similar to the southcentral Alaska region than to the Kodiak or Alaska Peninsula/Aleutian Islands regions. For the period of 1992 and 2000, regional processors accounted for 21 percent of the A-R-S-O ("other groundfish") species category, but one percent or less for flatfish, Pacific cod, pollock, and groundfish taken as a whole. The top three southeast Alaska region ports account for almost all of the region's reported processing. In alphabetical order, they are Petersburg, Sitka, and Yakutat. All three communities support diverse fisheries, pursued by fishers participating in multiple fisheries. Of most importance are salmon and halibut. The main groundfish fisheries are rockfish and sablefish.

The regionally important groundfish processing ports of Petersburg, Sitka, and Yakutat each have quite different histories. The economy of Petersburg historically has been based on commercial fishing and timber harvests. "Peter's Burg" was founded by Peter Buschmann, who built the Icy Strait Packing Company cannery, a sawmill, and a dock by 1900. His family's homesteads grew into the community, populated largely by people of Scandinavian origin. By 1920, 600 people lived in Petersburg year-round. During this time, fresh salmon and halibut were packed in glacier ice for shipment. Alaska's first shrimp processor, Alaska Glacier Seafoods, was founded in 1916. A cold storage plant was built in 1926. The cannery has operated continuously since its founding, and is now known as Petersburg Fisheries, a subsidiary of Icicle Seafoods, Inc. Petersburg has developed into one of Alaska's major fishing communities with the largest home-based halibut fleet in Alaska, but landings of shrimp, crab, salmon, herring and other fish are also locally important. Several processors operate cold storage, canneries and custom packing services, employing over 1,100 people during the peak season. The state runs the local Crystal Lake Hatchery, which contributes to the local salmon resource.

Sitka is one of the oldest communities in Alaska. In 1804, the Russian Empire occupied the area, dubbing it New Archangel, until the sale of Alaska in 1867. For sixty-three years Sitka was Russia's major Pacific port with ships calling from many nations, and headquarters of the Russian-American Company—in its heyday the most profitable fur trading company in the world. Furs destined for European and Asian markets were the main export, but salmon, lumber and ice were also exported to Hawaii, Mexico and California. In 1878 one of the first canneries in Alaska was built in Sitka. During the early 1900s, gold mines contributed to its growth. After the U.S. purchased Alaska in 1867, Sitka remained the capital of the Territory until 1906, when the seat of government was moved to Juneau. During World War II, the town was fortified and the U.S. Navy built an air base on Japonski Island across the harbor, with 30,000 military personnel and over 7,000 civilians. The U.S. Coast Guard now maintains the air station and other facilities on the island. The Alaska

Pulp Corporation, the major employer in Sitka, closed in September 1993, forcing nearly 400 persons into unemployment. The city is home to a sizable fishing fleet, a U.S. Coast Guard Air Station, which handles marine search-and-rescue missions, a campus of University of Alaska southeast and the private Sheldon Jackson College. Founded in 1878 the college is the oldest school in Alaska. The economy is diversified with fishing, fish processing, tourism, government, transportation, retail, and health care services. Sitka is a port of call for many cruise ships each summer and fish processing provides seasonal employment. Regional health care services provide approximately 675 jobs. The U.S. Forest Service and U.S. Coast Guard are significant federal employers.

In the 18th and 19th centuries, English, French, Spanish and Russian explorers came to the area around Yakutat. The Russian-American Company built a fort in Yakutat in 1805 to harvest sea otter pelts. In 1884, the Alaska Commercial Company opened a store in Yakutat. By 1886, the black sand beaches in the area were being mined for gold. In 1889 the Swedish Free Mission Church had opened a school and sawmill in the area. A cannery, sawmill, store and railroad were constructed, beginning in 1903 by the Stimson Lumber Company. Most residents moved to the current site of Yakutat to be closer to this cannery, which operated through 1970. During World War II, a large aviation garrison and paved runway were constructed. Troops were withdrawn after the war, but the runway is still in use. The city of Yakutat was formed in 1948, but in 1992, the city was dissolved and a borough was organized. Fishing and subsistence activities are prevalent, and Yakutat's economy depends on fishing, fish processing and government employment. A cold-storage plant is the major private employer, although lodges and fishing charters in the Situk River drainage provide some jobs. Subsistence hunting and fishing activities focus on salmon, trout, shellfish, deer, moose, seals, bears and goats.

Population. In 2000, the region had a total population of 74,820. There is no clear common regional dynamic of community growth in the southeast Alaska region. Among the important processing communities, Petersburg, Yakutat, and Sitka all display different patterns. Southeast Alaska is ethnically mixed, but communities differ markedly in this matter. Furthermore, ethnic diversity is more limited in the southeast Alaska region than in the other Alaska regions considered in this document. The main groups present are Caucasians and Alaska Natives, with other groups present only in relatively small percentages. In Sitka and Petersburg, Caucasians are the great majority of the population (74 and 87 percent, respectively), with Alaska Natives at 21 and 10 percent, respectively. Yakutat is 55 percent Native and 43 percent Caucasian. This overall population composition reflects the general identity or 'character' of each community, as the contemporary demographics of Petersburg highlights its Norwegian fishing history, Sitka its diverse Native/Russian-American history, and Yakutat its Native heritage. Males outnumber females in the region, but no community shows the great differences that are present in the four large groundfish ports of the Alaska Peninsula/Aleutian Islands region.

Employment and Income. Fisheries in general, and groundfish fisheries in particular, are relatively small contributors to southeast Alaska region employment, especially compared to the government, services, and retail sectors. For the three communities of most concern, fishing and fish processing are more important in absolute terms than the 'average' regional community. Still, the groundfish fishery does not provide a large base for regional employment. There are fewer overall economic opportunities in Yakutat compared to the other two communities.

Tax and Revenue. In contrast to some Alaska groundfish communities in other regions, revenues directly resulting from local landings or processing of groundfish are not the basis for local taxation in the southeast

Alaska region. Only Yakutat has a local fish tax, and it applies to salmon rather than to fish in general (and thus does not apply to groundfish). Shared state fisheries taxes do generate revenue for local communities, however. The region's share of the fisheries business tax and fishery resource landing tax amounted to $2,221,926 in 1999, which was 88 percent of such shared revenue for the region.

Inshore Processing. Most southeast Alaska regional groundfish processing occurs in Petersburg, Sitka, and Yakutat. These communities differ in the degree to which they participate in groundfish fisheries and in the mix of species that they exploit. Of greatest significance regionally among groundfish is A-R-S-O, the mixed category that lumps Atka mackerel, rockfish, sablefish, and "other" (non-pollock, non-cod, and non-flatfish) groundfish. Most of the active processors in this region use groundfish only as a supplementary product acquired as bycatch. Rockfish are targeted only sometimes as a primary product, and total volume is still low. The groundfish fishery is important for components of the local fleet, but serves a secondary role for most processors. Southeast Alaska processing plants extract a large return from the fish that they process, with a relatively high utilization rate, compared to the Kodiak and Alaska Peninsula/Aleutian Islands regions. At 74 percent in 1999, utilization was over twice that of the Alaska Peninsula/Aleutian Islands region. Product was valued at $5,665 per ton in 2001, which was 6 times greater than the Alaska Peninsula/Aleutian Islands region and 28 percent higher than the comparable value of the southcentral Alaska region, the next closest region. Total product value was less than one-eighteenth of that of the Alaska Peninsula/Aleutian Islands region, and total retained volume was less than one percent of the volume of that region. For the most part, southeast regional processors tend to concentrate on higher-value, low-volume species such as sablefish and rockfish that are typically sold whole or as headed and gutted product. In 2001, A-R-S-O accounted for 94 percent of the volume and over 99 percent of the value of all groundfish processed in the region. Pacific cod accounted for one percent of the volume and two-tenths of one percent of the value of the groundfish processed in the region; flatfish accounted for the virtual remainder of the regional volume (4 percent), but its value was negligible on a regional basis. In 2000, 13 regional plants reporting groundfish processing operated in Hoonah (1), Juneau (2), Ketchikan (2), Petersburg (2), Pelican (1), Sitka (3), and Yakutat (2).

Processing Ownership. Groundfish processing capacity in the southeast Alaska region owned by residents of the region is concentrated in two sectors, inshore processing plants and longline catcher processors. A substantial percentage (half or more) of regional onshore processing capacity is owned by residents of other areas. It appears that regional pollock and flatfish processing is concentrated primarily in non-locally owned onshore facilities. For regionally owned facilities, groundfish of greatest importance are Pacific cod and the A-R-S-O category (mainly sablefish and rockfish). In 2001, catcher processor wholesale product value was $10.7 million, while shoreplant wholesale product value was $8.0 million. No motherships were owned by regional residents.

Catcher Vessel Ownership and Activity. Ownership patterns for catcher vessels are much the same as for processors, in that they indicate a fishery more dependent on limited quantities of Pacific cod, rockfish, and sablefish pursued with longline gear rather than higher volumes of fish pursued with trawl gear. Most locally owned vessels are relatively small and use longline gear for groundfish (and probably participate in other fisheries). Sitka, Petersburg, Juneau, and Ketchikan are the most important communities in terms of regional vessel ownership. Over the 1992 to 2000 period, Sitka vessels accounted for 30 percent of the value of the groundfish landed by the regionally owned fleet, and for 29 percent of the vessels in that fleet. Petersburg residents accounted for 17 percent of the value and 16 percent of the regionally owned fleet, while Juneau residents owned 13 percent of both value and vessels during this period. Ketchikan resident-owned vessels accounted for 7 percent of the ex-vessel value of landings by regionally owned vessels during 1992 to 2000, and 7 percent of the regionally owned fleet. No other community accounted for more than 4 percent of the regional total for either value or vessels. In 2001, 74 percent of the harvest value came from the eastern GOA, 20 percent from the central GOA, and 3 percent from the western GOA. Approximately 2 and one percent came from the Aleutian Island and the Bering Sea areas, respectively. It is likely that regionally owned vessels harvest and deliver nearly all fish in the A-R-S-O category. In 2001, A-R-S-O accounted for 77 percent of the volume and 97 percent of the value of the harvest, while Pacific cod represented 23 percent of the volume of the total groundfish harvest and 3 percent of the value. The local fleet is a multi-species, multi-gear fleet concentrated in Sitka and Petersburg. For groundfish, the fleet targets sablefish and rockfish. Thus, most of the Pacific cod and pollock processed by the region's shoreplants is harvested and delivered by non-local vessels.

Harvest Diversity. In terms of the fishing annual round, groundfish and non-groundfish species tend to complement each other. The importance of groundfish as a proportion of total ex-vessel value has remained relatively stable, between 30 and 40 percent in recent years. Halibut and salmon each contribute about 25 percent each of the total ex-vessel value. The fleet is relatively diversified, with more than 80 percent of groundfish catcher vessels owned by southeast Alaska region residents participating in the halibut fishery, and about 70 percent of groundfish vessels participating in the salmon fishery. Twenty-five percent of the vessels also fish for crab. About 60 percent participate in fisheries other than halibut, salmon, and crab (NPFMC 2002d).

Processing Diversity. Groundfish has accounted for roughly 20 to 30 percent of ex-vessel value at regional processing facilities over the period from 1991 to 1998, with a gradual increase in value. Groundfish accounts for roughly 29 percent of the value of total plant production, compared to 40 percent for salmon and 20 percent for halibut (NPFMC 2002d).

Subsistence. Subsistence utilization in the regionally important groundfish communities of Petersburg, Sitka, and Yakutat ranges between about 200 and 400 pounds per capita. Groundfish represents 1 to 5 percent of the total subsistence resources consumed. No community in the southeast region is noted to have a regular pattern of harvest for Steller sea lions.

Tables 3.9-57 through 3.9-62 summarize information on the southeast Alaska regional engagement with the groundfish fishery through 2001.

Washington Inland Waters Region

Overview. The Washington inland waters region spans a good portion of northwestern Washington, as illustrated in Figure 3.9-13. The Washington inland waters region as a whole, and especially the greater Seattle area in particular, is engaged in all aspects of the overall North Pacific groundfish fishery, and is particularly heavily involved in the Bering Sea pollock fishery. While this region is distant from the harvest areas, it is the organizational center of much of the industrial activity that comprises the human components of the fishery. Clearly, specific industry sectors based in or linked to Seattle are substantially engaged in or dependent on the North Pacific groundfish fishery. The scale and diversity of the Washington inland waters region makes a socioeconomic assessment directly related to the Alaska groundfish fishery very complex. Seattle's relationship to the Alaska groundfish fishery in general (and the Bering Sea pollock fishery in particular) is paradoxical. When examined from certain perspectives, Seattle is arguably more involved in the Alaska groundfish fishery than any other community. One example is the large absolute number of Seattle jobs in the Alaska groundfish fishery compared to all other communities, whether counted in terms of current residence, community of origin, or community of original hire (setting aside the matter of where the jobs are actually located). On the other hand, when examined from a comparative and relativistic perspective, it could be argued that the fishery is less important or vital for Seattle than for the other communities considered. Using the same example, the total number of Alaska groundfish-fishery-related jobs in greater Seattle compared to the overall number of jobs in Seattle is quite small, in contrast with the same type of comparison for the much smaller Alaska coastal communities. When examined on a community-wide basis, one perspective is that Seattle as a whole is more engaged in, but less dependent upon, the groundfish fishery than all of the other previously mentioned "groundfish communities." An extended groundfish-oriented community profile of Seattle is available elsewhere (NPFMC 2002d).

Regional Economy. As can be expected of a region encompassing a large metropolitan area and containing 3.9 million residents, retail trade and services are extremely important economic sectors and are the two largest economic sectors in terms of employment. Manufacturing employs more people than the state and local government sector, followed by finance, construction, wholesale trade, and transportation. The military, civilian federal, agricultural, and mining sectors are relatively small. The fishing industry has a substantial presence in parts of the Washington inland waters region, but is greatly overshadowed in terms of employment by other industry sectors. During the period 1992-2001, between 3,718 and 5,973 Washington inland waters region residents were employed annually by Alaska groundfish processing sectors. At-sea processor sectors (motherships, trawl catcher processors, and longline catcher processors) are by far the most significant contributors. Due to the methodology employed, in which all employment for these entities accrues to the region of the residence of the owner, regional employment attributable to these sectors is probably overstated in absolute terms. On the other hand, many entities in these sectors have various business relationships with Alaska CDQ groups, which has resulting increased Alaska Native employment (and other sources of revenue and income for Alaska Native entities and individuals) as discussed in detail Section 3.9.4 (as this type of detail, unique to the CDQ program, is not otherwise well captured in the economic model). (This type of interregional employment tie is also seen where other entities have special arrangements to foster Alaska, and especially Alaska Native, hire.) Furthermore, shoreplant employment for Washington inland waters region residents may be understated, because all such employment, except for head office staff, is attributed to the region where the plant is located, and much shoreplant recruiting takes place in the Washington inland waters region (as well as elsewhere in the Pacific Northwest and beyond). Payments to labor for processing employment ranged between $232 million and $323 million during this same period. The Washington inland waters region is also home to a very large proportion of the support service industry related to the groundfish fishery. This activity is captured in the regional baseline figures of a total direct, indirect, and induced labor income of $560 million and employment of about 10,300 FTEs, both of which are easily more than double the analogous figures for the region with the next highest levels of total groundfish associated income and employment (the Alaska Peninsula and Aleutian Islands region).

Processing Ownership. Ownership of Alaska groundfish processing capacity is highly concentrated among owners with residence in the Washington inland waters region. This concentration or overwhelming dominance applies to shoreplants, catcher processors and motherships, and varies in degree between sectors. In 2001, Washington inland waters regionally owned processors reported processing 1.9 million tons of groundfish (97 percent of all Alaskan groundfish processed in that year). In terms of estimated wholesale value, Washington inland waters regionally owned processors processed $1.3 billion worth of groundfish in 2001 (95 percent of the total fishery). In 2001, wholesale product value from catcher processors owned by regional residents was $631.8 million, from shoreplants was $589.7 million, and from motherships was $86.9 million.

Catcher Vessel Ownership. Residents of the Washington inland waters region own catcher vessels in each vessel class that participates in the Alaska groundfish fishery. Numbers in all categories except the smaller vessels (fixed gear vessels less than 60 feet [and especially those less than 32 feet] and trawl vessels less than 60 feet) are large relative to ownership levels in the Alaska regions. Catcher vessels owned by residents of the Washington inland waters region tend to be larger than those owned by residents of Alaska, and this comparison emphasizes the region's concentration of ownership (and participation) in the BSAI groundfish fisheries. This is especially true for trawl vessels in general and large, AFA-eligible trawlers in particular. Catcher vessel ownership in this region is strongly concentrated in Seattle. During the 1992 to 2000 period, Seattle residents owned 45 percent of all regionally owned vessels, and these vessels, in turn, accounted for 65 percent of the total regionally owned vessel value of landings. Outside of Seattle, regional vessel ownership is widely dispersed. Residents of no other community accounted for more than 7 percent of the regionally owned vessels, or more than 5 percent of the regionally owned vessel landings value during this period, and a total of 70 communities have at least one or more vessels in this fleet. Catcher vessels owned by Washington inland waters region residents accounted for 1,238 employees in 2001, with payments to labor of $54 million. Harvest retained by these vessels is heavily concentrated in the Bering Sea FMP area. In 2001, 81 percent of retained harvest ex-vessel value came from the Bering Sea, 7 percent from the central GOA, and between 3 and 5 percent came from each of the eastern GOA, western GOA, and Aleutian Islands regions. In terms of volume of retained harvest, in 2001, 95 percent was pollock, 4 percent Pacific cod, and less than one percent each of A-R-S-O and flatfish. In terms of value, 75 percent derived from pollock, 10 percent from Pacific cod, and 14 percent from A-R-S-O for the same year. Flatfish value was negligible on a regional basis. Within the region in 1999, 43 percent of the vessels representing 67 percent of the volume and 62 percent of the value of the harvest were located in Seattle, and no other community in the Washington inland waters region had residents with ownership of more than 6 percent of the region's vessels or 10 percent of the region's total volume or value of harvest.

Catcher Vessel Diversity. While Alaska groundfish make up the greater part of the ex-vessel value of the harvest by Alaska groundfish catcher vessels owned by Washington inland waters region residents, other fisheries are seasonally important. Although harvest volumes and values vary, over the period 1988-1998, groundfish has amounted to about 60 percent of the ex-vessel value of the harvest for these vessels. In 1998 specifically, groundfish comprised 57 percent of the ex-vessel value of the annual harvest round. About 27 percent was from crab, 11 percent from halibut, and 5 percent from salmon. Among regionally owned Alaska groundfish vessels, 47 percent also fished for halibut, about 28 percent also fished for crab, about 28 percent also fished for salmon, and about 27 percent also fished for other species in Alaska FMP areas (NPFMC 2002d).

Tables 3.9-63 through 3.9-68 summarize information on the Washington inland waters regional engagement with the groundfish fishery through 2001.

Oregon Coast Region

Overview. For the purposes of this analysis, the Oregon coast region is defined as the area encompassing Tillamook County, Lincoln County, and Clatsop County, as illustrated in Figure 3.9-14. This area includes those ports and communities in Oregon with the most direct ties to the Alaska groundfish fishery, and had a population of 104,955 in 2000. The Oregon coast region has long had significant involvement in the Alaska groundfish fishery, from the development of the joint venture fishery through the present. The most visible aspect of this participation is the fleet of catcher vessels based in Oregon that participate in a variety of fisheries across the various Alaska regions. Though Oregon coast region residents own fewer catcher vessels than the residents of any of the other regions profiled (35 in 2001), these vessels harvested more North Pacific groundfish by volume than the vessels from any other region except the Washington inland waters region. In value of harvest, the Oregon coast region ranked far behind the Washington inland waters region but were very close to the Kodiak Island and Alaska southeast regions, but well ahead of the other two

Alaska Regions. This activity is highly concentrated in the community of Newport. For the period 1988-1998, Newport accounted for 72 percent of the total harvest volume and 67 percent of the total harvest value of Alaska groundfish by Oregon coast region owned vessels. No other regional port accounted for eight percent or more of the regional total. Oregon coast region ports are important for local fisheries as well as the distant Alaska fisheries. Most of the fish landed in Oregon is delivered to Astoria or Newport, the county seats of Clatsop and Lincoln counties, respectively. Onshore facilities to process whiting (from Pacific Northwest waters) are concentrated in Newport.

Regional Economy. The Oregon coast region economy is relatively diversified and relies heavily on the retail, service, and government sectors. Fish and timber are also significant components of the multi-industry "agriculture, forestry, fishing, and other" and "manufacturing" categories. Manufacturing, as measured by earnings, is similar in magnitude to the retail trade, service, and government sectors. As an aggregated category, however, it is not clear how much of this magnitude is due to fish-related activity. It is almost certain that none of this manufacturing activity is related to Alaska groundfish. There are no onshore plants in this region that process Alaska groundfish, and only one regionally owned longline catcher processor in the years 1992-1994 (none at present). Thus, it would appear that none of this region's processing employment is attributable to Alaska groundfish.

Processing Ownership. There is no current Oregon coast regional ownership of Alaska groundfish processing capacity, and such ownership has been limited in the past.

Catcher Vessel Ownership. Catcher vessel ownership of Alaska groundfish vessels in this region is highly concentrated in Newport. Residents of Newport owned 44 percent of the groundfish vessels owned by the residents of the region over the period 1992 to 2000, and these vessels, in turn, accounted for 66 percent of the value of all groundfish landings by regionally owned vessels. No other community in the region accounted for more than 14 percent of regionally owned vessels, and none accounted for more than 6 percent of the total value of landings made by regionally owned vessels. On all measures, Newport is clearly the dominant Oregon coast region community in terms of engagement with North Pacific groundfish fisheries in general, and the Bering Sea pollock fishery in particular. Of the vessels owned by Oregon coast region residents that participate in the Alaska groundfish fishery, trawlers predominate, followed by pot vessels, longliners, and miscellaneous 'other' vessels in about equal numbers. Trawlers are the most active and productive component of this fleet. They are based primarily in Newport or the nearby area. In employment related to the Alaska groundfish fishery on regionally owned vessels, trawlers supplied the bulk of opportunities in 1998 (about 67 percent of the total). Pot vessels provided 16 percent and longliners about 18 percent. In 2001, retained harvest ex-vessel value derived 64 percent from the Bering Sea, 33 percent from the central GOA, and approximately one percent each from the eastern GOA and the western GOA. Value from the Aleutian Islands was negligible on a regional basis. On a species basis, in 2001 pollock accounted for 83 percent of volume and 62 percent of value of regionally owned vessels, while Pacific cod accounted for 11 percent of volume and 29 percent of value. A-R-S-O and flatfish accounted for about 3 percent of volume each, and approximately 7 percent and 2 percent of value, respectively.

Catcher Vessel Diversity. Catcher vessels owned by Oregon coast region residents have a specific dependence on the Alaska groundfish fishery, but generally participate in other Alaska fisheries. As a class, these vessels derive a clear majority of their Alaska ex-vessel value from groundfish activity. In 1998 groundfish accounted for almost two-thirds of the Alaska ex-vessel value accruing to this fleet. Crab make up about one-quarter of the ex-vessel value. About half of the groundfish vessels also participate in the halibut fishery, and about one of five participate in the salmon and crab fisheries. About one-third of the Oregon-owned groundfish catcher vessel fleet participates in Alaska fisheries other than groundfish, halibut, crab, or salmon (NPFMC 2002d).

Tables 3.9-69 through 3.9-74 summarize information on Oregon coast regional engagement with the groundfish fishery through 2001.

3.9.4 Community Development Quota Program

3.9.4.1 Community Development Quota Overview

The CDQ program region differs from the Alaska and Pacific Northwest regions and communities profiled by the nature of its engagement with and dependence upon the Alaska groundfish fisheries. The communities within this region primarily engage in the fishery through the auspices of the program rather than through historic participation in the fishery, so the focus of this section is the program itself rather than a characterization of the many communities in the region.

CDQ Establishment and Purpose

In 1992 the CDQ program was developed to facilitate the participation of BSAI community residents in the fisheries off their shores, as a means to develop a local community infrastructure and increase general community and individual economic and social well-being. The CDQ program was granted in perpetuity through the MSA authorized by the U.S. Congress in 1996. The State of Alaska is responsible for the administration and monitoring of the program. The state administers the program jointly through the ADCED (the lead agency) and the ADF&G.

The CDQ program is a federal program that allocates a portion of the TAC (or GHL, as appropriate) for federally managed BSAI species to eligible communities in western Alaska. Originally involving only the pollock fishery, the program has in recent years expanded to become multi-species in nature. The CDQ program includes such species as pollock, Pacific cod, Atka mackerel, flatfish, sablefish, and other groundfish, along with halibut, and crab. Currently, the CDQ program is allocating portions of the groundfish fishery that range from 10 percent for pollock to 7.5 percent for most other species. The CDQ program has contributed to infrastructure development projects within the region as well as loan programs and investment opportunities for local fishermen. In recent years the program has provided more than 1,000 jobs annually for region residents and yearly wages have exceeded $8 million.

Sixty-five Alaska Native Claims Settlement Act (ANCSA) villages near the Bering Sea have established eligibility under federal and state regulations, and these villages formed a total of six non-profit regional groups through which they participate in the program. The State of Alaska and the NOAA Fisheries periodically allocate percentages of each species, based upon its evaluation of the Community Development Plans submitted by individual CDQ groups. The six CDQ groups are: Aleutian Pribilof Island Community Development Association (APICDA); Bristol Bay Economic Development Corporation (BBEDC); Central Bering Sea Fishermen's Association (CBSFA); Coastal Villages Region Fund (CVRF); Norton Sound Economic Development Corporation (NSEDC); and Yukon Delta Fisheries Development Association (YDFDA). The groups have established partnerships with fishing corporations. Local hire and reinvestment of proceeds in fishery development projects are a required part of the program.

In addition to each CDQ group filing a management plan with the state when they apply for their requested share of the overall CDQ allocation, they also file quarterly reports that detail their activities and track their progress in relation to the goals they have set in their management plans. The state can adjust the percentages awarded to each group from one allocation period to the next, based on the state's evaluation of various factors documented need, adequacy of the proposed plans to use the requested allocation to meet those needs, past performance, and perhaps other needs. Reports summarizing and/or reviewing the activities of the CDQ program have been prepared for several purposes (NPFMC 1998d, NRC 1999, ADCED 2001, NMFS 2001b), and the existing conditions portion of this regional profile is largely abstracted from the most recent of two of these documents, the Steller Sea Lion Protection Measures SEIS (NMFS 2001b) and the BSAI Crab Rationalization Program Alternatives analysis (NPFMC 2002d).

CDQ Performance Overview

Since its inception, the CDQ program has contributed to fisheries infrastructure development. According to the ADCED, during the first decade of the program approximately 9,000 jobs have been created with wages totaling more than $60 million. As annual royalties grow, the revenue streams have permitted development and accumulation of considerable savings and investment capital within the CDQ groups, for use in a variety of future investments. Data suggest that CDQ groups, when taken as a whole, have retained almost half of their gross revenues in some form of equity, whether infrastructure projects, vessel ownership, or cash. Since 1992, the CDQ group's equity growth has averaged 37 percent per annum, or slightly more than $10 million each year. It has been reported by the State of Alaska that, by 1997, CDQ groups had more than 200 people employed in the pollock fishing industry alone, 846 individuals in CDQ training and a total expenditure by CDQ groups of $1,041,309. From 1993 to 1997, CDQ programs generated approximately 1,000 employment positions a year, with associated annual total wages of about $5 million to $8 million. Management and administration accounted for 6 percent of the jobs and 23 percent of the wages. This level of direct engagement in the fishery can only enhance the control communities may exercise over the joint economic activity. CDQ partnerships bring training and employment within the partners' fishing operations and other development benefits, as well as providing vessel loan programs; education, and other CDQ-related benefits. CDQ groups and their residents are able to learn first hand how the industry functions. They are better able to take part in decisions that directly affect business operations and, thus, profitability. A brief overview of the past/present effects of actions and events on CDQ is presented in Table 3.9-127.

CDQ Communities

CDQ communities are remote, isolated settlements with few commercially valuable natural assets with which to develop and sustain a viable, diversified economic base. As a result, economic opportunities have been few, unemployment rates have been chronically high, and communities (and the region) have been economically depressed. CDQ communities border some of the richest fishing grounds in the world, but they have largely been unable to exploit this proximity. The full Americanization of the BSAI fisheries occurred relatively quickly. However, the very high capital investment required to compete in these fisheries precluded small communities from participating in their development. The CDQ program serves to ameliorate some of these circumstances by extending an opportunity to qualifying communities to directly benefit from the productive harvest and use of these publicly owned resources.

As shown in Table 3.9-75, the six CDQ groups contain between one and 21 communities in each group. As seen in this same table, CDQ communities are predominantly Alaska Native villages, with Alaska Native residents comprising 86.8 percent of the combined total population of all CDQ communities. Table 3.9-76 summarizes the six CDQ groups in terms of their membership, approximate populations, and office locations. The total population of the 65 CDQ communities in 2000 was estimated to be 27,073. However, this population figure may include a substantial number of individuals who are not year-round residents. The administrative offices of CDQ groups tend to be located in regional hub communities, near government or industry partner offices, and/or near community or other ongoing projects.

The CDQ communities are geographically dispersed, extending westward to Atka, on the Aleutian chain, and northward along the Bering coast to the village of Wales, near the Arctic Circle, as shown in Figure 3.9-15. According to Sec. 305(i)(1)(B) of the MSA, to be eligible to participate in the CDQ program a community must:

- Be located within 50 nm from the baseline from which the breadth of the territorial sea is measured along the Bering Sea coast from the Bering Strait to the western most of the Aleutian Islands, or on an island within the Bering Sea.

- Not be located on the GOA coast of the North Pacific Ocean.

- Meet criteria developed by the Governor of Alaska, approved by the Secretary, and published in the Federal Register.

- Be certified by the Secretary of the Interior pursuant to the Alaska Native Claims Settlement Act (43 USC 1601 et seq.) to be a Native village.

- Consist of residents who conduct more than one-half of their current commercial or subsistence fishing effort in the waters of the Bering Sea or waters surrounding the Aleutian Islands.

- Not have previously developed harvesting or processing capability sufficient to support substantial participation in the groundfish fisheries in the Bering Sea, unless the community can show that the benefits from an approved Community Development Plan would be the only way for the community to realize a return from previous investments.

CDQ Allocations and Harvest

In 1991, NPFMC recommended to the Secretary of Commerce that a fishery CDQ program be created. As initially envisioned, the CDQ program set aside 7.5 percent of the BSAI annual TAC for Alaska pollock for allocation to qualifying rural Alaskan communities. The program was initially proposed to run for a period of 4 years, lasting from 1992 through 1995, but was subsequently extended for an additional 3 years, carrying it through 1998. In subsequent actions, a CDQ program for BSAI halibut and sablefish followed and was implemented in 1995. A CDQ program for BSAI crab was initiated in 1998, and the multi-species groundfish CDQ program was implemented in late 1998. The NPFMC also extended the pollock CDQ allocations permanently by including pollock in the multi-species groundfish CDQ program. The AFA of 1998 increased the pollock allocation for the CDQ program to 10 percent of the annual TAC.

Today, under the current regulations all groundfish and prohibited species caught by vessels fishing for CDQ groups accrue against the CDQ allocations and none accrue against the non-CDQ apportionment of the TAC or prohibited species catch limits. The CDQ groups are required to manage their catch to stay within all of their CDQ allocations. Each CDQ group is allocated a share of the suite of the species subject to CDQ allocations, although not all groups receive allocations of all species or regional populations. The CDQ allocations recommended by the state for 2001-2002 are displayed in Table 3.9-77. In 2001, these percentages represented approximately 185,000 metric tons of groundfish (Table 3.9-78).

Additional details on the harvest amount and wholesale value of the groundfish CDQ allocations are presented in Table 3.9-79 and Table 3.9-80. As noted above, prior to implementation of the multi-species groundfish CDQ program in 1998, the only groundfish species for which CDQ allocations existed were pollock and sablefish. However, other groundfish species were harvested incidentally. After 1998, CDQ allocations became available for all groundfish species, and the harvest of some species such as Pacific cod and Atka mackerel increased.

As shown in Table 3.9-79, pollock dominates the volume of groundfish landings over the years provided, varying between approximately 98 percent of volume each year from 1993-1997 before dropping to around 82 percent by 1999-2000. The current dominant economic importance of pollock and Pacific cod to the CDQ program among the various groundfish species may be seen in Table 3.9-80. As shown, in 2000, pollock and Pacific cod when added together account for $107.67 million (or 96.3 percent) of the $111.80 million total wholesale value of CDQ allocations for all groundfish species for that year. Further, as shown in that same table, wholesale value of pollock value was almost six times greater than that of Pacific cod, and the wholesale value of Pacific cod, in turn, was almost eight times greater than Atka mackerel, the next most valuable groundfish species for that same year (Table 3.9-80).

Table 3.9-81 shows the seasonal variability in the value of groundfish catches. The bimodal distribution in the groundfish fishery is a function of the winter/spring and fall seasons, the timing of which has changed somewhat in the last few years. Fishing is usually more lucrative in the early portion of the year because of the relatively high value of pollock roe.

3.9.4.2 Community Development Quota Group Profiles

The six CDQ groups are made up of regional alliances of Alaska Native villages on or near the Bering Sea. The CDQ groups have emerged through the establishment of a management structure and the formulation of a detailed business plan. Each group is a CDQ corporation with a board of directors made up of representatives from the communities, executive officers, and professional staff. To facilitate interaction with industry partners and government oversight agencies, most of the CDQ groups established headquarters in Juneau, Anchorage, or Seattle.

The communities are required to invest profits in fishery-related assets such as fishing vessels, processing plants, and port facilities. Contractual arrangements are not typically limited to payment of royalties per ton of quota but also include provisions for training and employment of residents of CDQ villages, scholarship programs, and a variety of other considerations. Some of the groups have used revenue sharing agreements that allow the royalty to vary with product mix and first wholesale prices. Increasingly CDQ groups are taking equity positions in existing commercial harvesting and processing operations, which then use their CDQ allocations. Individual groups have followed a variety of strategies for using their CDQ allocations, and for the investment or other use of the proceeds. Most have formed stable partnerships with established fishing industry participants and have, or are seeking to, invest in the fishery. The following CDQ group profiles are adapted from those contained within the inshore/offshore pollock allocation amendment to the Bering Sea groundfish FMP as updated in subsequent NMFS/NPFMC documents. The dominant importance of pollock and Pacific cod to the CDQ program can be seen in the fact that together they accounted for a full 90 percent of all CDQ royalties for all species (including non-groundfish species) included in the program in 2000.[21] It is important to note, however, as shown in subsequent sections, individual fisheries wholesale value and species royalty rankings do not necessarily directly correspond to levels of employment.

Aleutian Pribilof Island Community Development Association

The communities represented by APICDA are relatively small and located adjacent to the BSAI fishing grounds. As detailed elsewhere (Section 3.9.3), the Aleutian Islands/Alaska Peninsula region is the center of the BSAI groundfish fishery, with Unalaska, Akutan, King Cove, and Sand Point being its primary ports. While all of these communities are within the geographic span of APICDA, only Akutan is a CDQ group member. Unalaska, the largest community in the region and the hub of the Bering Sea fishery, is not a CDQ community but is an *ex officio* member of APICDA and has a non-voting member of the APICDA Board of Directors. Unalaska residents are eligible for APICDA training and education opportunities, many of which are located in Unalaska to take advantage of proximity to the industry, rather than in the other member villages. (King Cove and Sand Point were not eligible for CDQ membership because they are located outside the overall CDQ eligible region [they are located on the GOA], and because they were the sites of substantial existing commercial fisheries development, as detailed elsewhere [Sections 3.9.3 and 3.9.6].).

Currently, APICDA is allocated 14 percent of the pollock and 16 percent of the Pacific cod CDQ allocations, which are shared among its inshore and offshore partners in such a way as to maximize the benefit to APICDA. Because of proximity to the fishing grounds and year-round access to ice-free waters, APICDA's focus is primarily on community development and employment opportunities that occur in or near each community. These villages do not have the same need for factory trawler employment, as do residents of many other CDQ communities, who do not have the same opportunity for local fishery development. This

[21] As of 2003 a preferred alternative amendment to the BSAI Crab FMP is being analyzed that would increase CDQ allocations for crab from 7.5 percent to 10 percent and bring more species under the program umbrella. Given the state of crab stocks, however, and the relative total values of the fisheries involved, whether or not this amendment is approved will notchange the dominant nature of groundfish within the overall CDQ program.

is reflected in APICDA's employment statistics, which show one of the highest total employment levels, but a relatively low number of pollock processing jobs. APICDA also has a wide variety of investments in different sectors of the fishery, as well as in tourism, and other areas.

APICDA has employment provisions with both its inshore and offshore partners and has invested, both with them and individually, in a number of fisheries-based development projects in several of its villages, creating a variety of employment opportunities. Though the group has placed residents with all three pollock sectors, APICDA residents in general have shown a preference for non-pollock employment, with the single largest source being renovation and operation of a halibut processing plant in Atka.

Bristol Bay Economic Development Corporation

BBEDC represents 17 villages distributed around the circumference of Bristol Bay, including Dillingham, the second-largest CDQ community with approximately 2,200 residents and the location of BBEDC's home office. BBEDC is currently allocated 21 percent of the pollock and 20 percent of the Pacific cod CDQ harvest.

To date, BBEDC has focused its community development efforts primarily on creating offshore employment opportunities, and it has employed more village residents in pollock processing jobs than any other group. The group changed from one offshore partner to another before the 1996 harvest. BBEDC's current partner is said to hire approximately 20 percent of its crew from CDQ villages.

BBEDC has also invested in a variety of fishing vessels, including part-interest in two pollock catcher processors and a freezer longliner. However, BBEDC also has a program to evaluate investments in regional infrastructure. The group also has active vocational training and internship programs with its offshore partner, and provides internship opportunities with out-of-region and local businesses to develop administrative and other specialized skills. BBEDC is also helping to promote workforce readiness skills through the four Bristol Bay school districts.

Central Bering Sea Fisherman's Association

CBSFA is unusual among CDQ groups in that it represents a single community, St. Paul in the Pribilof Islands. St. Paul is strategically located to serve the Bering Sea fishing industry. As a result, CBSFA has focused attention on working with other island entities to improve St. Paul's harbor facility and on expanding the island's small boat fleet. The group also operates a revolving loan program to provide boat and gear loans to resident fishermen. CBSFA has primarily invested in crab vessels and has a small ownership interest in American Seafoods. CBSFA has been working with industry partners to explore the possibility of developing a multi-species processing facility in St. Paul. Currently the CBSFA is managing 4 percent of the pollock harvest and 10 percent of the Pacific cod harvest.

Reflecting the focus of St. Paul residents on developing local fishing ventures and infrastructure, CBSFA has not seen much demand among residents for off-island processing jobs, either offshore or inshore. The group is partnered with a large offshore company and would like to build on the benefits of product offloads at St. Paul harbor and the attendant support services its residents can provide. Currently, CBSFA receives 4 percent of the pollock and 10 percent of the Pacific cod CDQ harvest.

Coastal Villages Region Fund

CVRF currently manages 24 percent of the pollock and 17 percent of the cod CDQ harvest for its 21 member villages. The villages are located along the coast between the southern end of Kuskokwim Bay and Scammon Bay, including Nunivak Island. This remote area is poorly located to engage in the current Bering Sea fisheries. Furthermore, its residents, for the most part, have had little experience with commercial enterprise. CVRF has focused on helping residents adjust to working conditions outside of the immediate area and employs a training coordinator who actively recruits residents for employment and internship opportunities. CVRF sees a distinct employment advantage in the offshore sector for its residents, primarily because of shorter time commitments and higher wages. However, the group currently has both inshore and offshore partners. has purchased 22.5 percent of American Seafoods, the largest offshore fishing company in the Bering Sea. This investment includes seven factory trawlers.

CVRF provides employment to fishermen through its nearshore CDQ halibut fishery and on a longline vessel that harvests CDQ sablefish. The group continues to be interested in establishing salmon processing facilities both on the Kuskokwim and elsewhere in the region, as well as halibut processing facilities.

Norton Sound Economic Development Corporation

Fifteen villages make up the region represented by NSEDC, which ranges from St. Michael to Diomede. The geographic expanse and diversity of interests among NSEDC's communities are challenging, as are the hurdles to developing local fisheries in this remote area that is ice-bound in winter.

Nevertheless, NSEDC has actively pursued both local fisheries and Bering Sea pollock investment strategies. The group has purchased approximately 50 percent of its offshore processor partner, Glacier Fish Company, including two catcher processors and a seafood marketing subsidiary. Together with the Glacier Fish Company, NSEDC owns the Norton Sound Fish Company, which operates a longline vessel and employs significant numbers of region residents. The group also owns independently two tender vessels specially built for the Norton Sound region.

NSEDC has developed or planned fisheries development projects in several villages, including Norton Sound Crab Company in Nome and commercial halibut operations on St. Lawrence Island. Glacier Fish Company hires residents of the Bering Sea region on a preferential basis for CDQ fishery operations. NSEDC operates an employment and training office in Unalakleet. This CDQ group currently receives 23 percent of the pollock and 18 percent of the Pacific cod CDQ allocations.

Yukon Delta Fisheries Development Association

YDFDA represents five communities. The group's emphasis has been on creating employment opportunities in the Bering Sea fishery through its mothership partner and through other pollock processors, both inshore and offshore. Another area of focus has been on a comprehensive training program that includes a combination trawl/pot/longline vessel and a 47-foot longline crab vessel. YDFDA has received steadily increasing CDQ pollock allocations and currently receives 14 percent of the pollock and 19 percent of the cod CDQ allocations. YDFDA faces the challenges of representing a region with few natural resources to develop, long distances to most viable fisheries, and relatively undeveloped human resources with respect to active participation in a commercial economy setting. While the group places residents in jobs with all three sectors, it indicates that offshore and mothership employment are most useful for its residents. The group's CDQ royalties fund a variety of training activities encompassing technical and office skills.

3.9.4.3 Economic Impacts of the Community Development Quota Program

Revenue Generation

To be eligible to participate in the CDQ program, CDQ communities could have no current or historical linkage to the fisheries in question at the time of the program's implementation. Therefore, it has been necessary (with the exception of some of the halibut CDQs) for each CDQ group to enter into a relationship with one or more of the large commercial fishing companies that participate in the fishery. The CDQ community brings the asset of preferential access to the fish while the partnering firm brings the harvesting/processing capacity and experience in the fishery. The nature of these relationships differs from group to group. In every case, the CDQ community receives royalty payments on apportioned catch shares. Some of the agreements also provide for training and employment of CDQ community members within the partners' fishing operations, as well as other community development benefits. Each of the six groups negotiates a specific price per metric ton for the use of the apportioned CDQ shares, or a base price plus some form of profit sharing.

Based upon reports of consistently high bid-prices for CDQ shares (see, for example, testimony before NPFMC on the impacts of Inshore/Offshore III on the pollock CDQ program), the partnering companies also apparently receive substantial benefits from these CDQ relationships. These benefits may include preferred access to the resource, resulting in better yields and more valuable product forms (e.g., roe), and the more efficient use of capacity. The positive aspects of the CDQ pollock fishery probably contributed to the successful implementation of the offshore cooperative management system.

For the years 1992 through 1998, pollock CDQ royalties fluctuated between $17 million and $20 million per year (Figure 3.9-15). Royalty income rose substantially in 1999 and 2000 because both the TAC and lease price of pollock CDQ shares increased. Stronger overseas markets for groundfish products and a shift by processors to higher value products were among the reasons for the increase in CDQ lease values. In 2000, the CDQ groups received over $33 million in pollock CDQ royalties.

While pollock still dominates the program in terms of total royalties, royalties from the multi-species program provided an additional $7.3 million to the CDQ groups in 2000 (ADCED 2001). Of the 2000 total of approximately $40.5 million for all species, pollock accounted for approximately 82 percent of all royalties, while all other species combined represented approximately 18 percent of total royalties. The percentage of the total 2000 royalties generated by each non-pollock species were as follows: Pacific cod - 8 percent; opilio crab - 5 percent; Bristol Bay red king crab - 3 percent; and other species, including sablefish, Atka mackerel, halibut and turbot - 2 percent. The non-pollock royalty proportions have changed somewhat in recent years, particularly with the BSAI crab fisheries phasing into the program beginning in 1998.

Asset Accumulation

The revenue stream from the lease of CDQ allocations has permitted the development of considerable savings within the CDQ groups. These savings provide important capital for making investments, and asset accumulation by CDQ communities is one empirical measure of the performance of the program. Amassment of equity interest in real assets represents a clear community development strategy. Data suggest that CDQ groups, when taken as a whole, have retained almost half of their gross revenues in some form of equity, whether vessel ownership, processing facilities, marketable securities, loan portfolios, and IFQ holdings. The value of CDQ assets in aggregate increased from $1.5 million in 1992 to over $157 million in 2000 (ADCED 2001).

Another benefit of capital asset acquisitions and venturing with industry participants is the enhanced control communities may exercise over the joint economic activity. As members in fishing companies with ownership interest, the CDQ groups are better able to take part in decisions that directly impact business operations and, thus, profitability. Also, the opportunity for technology transfer and hands-on experience (whether operational or managerial) occurs from the industry partner to the CDQ group. CDQ groups and their residents are able to learn first-hand how the industry functions. This increases the likelihood of local control as CDQ residents, who have spent time learning from established industry partners, may one day be in control of their own operations and be able to operate independent of the CDQ program. In the interim, expanded employment opportunities, made available through vessel acquisition and partnering with established industry members, increase the sharing of benefits that accrue from the CDQ activities.

Increasingly, CDQ groups are using their CDQs to leverage capital investment in harvesting/processing capacity. Acquisition of ownership interest in commercial fishing operations and other fisheries-related enterprises is one important means of directly adding to a CDQ group's economic sustainability, consistent with the program's mandate. Current equity acquisitions in vessels are presented in Table 3.9-82. The table also specifies, if applicable, the catcher vessel class or catcher processor class in which each vessel has been included for the sector analysis.

All six CDQ groups have acquired ownership interests in the offshore pollock processing sector. In addition, APICDA and NSEDC have invested in inshore processing plants, some of which process groundfish (Table 3.9-83). These inshore plants include both shorebased and floating processing facilities.

In most of the processing ventures in which CDQ groups have invested, the groups are minority owners. However, the revenues derived from these investments may be substantial. An overview of the relative economic importance of investments in the offshore and inshore groundfish processing sector may be acquired by examining the historical quantity and value of groundfish processed by catcher processors and inshore plants in which CDQ groups currently have an equity interest (Table 3.9-84 and Table 3.9-85). The groundfish processed by these enterprises accounted for about 14 percent of the total tonnage and 15 percent of the total wholesale value of groundfish processed in the Alaska fishery in 1999 and 2000. Overall, it is estimated that the ownership shares of CDQ groups represents approximately 27 percent of the total groundfish revenues of these enterprises based on a weighted average of wholesale product revenue.

The most important component that CDQ groups bring into investments in the offshore groundfish processing sector is quota (ADCED 2001). As shown in Table 3.9-84 and Table 3.9-85, CDQ catch accounts for a substantial portion of the total amount and value of groundfish processed by the companies in which the groups have invested.

The vessel list in Table 3.9-82 shows that CDQ groups have also invested in catcher vessels harvesting groundfish and other species. An overview of the relative economic importance of investments in these enterprises may be obtained by examining the historical quantity and value of groundfish caught by catcher vessels in which CDQ groups currently have an equity interest (Table 3.9-86). The groundfish harvested by these fishing operations accounted for about two percent of the total tonnage and three percent of the total ex-vessel value of groundfish harvested in the Alaska fishery in 1999 and 2000. Overall, it is estimated that the ownership shares of CDQ groups represents approximately 50 percent of the total groundfish revenues of these enterprises based on a weighted average of ex-vessel revenue.

Employment and Income

At the time of the 1990 U.S. Census, all the communities in rural, western Alaska were experiencing relatively high levels of unemployment, ranging from 9 percent in the Bristol Bay area to 31 percent in the Yukon Delta area (ADCED 2001). While these high unemployment rates partly reflect the seasonality of employment opportunities and the timing of the census in April, they also may show the effects of limited employment opportunities. All of the communities in the CDQ areas had median incomes that were lower than the state median income (ADCED 2001). The median income of the Central Bering Sea area and the Bristol Bay area was less than ten percent below the state level, but in the Yukon Delta area and the Aleutian Pribilof area the median income was only slightly greater than half the state level (ADCED 2001). The poverty rates in all the CDQ areas except the Central Bering Sea were at least twice the state rate of seven percent.

Employment opportunities have been one of the most tangible direct effects of the CDQ program for many western Alaska village residents. Indeed, the CDQ program has had some success in securing career track employment for many residents of qualifying communities, and has opened opportunities for non-CDQ Alaskan residents, as well. Jobs generated by the CDQ program included work aboard harvesting vessels, internships with the partner company or government agencies, work at processing plants, and administrative positions. As noted in Section 3.9.3, due to the unique nature of the CDQ program, much of this employment (as well as other groundfish related economic activity, including other income and revenue) is not well captured in the regional analysis of the groundfish fishery (and is therefore presented in detail in this section).

Table 3.9-87 summarizes the total annual CDQ employment and wages presented in quarterly reports. The CDQ program has created an excess of $8 million in wages annually since 1998. As shown in Table 3.9-87, non-pollock fisheries, although accounting for a relatively small proportion of total CDQ fisheries value or royalties, account for a significant majority (62.5 percent) of CDQ employment and almost half (47.6 percent) of total wages earned in 2000.

From 1993 through 2000, CDQ management and administration accounted for about 6 percent of the jobs and 24 percent of the wages. Pollock harvesting and processing accounted for 24 percent of the jobs and 26 percent of the wages. Other fisheries, which include halibut, salmon, sablefish, herring and crab related employment, accounted for 51 percent of the jobs and 34 percent of the wages. Finally, other employment, including internships, accounted for 18 percent of the jobs and 15 percent of the wages.

An overview of the relative impacts of the CDQ program may be gained by comparing income generated by the CDQ program with the total income in CDQ communities. Adjusted gross income data by zip code are available from the Internal Revenue Service for two years during the period that the CDQ program has existed - 1997 and 1998. The total adjusted gross income for all CDQ communities in these two years was $242,200,000 and $252,600,000, respectively. In addition, an estimate of adjusted gross income can be derived for 1999, the most recent year for which personal income data are available from the Regional Economic Information System of the U.S. Bureau of Economic Analysis for Alaska boroughs and census areas. In 1997 and 1998, adjusted gross income in CDQ communities was approximately 27.5 percent of the total personal income in the boroughs and census areas in which CDQ communities are located. Applying this percent to the 1999 Regional Economic Information System personal income data yields an estimated adjusted gross income of $259,800,000 in CDQ communities for that year.

Table 3.9-88 shows CDQ wages in 1997 and 1998 as reported to ADCED and total adjusted gross income for all CDQ communities as estimated above. CDQ-related income accounted for about 4.1 percent of the total income in CDQ communities by 1999.

While this analysis is based on the best information available, it yields only a rough approximation of the contribution of CDQ wages to regional income. As noted above, CDQ management and administration account for nearly one-fourth of CDQ wages. Many of the individuals in administrative positions work and reside in non-CDQ communities (Table 3.9-76). By including the wages of those individuals, this analysis overestimates the contribution of CDQ wages to the total income of CDQ communities. Some level of error may also have been introduced in the analysis because Internal Revenue Service income data are reported by zip code. The incomes of a number of small non-CDQ communities that share a zip cope with CDQ communities were included in the figure for total adjusted gross income. However, given the small size of the non-CDQ communities included, it is unlikely that the introduced error appreciably changed the analysis results. Similarly, the incomes of certain CDQ communities (Kongiganak, Napaskiak, Newtok and Oscarville) were omitted from the total adjusted gross income figure because their zip code overlapped with the relatively large non-CDQ community of Bethel. Again, the introduced error is likely insignificant due to the small size of the CDQ communities omitted.

Adjusted gross income data obtained from the Internal Revenue Service for 1997 and 1998 can also be used to examine the contribution of CDQ wages of each CDQ group (Table 3.9-89). Among the factors that account for the differences across groups is the presence or absence of communities with comparatively large populations and diverse economies. For example, the CDQ communities of King Salmon and Dillingham in the BBEDC region and Nome in the NSEDC region contributed about half of the total adjusted gross income for all CDQ communities in 1997 and 1998. The higher level of economic activity in these towns results in higher per capita incomes and reduces the relative importance of CDQ wages.

Indirect Employment and Income Effects

Some of the income earned in CDQ jobs, as well as spending for supplies and services in support of CDQ projects, passes through local merchants, service providers, and others before leaking out of the region in exchange for imports. The additional employment and income generated in this way is referred to as indirect economic impacts. In an area such as western Alaska, where very few goods and services are provided locally, money leaks out of the region relatively quickly. Nevertheless, every extra contribution to jobs and income helps, and these additional economic impacts of the CDQ program should not be overlooked.

Training and Education

Training of CDQ community residents has been a primary objective for all the CDQ groups from the outset of the program and has been promoted as an essential means to a sustainable locally based fishery economy. Each CDQ group provides training for their residents, based not only upon the individual needs of the trainee, but upon the overall needs of the community.

Training programs span the range of educational opportunities, from vocational and technical training, to support for higher education at college and university levels. CDQ groups have spent nearly $8 million directly on training expenditures involving over 7,000 residents since 1993 (ADCED 2001). These investments are wholly dependent upon the revenues generated by the CDQ apportionments and, therefore, are another empirical measure of benefits deriving from the groundfish fisheries of the BSAI management area.

3.9.5 Subsistence

The subsistence use of natural resources by Alaska Native peoples represents a set of relationships to the local environment and a continuity of use that stretches back to prehistoric times, despite changes in technology and society. Subsistence activities are a central element of contemporary village life that often involve myriad social and cultural elements and whose importance ranges from being a basic component of physical sustenance to a part of relationships involved with a sense of group identity and individual feelings of well-being. Subsistence is also important to many of Alaska's non-Native residents, despite greater or lesser differences between groups in the specific cultural context of subsistence. For more than a few non-Native Alaska residents, a lifestyle that includes subsistence pursuits as a key element (or at least an opportunity) influences such basic life decisions as whether or not to move to, or remain in, rural Alaska. The importance of subsistence crosses social and cultural boundaries, and different subsistence pursuits may feel the impact of commercial use of the same or interrelated natural resources. As noted in the following subsections, the commercial groundfish fishery overlaps with a number subsistence related activities in a variety of ways.

3.9.5.1 Introduction

This section provides information on existing subsistence conditions relevant to the subsequent impact analysis of the proposed alternatives. This section is divided into three main discussions:

Regional Summaries of the Use of Groundfish and Other Subsistence Resources. These summaries provide information on current levels of the direct use of groundfish as a subsistence resource, as well as information on the current levels of use of other subsistence resources on a region-by region basis in order to put the use of groundfish into a broader subsistence context. In this manner, the importance of groundfish as a subsistence resource under existing conditions can be gauged both in absolute and relative terms (or engagement and dependence terms) to allow for subsequent analysis of potential impacts by alternative.

Subsistence Use of Steller Sea Lions. This discussion is specifically included due to the central role Steller sea lion population dynamics have played in recent groundfish fishery management strategies and are likely to continue to play under at least some future management approaches. Information is provided on differential use of Stellers by community and region. Steller sea lion subsistence is also presented as a stand-alone or special case consideration as different groundfish management approaches may have an impact on this subsistence resource that is likely different than other indirect subsistence impacts.

Other Relevant Subsistence Activities. This discussion focuses on subsistence activities other than groundfish and Steller sea lion subsistence that may or may not be subject to a range of impacts from the various groundfish fishery management approaches. These include subsistence salmon fisheries, and joint production opportunities. Subsistence salmon concerns span a wide geography in western and interior Alaska, while joint production issues are confined, by definition, to direct participants in the commercial groundfish fishery.

3.9.5.2 Regional Groundfish Subsistence Summaries

The following sections provide a region-by-region groundfish oriented summary of subsistence activity levels in each of the four Alaska regions analyzed. Groundfish subsistence occurs over a very large geographic area, but in general, subsistence groundfish use levels are low in comparison to use levels of subsistence resources overall, and in relation to other fish resources in particular. There is little, if any, indication that subsistence groundfish use is likely to experience direct impacts under any of the currently contemplated commercial groundfish fishery management alternatives, but there is a potential for joint production type of impacts where commercial and subsistence activities overlap. Given this set of circumstances, these summaries focus primarily on the regionally important groundfish communities identified in Section 3.9.3 and place the role of groundfish in the context of overall subsistence activities, including non-fishing related subsistence. The ability to differentiate between subsistence use of groundfish retained from commercial catches as opposed to the subsistence use of groundfish that were targeted for take during exclusively subsistence activities is not possible with the available data. In practical terms, however, this does not present difficulties analyzing the level and relative importance of groundfish subsistence use in general. In general, given the relatively low dependency on direct groundfish subsistence use, and the fact none of the alternatives would restrict subsistence groundfish take nor cause a decline in groundfish stocks, the potential impacts of any of the alternatives on subsistence uses of groundfish are not likely to be substantial. There is, however, variation between communities and regions and, as a result, localized effects will need to be considered. Within each of the summaries, the major species of groundfish within overall groundfish utilization are also specified, and this varies from community to community. (In the discussion in this section, as in other parts of this document, halibut and sablefish are not included as part of the "groundfish" category.)

The information presented in each of the regional summaries is extracted from the ADF&G Community Profile Database. The Community Profile Database is a compilation of the data collected by community surveys, primarily focused on wildlife harvest documentation, but also typically including associated demographic and economic information as well.

Unfortunately, analysis of trends is largely not possible with these data. Community surveys are not conducted on a regular schedule, but rather are typically performed in relation to other ongoing studies or directed towards specific resource management questions. Thus, the time series information from some communities and for some resource categories is better than for others. For some communities only one survey is available, and such information can be quite dated. Furthermore, even for communities with multiple years of information available, the interpretation of the differences from year-to-year can be problematic.

Since community subsistence activities and harvests vary each year, and surveys are not conducted annually or even within an overall temporal sampling design, the results from different years cannot simply be averaged. Where information for more than one year is available, ADF&G has addressed this problem by designating one year's results as "most representative" of the overall pattern of subsistence activities and level of harvest for that given community. This designation is based on ethnographic and other non-survey community context information. Where available, information on subsistence groundfish use from years that are not "most representative" are presented below. Where information from only one year is available, it is by definition the "most representative" year, but must only be used as an estimate given the amount of variation from year-to-year. This limitation is especially important for communities for which information is rather dated.

Subsistence in the Alaska Peninsula and Aleutian Islands Region

Subsistence resource use by residents of the regionally important groundfish communities of Unalaska, Akutan, Sand Point, and King Cove are is characterized in this section. All of these communities feature subsistence activity, with consumption ranging from about 200 pounds per capita to over 450 pounds per capita. Groundfish ranges from about 4 to 9 percent of total subsistence resource consumption.

Residents of Unalaska are reported to harvest and consume about 195 pounds of subsistence resource per capita, based on a 1994 survey of an estimated 700 year-round households, for a total ADF&G effective population[22] of 1,825 individuals (ADF&G 2000a). Of the subsistence total, 28 percent was salmon, 42 percent was non-salmon fish (of which various groundfish are a component), 5 percent was land mammals, 5 percent was marine mammals, one percent was birds and eggs, 14 percent was marine invertebrates, and 6 percent was vegetation. Groundfish average about 7 percent of the total per capita subsistence consumption (14 pounds per capita). The major contributors to this component are cod (8 pounds) and rockfish (5 pounds).

Residents of Akutan are reported to harvest and consume about 466 pounds of subsistence resource per capita, based on a 1990 survey[23] of an estimated 31 year-round households, for a total ADF&G effective population of 102 individuals (ADF&G 2000a). Of the subsistence total, 26 percent was salmon, 31 percent was non-salmon fish (including groundfish), 6 percent was land mammals, 23 percent was marine mammals, 6 percent was birds and eggs, 6 percent was marine invertebrates, and 2 percent was vegetation. Groundfish average about 9 percent of the total per capita subsistence consumption (43 pounds per capita). The major contributors to this component are cod (29 pounds) and rockfish (11 pounds).

[22] ADF&G calculates an "effective population" based on a unique determination of long-term residency that varies from typical community population counts. As a result, the ADF&G effective population for a given community will not normally correspond with either local or U.S. Bureau of the Census counts. For this reason, "effective population" figures are presented in the discussions in this section, and it should be borne in mind that per capita subsistence consumption figures presented represent total resources harvested divided among a population smaller than what are typically considered community residents (resulting in higher per capita figures than if standard total population figures were used). For the purposes of this analysis, per capita figures are perhaps most useful if they are conceived of as being applicable to those residents who are most likely to engage in subsistence production or consumption.

[23] More recent (1996) subsistence survey information for Akutan covers only bird and egg resources harvest levels.

Residents of Sand Point are reported to harvest and consume about 256 pounds of subsistence resource per capita, based on a 1992 survey of an estimated 204 year-round households, for a total ADF&G effective population of 606 individuals (ADF&G 2000a). Of the subsistence total, 54 percent was salmon, 21 percent was non-salmon fish (including groundfish), 11 percent was land mammals, 2 percent was marine mammals, 2 percent was birds and eggs, 7 percent was marine invertebrates, and 3 percent was vegetation. Groundfish average about 9 percent of the total per capita subsistence consumption (22 pounds per capita), most of which are cod (12 pounds) and rockfish (8 pounds).

Residents of King Cove are reported to harvest and consume about 256 pounds of subsistence resource per capita, based on a 1992 survey of an estimated 158 year-round households for a total ADF&G effective population of 560 individuals (ADF&G 2000a). Of the subsistence total, 53 percent was salmon, 17 percent was non-salmon fish (including groundfish), 15 percent was land mammals, one percent was marine mammals, 4 percent was birds and eggs, 7 percent was marine invertebrates, and 3 percent was vegetation. Groundfish average about 4 percent of the total per capita subsistence consumption (10 pounds per capita). The major contributors to this component are cod (6 pounds) and rockfish (2.5 pounds).

Subsistence in the Kodiak Island Region

As discussed in Section 3.9.3, the city of Kodiak itself is the single regionally important groundfish community. Subsistence in Kodiak may be characterized as follows:

Residents of the City of Kodiak are reported to harvest and consume about 151 pounds of subsistence resource per capita, based on a 1993 survey of an estimated 1,994 year-round households, for a total ADF&G effective population of 6,058 individuals (ADF&G 2000a). Of the consumption total, 32 percent was salmon, 40 percent was non-salmon fish (including groundfish), 15 percent was land mammals, 6 percent was marine invertebrates, and 7 percent was vegetation. Groundfish average about 8 percent of the total per capita subsistence consumption (12 pounds per capita). The major contributors to this component are cod (4.8 pounds), rockfish (3.6 pounds), and greenling (2.4 pounds). For the three other years for which survey information is available (1982, 1991, and 1992) the annual groundfish subsistence harvest per capita ranged from 5 to 10.5 pounds, representing from 3.4 to 6.6 percent of the total per capita subsistence harvest for Kodiak during those years.

Subsistence in the Southcentral Alaska Region

Cordova, Homer, Nikiski, Seward and Anchorage are the regionally important groundfish communities in the southcentral region, as discussed in Section 3.9.3. With the exception of Cordova, available subsistence data for groundfish for these communities show a much lower level of use than similar data show for the Aleutian and Kodiak Island regions.

Residents of Cordova are reported to harvest and consume about 179 pounds of subsistence resource per capita, based on a 1997 survey of an estimated 830 year-round households, for a total ADF&G effective population of 2,507 individuals (ADF&G 2000a). Of the total of subsistence resources, 35 percent was salmon, 24 percent was non-salmon fish (including groundfish), 30 percent was land mammals, 2 percent was marine mammals, one percent was birds and eggs, 3 percent was marine invertebrates, and 5 percent was vegetation. Groundfish average about 4 percent of the total per capita subsistence consumption (7 pounds per capita). The major contributors to this component are rockfish (5 pounds) and cod (1 pound). For the five other years for which survey information is available (1985, 1988, 1991, 1992 and 1993) the groundfish subsistence harvest per capita ranged from 6.7 to 15.5 pounds, representing from 4 to 6.6 percent of the annual total per capita subsistence harvest in Cordova during those years.

Homer was designated by the Federal Subsistence Board as a "rural" community in May 2000. Prior to that time, Homer residents had not been federally qualified subsistence users and, as a result, no data were collected for many years leading up to the change in designation. The rural designation was also recent enough that no data have been collected since the community's change in status. As a result, the only available information on Homer's community subsistence use pattern is over 20 years old.

Residents of Homer are reported to harvest and consume about 94 pounds of subsistence resource per capita, based on a 1982 survey of an estimated 1,798 year-round households, for a total ADF&G effective population of 5,633 individuals (ADF&G 2000a). Of the total of subsistence resources, 21 percent was salmon, 32 percent was non-salmon fish (potentially including groundfish), 25 percent was land mammals, 2 percent was birds and eggs, 18 percent was marine invertebrates, and 2 percent was vegetation. No groundfish were reported as part of the Homer subsistence harvest, but based on experience elsewhere, this probably reflects a relatively low level of harvest. This lack of reporting may be due to incidental take while targeting some other species, rather than no take whatsoever.

Similar to Homer, Nikiski had been classified as "non-rural" (non-subsistence) communities until the Federal Subsistence Board changed their classification in May 2000, when the board designated all communities on the Kenai Peninsula as "rural." The ADF&G subsistence does not contain any information for Nikiski, but does include some historical harvest information for nearby Kenai. The information for Kenai is summarized here as it is the information most likely to be indicative of the type of subsistence use that occurs in Nikiski. Residents of Kenai are reported to harvest and consume about 84 pounds of subsistence resource per capita, based on a 1993 survey of an estimated 2,274 year-round households, for a total ADF&G effective population of 6,372 individuals (ADF&G 2000a). Of the total of subsistence resources, 46 percent was salmon, 19 percent was non-salmon fish (including groundfish), 20 percent was land mammals, one percent was marine mammals, one percent was birds and eggs, 6 percent was marine invertebrates, and 6 percent was vegetation. The amount of groundfish harvested was negligible (0.32 pounds per capita). Similarly, for the three other years for which survey information is available (1982, 1991, and 1992) the groundfish subsistence harvest per capita ranged from 0 to 0.7 pounds, representing from 0 to 1.0 percent of the total subsistence harvest during those years.

Seward cannot be described in terms of its residents' subsistence use patterns because there is no available information. Like Homer and Nikiski (and the other communities on the Kenai Peninsula), Seward was classified as a "non-rural" community until May 2000. Based on general community characteristics, Seward's pattern of subsistence resource use is likely similar to that seen in Homer, where groundfish subsistence use is negligible.

Anchorage cannot be described in terms of its residents' subsistence use patterns based on existing data because Anchorage is defined as a "non-rural" community and thus its residents are not federally qualified subsistence users. While there may be some minimal per capita groundfish take through sport fishing, this is considered negligible for this analysis.

Subsistence in the Southeast Alaska Region

Petersburg, Sitka, and Yakutat are the regionally important groundfish communities in this region, as described in Section 3.9.3. Total subsistence resource consumption ranges between about 200 and 400 pounds per capita in these communities, with groundfish ranging between 1 and 5 percent of the total annual consumption.

Residents of Petersburg are reported to harvest and consume about 198 pounds of subsistence resource per capita, based on a 1987 survey of an estimated 1,123 year-round households, for a total ADF&G effective population of 3,739 individuals (ADF&G 2000a). Of the subsistence resource total, 23 percent was salmon, 22 percent was non-salmon fish (including groundfish), 29 percent was land mammals, 2 percent was birds and eggs, 19 percent was marine invertebrates, and 4 percent was vegetation. Groundfish average about 2 percent of the total per capita subsistence consumption (3.5 pounds per capita), most of which are cod and rockfish.

Residents of Sitka are reported to harvest and consume about 205 pounds of subsistence resource per capita, based on a 1996 survey of an estimated 3,053 year-round households, for a total ADF&G effective population of 8,535 individuals (ADF&G 2000a). Of the subsistence resource total, 28 percent was salmon, 26 percent was non-salmon fish (including groundfish), 25 percent was land mammals, 4 percent was marine mammals, 13 percent was marine invertebrates, and 3 percent was vegetation. Groundfish average about 5 percent of the total per capita subsistence consumption (9.9 pounds per capita). The major contributors to this component are rockfish (5 pounds) and greenling (3 pounds). Similarly, for the only other year for which a survey was conducted (1987), subsistence groundfish were about 6 percent (8.7 pounds per capita) of the total subsistence harvest.

Residents of Yakutat are reported to harvest and consume about 398 pounds of subsistence resources per capita, based on a 1987 survey of an estimated 169 year-round households, for a total ADF&G effective population of 589 individuals (ADF&G 2000a). Of the subsistence resource total, 54 percent was salmon, 19 percent was non-salmon fish (including groundfish), 4 percent was land mammals, 8 percent was marine mammals, one percent was birds and eggs, 10 percent was marine invertebrates, and 4 percent was vegetation. Groundfish average about one percent of the total per capita subsistence consumption (5 pounds per capita). The major contributors to this component are flounder (2.5 pounds), cod (1.5 pounds), and rockfish (1 pound). For the only other year for which a community survey was conducted (1984), subsistence groundfish comprised about 3.5 percent (12.7 pounds per capita) of the total subsistence harvest, most of which were greenling (4.1 pounds), rockfish (3.2 pounds), flounder (3.1 pounds), and cod (2.1 pounds).

3.9.5.3 Subsistence Use of Steller Sea Lions

This section presents information on the subsistence harvest and consumption of Steller sea lions in Alaska by region and community for recent years. As discussed in previous sections of this Programmatic SEIS, a number of Alaska groundfish management actions have in recent years been linked to the interrelationship of groundfish and Steller sea lion populations. Because of this focus, this section examines subsistence use of Steller sea lions by community and region, including information on relative dependency on Stellers among other subsistence resources where data permit, and discusses the relationship of subsistence activities to the Steller sea lion population dynamics.

It should be noted that most of the documented harvest information is for years when Steller sea lions were classified as "threatened," before the western stock of Steller sea lions was reclassified in 1997 as "endangered." How this official change in status per se has influenced subsistence take, if at all, is unknown. Further, it is also important to note that while subsistence use of other resources is open to a broader spectrum of residents of coastal Alaskan communities, the take of marine mammals is restricted to the Alaska Native portion of the population under the terms of the MMPA of 1972 (as reauthorized in 1994 and amended through 1997; the specific subsistence exemption for Alaska Natives is found in Section 101 [16 USC 1371]). Therefore, any subsistence impacts to Steller sea lions would be concentrated among Alaska Native residents of these communities.

Steller Sea Lion Subsistence Methods

Steller sea lions are taken by a number of methods throughout the year. Unlike a number of other subsistence activities that are more broadly participatory, hunting for sea lions is a relatively specialized activity, and a relatively small core of highly productive hunters from a limited number of households account for most of the harvest. For the years surveyed, individuals from only 20 to 29 percent of all households in the relevant communities actually hunted sea lion (Wolfe 2001). Once harvested, sea lion is distributed among a much wider range of households (Wolfe and Hutchinson-Scarbrough 1999, Wolfe 2001).

There has been some change in harvesting techniques over recent years, and there is also variation by region. For Kodiak Island communities, the sea lion harvest used to take place at their haulouts, and 20 or 30 were transported at a time aboard purse seiners. Thus, one or two hunters could supply an entire village. Currently, hunting sea lions involves two or three individuals using skiffs to hunt swimming sea lions in open water. The hauling capacity of such skiffs is one or two animals, and Kodiak hunters prefer to take young adults of medium size rather than large bulls or young pups. Some sea lions are taken from shore locations where sea lions are known to swim close to the shoreline. The animal is then retrieved using a skiff. Peak months for harvest are October through December (Hayes and Mishler 1991).

Hunting methods vary somewhat in the Aleutians and Pribilof Islands and are documented in Wolfe and Mishler (1995). Pribilof Island residents hunt sea lions almost exclusively from the shore and target swimming juvenile (mid-size) males. On St. Paul Island sea lion hunting is most commonly done from shore at Northeast Point, accessible by truck. St. Paul hunters take advantage of known sea lion "swimways." Once shot, the hunter waits for the wind and sea to bring the carcass to shore, as heavy seas generally preclude the use of a skiff. A "sea dog" (a retrieval device consisting of a piece of wood with hooks attached to a 30- to 40-foot rope) assists in this process. Not all animals are recovered, but hunters try to shoot only those animals for which there is a high probability of eventual recovery. Hunters will at times hunt from skiffs in calm weather. Sea lion hunting on St. Paul occurs mainly from September through May. Sea lion hunting on St. George is similar to that of St. Paul, being predominately shore-based. Harvest occurs mainly from January through May. Sea lion harvest in the Aleutian Chain (Atka, Unalaska, Akutan, and Nikolski) occurs mostly from skiffs in open water, and hunters target both sexes. When skiff travel is risky or for a change of pace, sea lion hunting is also done from concealed shore stations. Aleutian Chain hunters will concentrate effort near haulout locations, and take more adult and female animals than do Pribilof Island hunters. Seasonality of sea lion harvest is quite variable, and appears to be dependent on sea lion abundance and distribution.

Harvest Levels and Regional Variation

Historical documented subsistence harvests of Steller sea lions are presented in Tables 3.9-90 through 3.9-93. These figures represent both recovered and “struck and lost” animals.

Table 3.9-90 presents information derived from ADF&G surveys of all subsistence resources harvested by a given community plus the specific Steller sea lion harvest. Together, these two types of information allow for an assessment of the relative dependency of a community on Steller sea lions within the overall subsistence harvest. A major caveat for the information contained in this table is that each community was surveyed only a limited number of times and for different years than most other communities, meaning comparability between communities is limited. It is also important to note that the documented Steller sea lion percentage of total subsistence harvest shown in the table is a measure of the past use and reliance upon this resource, and almost certainly does not represent the current harvest, which generally is assumed to be much lower than that in the past. For Atka, Akutan, St. George, and St. Paul (and perhaps Unalaska and several other communities) it can be seen that Steller sea lions have in the past represented a very significant subsistence resource in terms of relative contribution to overall community subsistence resource consumption. It should also be clearly noted that the information in Table 3.9-90 is not totally consistent with the information presented in Tables 3.9-91 through 3.9-93, which underscore the general lack of precision in the data. What is evident, however, is that the area of heaviest subsistence use of Steller sea lions is in southwestern Alaska, and is concentrated in relatively few communities.

Tables 3.9-91 through 3.9-93 present information from surveys documenting only sea lion (and harbor seal) subsistence harvest in all Alaskan communities for the period 1992 (the first year of focused surveys on sea lion and harbor seal harvests) through 2000, except for 1999, when no survey was conducted (due to lack of funding). (Subsequent information was collected for 2001, but is not available at the time of this writing.) Nine communities surveyed in previous years could not be included in the 2000 survey, however, as local surveyors could not be secured. For these communities (Anchorage, Atka, Homer, Hydaburg, Kenai, Nikolski, St. George, Tyonek, and Valdez), ADF&G estimated that the sea lion harvest in 2000 was the same as in 1998 (the most recent year for which harvest information was available). In addition, the 2000 harvest survey for a tenth community, St. Paul, was conducted independently by a local hunter association with funding from NOAA Fisheries. The results of this project were not available at the time of publication of Wolfe (2001), so estimates from 1998 were also used to represent the year 2000 sea lion harvest for this community in the ADF&G data set. As a result, caution must be taken in the interpretation of 2000 harvest data.

Of the 206 sea lions shown in Table 3.9-91 as “taken” in 2000, over half (104) are attributed to those communities assumed to have harvested the same number of sea lions in 2000 as in 1998 (Atka 17, Nikolski 1, St. George 20, St. Paul 58, and Valdez 8). All other communities were documented to have harvested 102 sea lions in 2000, while in 1998 these same communities harvested a total of 75 sea lions (an overall increase in harvest for 2000, primarily in Unalaska, compensating for a steep decline in Tatitlek). However, the independent St. Paul harvest project estimated that only 23 sea lions were taken in St. Paul during 2000 (Lestenkof and Zavadil 2001), 35 fewer than assumed by Wolfe (2001), so it is unclear whether actual totals for 2000 would have been higher or lower than the projected totals that appear in the tables. It is reasonable to assume, however, that the overall or longer term trend of decline in total harvest has continued in more recent years in parallel with the overall sea lion population decline, but year-to-year harvest in individual communities is considerably more variable (for example, Unalaska and Tatitlek). The reasons for such community variability are most likely related to local sea lion populations, hunting conditions, hunter characteristics, and the community context (Wolfe and Hutchinson-Scarbrough 1999, Wolfe 2001).

Table 3.9-92 provides break-out information by community for the Aleutian/Pribilof region for the period 1992 to 2000, while Table 3.9-93 provides similar information for communities in the combined Kodiak-Southcentral region. As shown, in years between 1992 and 2000, Atka, St. George, St. Paul, and Unalaska dominate subsistence take of Steller sea lions in the Aleutian/Pribilof region. Similarly, while there is a great deal of variation from year-to-year in the Kodiak-South Central area, the dominance of Old Harbor in most years is also clear.

Steller Sea Lion Populations and Subsistence Efforts

ADF&G has tried to address the possible linkage between the decline in the overall Steller sea lion harvest and a decrease in the sea lion subsistence harvest effort between 1992 and 1998 (Wolfe and Mishler 1997 and 1998, Wolfe and Hutchinson-Scarbrough 1999, Wolfe 2001). They note that while the total number of sea lions harvested for subsistence use has decreased, interpretation of this change is not straightforward. A number of factors could be at work. For example, take of sea lions has decreased at the same time that the number of people hunting sea lions has decreased. One possibility is that take is down simply because fewer people are hunting. While it is not clear that the annual average harvest per hunter has declined (although ADF&G has not investigated this in a rigorous manner), it is likely that declining Steller sea lion populations play a role in the decisions people make regarding whether to hunt or not. ADF&G states:

> *"… there are probably a variety of local factors related to the year-to-year changes in the number of households hunting sea lions in particular communities, including seasonal hunting conditions, local food needs, and personal circumstances of hunters. It is likely that the declines in the numbers of sea lion hunters in many communities are because sea lions are increasingly harder to find and consequently more difficult and expensive to hunt. As sea lions become scarcer in a community's hunting area, an increasing number of hunters in the community probably choose to stop hunting them. While the hunters that continue to hunt appear to maintain annual harvest rates similar to past years, hunters probably are investing more time and money in pursuit of the sea lions harvest. In addition to these factors, it is quite likely that some sea lion hunters have chosen to reduce their hunting activity because of perceived problems with sea lion populations" (Wolfe and Hutchinson-Scarbrough 1999:69, and essentially repeated in Wolfe 2001:77).*

In earlier documents, ADF&G had also suggested that another factor in the decrease of sea lion subsistence take may be the increased availability of seasonal wage employment in local communities (presumably including work in the groundfish fisheries). Some hunters may be choosing to work rather than to hunt, as a conscious economic choice of time allocation (Wolfe and Mishler 1997 and 1998). This explanation is not stressed as much in their 1999 report, being included in the phrase "… personal circumstances of hunters" (Wolfe and Hutchinson-Scarbrough 1999:69). It should be noted that hunting Steller sea lions requires a considerable amount of effort, and in most cases the cooperation of several people, so that time management and allocation could be a significant factor. An additional possible contribution to a decrease in sea lion subsistence harvest could be a cultural change in taste, so that the consumptive demand for sea lion may have decreased over time (for example, younger generations, less exposed to regular consumption of sea lions, may not desire sea lion as a foodstuff as much as elders do). While this was mentioned anecdotally during field research conducted for this project, no systematic information exists on this possible factor.

While the available information suggests some support for a direct relationship between the overall Steller sea lion population and the level of subsistence harvest, such support is not definitive and other factors cannot be excluded. Given the relatively small numbers involved, the concentrated efforts of a single hunter or just a few hunters can make relatively large percentage changes in community harvest totals. The weighting of factors is also not possible from the evidence available. It does appear that present Steller sea lion harvest methods are likely to be more successful, and certainly more efficient, when resource populations (and density) are higher. A number of factors may be at work, however, such that a recovery in Steller sea lion abundance may not necessarily result in a marked increase in subsistence take, but too little is known regarding the determinants of subsistence demand for Steller sea lions to reach any definitive conclusions.

3.9.5.4 Other Relevant Subsistence Activities

The communities of the Bering Sea and GOA regions engage in a wide range of subsistence activities other than direct groundfish and Steller sea lion use that may be directly or indirectly affected by the proposed alternatives. These activities include subsistence salmon fishing (which could potentially be affected by salmon bycatch in the groundfish fishery) as well as a wide range of subsistence activities that are facilitated by engagement in the groundfish fishery. Some subsistence activities are facilitated by engagement in the groundfish fishery either through joint production (using commercial groundfish vessels or gear for subsistence) or by applying income derived from the commercial fishery towards subsistence pursuits. While characterization of existing conditions for the entire range of subsistence activities that could be indirectly affected by the alternatives is not practical for inclusion in this document, information on subsistence salmon fisheries and a general level discussion on joint production opportunities are summarized in this section.

Subsistence Salmon Fisheries

Current Alaska groundfish fishery management includes provisions for the minimization of salmon bycatch, but salmon bycatch has remained a concern, particularly with respect to potential ongoing impacts to subsistence salmon fisheries. This issue has also been repeatedly noted in the public comment process for this Programmatic SEIS.

Overview

The following information on historic and current subsistence salmon harvest are summarized from ADF&G (2001a). This is the latest year for which data were available at the time of this writing (December, 2002). In 1999, fisheries in four management areas accounted for 77 percent of the total subsistence salmon harvest statewide. These were Yukon (232,070 salmon; 25 percent of the statewide total); Kuskokwim (202,413 salmon; 21 percent); Northwest Alaska (154,294 salmon; 16 percent); and Bristol Bay (143,756 salmon; 15 percent). The total estimated salmon subsistence harvest in Alaska in 1999 was 975,617 fish based on annual harvest assessment programs.

The species of most concern as bycatch in the groundfish fishery are chinook and chum, and of these two, chinook is considered a much larger potential problem. The largest subsistence harvests of chinook salmon in 1999 occurred in the Kuskokwim Area (77,660 salmon; 50 percent), followed by Yukon (50,515 salmon; 33 percent), Bristol Bay (13,009 salmon; 8 percent); and Northwest (6,242 salmon; 4 percent). Three areas dominated the subsistence chum salmon harvest in 1999: Yukon (162,670 salmon; 48 percent of the statewide harvest), Northwest (115,676 salmon; 34 percent), and Kuskokwim (47,612 salmon; 14 percent).

Given the dominance of the Yukon and Kuskokwim areas in total subsistence salmon harvest, and particularly in chinook harvests, those areas are profiled in overview in this section in order to illustrate the extensive geography of the fishery and the number of communities and households involved.

Yukon Region

In historic times as well as today, residents of the Yukon River area rely heavily upon fish for food, and salmon comprises the bulk of the total subsistence fish harvested. Although four salmon species are harvested in the Yukon drainage subsistence fishery, chinook, chum and coho salmon comprise the majority of the subsistence harvests, with subsistence harvests often far exceeding commercial harvests. Depending on the area of the drainage, subsistence fishing occurs from late May through early October. Fishing activities are either based from a fish camp or from the home village. Fishing patterns and preferred sites vary from community to community. Extended family groups, typically representing several households, often undertake subsistence salmon fishing and typically cooperate to harvest, process, preserve, and store salmon for subsistence use.

Chinook salmon are harvested and processed primarily for human consumption, although small kings and those fish deemed not suitable for human consumption are often fed to dogs. In addition, while chum and coho salmon are primarily taken for human consumption, relatively large numbers are harvested and processed to feed sled dogs. The practice of keeping sled dogs is more common in communities along the Upper Yukon River.

In 1999, it is estimated that 2,888 households in the Yukon region participated in the fishery (Table 3.9-94). The estimated 1999 total subsistence salmon harvest for the Yukon area broken down by species included 50,515 chinook (22 percent), 79,250 summer chum (34 percent), 83,420 fall chum (35 percent), 19,984 coho (9 percent), and 681 pink salmon (0.3 percent).

The estimated 50,515 chinook salmon harvested for subsistence in the Yukon Area in 1999 was near the recent five-year average of 51,609. These chinook accounted for approximately 22 percent of the total subsistence catch in the Yukon Area in 1999 (Figure 3.9-16). However, the estimated 1999 summer chum subsistence harvest of 79,250 was about 27 percent below the recent five-year average of 108,051 (Table 3.9-95). The 1999 estimated subsistence harvest of fall chum of 83,420 was about 17 percent below the recent five-year average. However, the five-year average includes harvests from 1995 to 1998, when regulatory restrictions were imposed to reduce fishing opportunity for fall chum subsistence. (A similar restriction was in place in 1994.) A comparison with years in which restrictions were not imposed suggests that the 1999 fall chum harvest is approximately 41 percent below the 1989 to 1993 five-year average (a period with more typical harvests).

Kuskokwim Area

The harvest of fish and wildlife for subsistence use is an important component of the mixed subsistence-cash economy throughout the Kuskokwim Area. During summer, early June through August, the day-to-day activities of many Kuskokwim Area households revolve around the harvesting, processing, and preserving of salmon for subsistence use. The seasonal movement of families from permanent winter communities to summer fish camps situated along rivers and sloughs, continues to be a significant element of the annual subsistence harvest effort. ADF&G Division of Subsistence studies in the region indicate that fish contribute as much as 85 percent of the total pounds of fish and wildlife harvested in a community annually, and salmon as much as 53 percent of the total annual harvest (Coffing 1991).

Approximately 1,700 households in the region annually harvest salmon for subsistence use. Many other households, which are not directly involved in catching salmon, participate by assisting family and friends with cutting, drying, smoking, and associated preservation activities (salting, canning and freezing). Subsistence catches of chinook salmon in the Kuskokwim Area exceed the commercial catch of this species.

There are 37 communities consisting of approximately 4,200 households with subsistence permits within the Kuskokwim Area (Table 3.9-96). The majority of the area households (3,059) are situated within the drainage of the Kuskokwim River. Bethel is the largest community in the region, containing approximately 1,508 households. Approximately 342 households are located in the northern Kuskokwim Bay communities of Kwigillingok, Kongiganak and Kipnuk. Residents of these three communities harvest subsistence salmon from the Kuskokwim River as well as from areas closer to the communities. Residents of Quinhagak, Goodnews Bay, and Platinum, located along the south shore of Kuskokwim bay, harvest salmon stocks primarily from the Kanektok, Arolik, and Goodnews River systems. Residents of Mekoryuk, Toksook Bay, Nightmute, Tununak, Newtok, and Chefornak, situated near the Bering Sea Coast, also harvest salmon from coastal waters as well as local tributaries.

The 1999 total subsistence salmon harvest estimates for the Kuskokwim Area was 77,660 chinook, 47,612 chum, 49,388 sockeye, and 27,753 coho salmon. Seventy-six percent of the overall subsistence salmon harvests in the Kuskokwim Area were taken by residents of communities located from Tuluksak downstream to Eek.

Chinook salmon are particularly sought after for subsistence use in the Kuskokwim Area and account for a large percentage (38 percent) of the total subsistence salmon catch (Figure 3.9-17). The 1999 subsistence chinook harvest was about 9 percent below the 1995-1999 average of 86,208 fish. The estimated sockeye harvest during 1999 (49,388 fish) was the highest it has been since 1993 (Table 3.9-97). The 1999 harvest was also 28 percent greater than the 1995 through 1999 harvest average of 38,379. Subsistence harvests of both coho and chum salmon have both experienced a general decline since 1989. The estimated harvest of 27,753 coho salmon in 1999 is 13 percent below the average harvest of 31,914 fish from 1995 through 1999. The harvest of 47,612 chum salmon during 1999 was the second lowest catch since 1985. The average harvest of chum salmon from 1995 through 1999 is 63,087 fish. Only in 1997 was the chum harvest lower.

On occasion, commercial fishers sometimes keep salmon caught during a commercial fishing period and take them home for subsistence use. During 1999, approximately 11 percent of the households which reported commercial fishing also reported that they kept salmon from their commercial catch for subsistence use. A total of 105 chinook salmon, 37 chum, 106 sockeye, and 140 coho salmon were reportedly retained from the commercial catch for subsistence use. The number of salmon retained from commercial fishing activities for subsistence use is usually relatively low. The lack of commercial fishing opportunities in 1999 is partly responsible for the low numbers retained.

Salmon Bycatch under Groundfish Fishery Existing Conditions

As detailed in the salmon prohibited species discussion (Section 3.5.2.2), the five species of Pacific salmon are divided into two FMP management groups: chinook salmon, and "other" salmon (chum, sockeye, coho, pink). (Steelhead trout have not been observed recently in either the BSAI or GOA and were not considered in that assessment.) All groundfish fisheries in the BSAI and GOA are prohibited from retaining any species of salmon except for those retained under the Voluntary Salmon Donations Permit that authorizes their retention for local food banks (BSAI Amendment 26, GOA Amendment 29). In 1999, over 3 million pounds were donated. Of the five salmon species, only the bycatch of chinook and chum salmon are of any serious concern in the BSAI and GOA. Pink, coho, and sockeye salmon populations in Alaska are considered healthy and bycatch in the groundfish fisheries represents only a minuscule portion of state harvests. These three species also are small components of bycatch in the groundfish fishery relative to chinook and chum salmon.

As detailed in Section 3.5.2.2, although the overall bycatch of chinook and chum salmon is also very small relative to state harvests, bycatch take could pose a threat to specific stocks (rivers of origin). Some western stocks of chinook salmon are currently depressed. In 2000, there were fishing closures in the Yukon and Kuskokwim river systems and it is possible that ADF&G escapement goals may not be realized over the immediate future. If individual stocks become so depressed that full closure of direct fisheries is insufficient to enable a rebound in the population, then any additional mortality, including bycatch, could negatively impact the stock. It is estimated that 58-70 percent of chinook salmon bycatch in the BSAI groundfish fisheries may originate from western Alaska stocks, but it is unknown what proportion of these salmon are specifically from depressed stocks. Analysts contend that there is insufficient information to determine the effects of BSAI bycatch and PSC limits on specific at-risk stocks within this western group.

As summarized in Appendix C, under BSAI Amendment 21b, the PSC limit represents about 19.2 to 36.9 percent of the combined Arctic-Yukon-Kuskokwim and Bristol Bay chinook salmon landings reported between 1997 and 1999. This is a substantial portion of the domestic harvest. In 1999, NPFMC adopted BSAI Amendment 58 which will (1) further reduce the chinook salmon bycatch limit from 48,000 to 29,000 fish over a four-year period, (2) implement year-round accounting of chinook salmon bycatch in the pollock fishery, (3) revise the boundaries of the Chinook Salmon Savings Areas, and (4) set more restrictive closure dates. This reduced PSC limit represents about 11.6 to 22.3 percent of the combined Arctic-Yukon-Kuskokwim and Bristol Bay chinook salmon landings reported between 1997 and 1999. PSC limits have not been established for salmon in the GOA, nor is bycatch considered a potential problem for subsistence fisheries under existing conditions. Some western Alaska stocks of chum salmon are also depressed, but analysts estimate that only about 19 percent of chum salmon bycatch in the BSAI is from western stocks. Because this is equivalent to only 1.3 to 1.5 percent of the combined Arctic-Yukon-Kuskokwim and Bristol Bay chum salmon landings reported between 1997 and 1999, bycatch represents a tiny fraction of landings even for depressed stocks.

A recent paper by Witherell *et al.* provides a compilation of the latest data on Alaska groundfish fisheries salmon bycatch under existing conditions:

"Chinook salmon Oncorhynchus tshawytscha and chum salmon O. keta are caught incidentally in Alaska groundfish fisheries, primarily in the walleye pollock Theragra chalcogramma trawl fishery. From 1990-2001, an average of 37,819 chinook salmon and 69,332 other salmon species (>95 percent are chum salmon) were incidentally caught annually in the Bering Sea and Aleutian Islands groundfish trawl fisheries, and 20,799 chinook salmon and 20,496 other salmon [> 95 percent are chum salmon] were incidentally caught annually in the GOA trawl fisheries. . . Bycatch is primarily juvenile salmon that are one or two years away from returning to the river of origin as adults. The origin of salmon taken as bycatch includes rivers in western Alaska, southcentral and southeast Alaska, Asia, British Columbia, and Washington. Analysis indicates that an incidental catch of 30,000 chinook salmon in the Bering Sea and Aleutian Islands groundfish trawl fisheries equates to about 14,581 adult chinook salmon from western Alaska. Similarly, a bycatch of 60,000 chum salmon in the Bering Sea and Aleutian Islands groundfish trawl fisheries equates to about 13,120 adult chum salmon from western Alaska. We estimated that, on average, salmon bycatch in the Bering Sea and Aleutian Islands groundfish trawl fisheries reduced the western Alaska chum salmon run by less than 0.2 percent, and reduced the western Alaska chinook salmon run by less than 2.7 percent. Impacts of salmon bycatch from the GOA groundfish trawl fisheries cannot be estimated at this time (Witherell et al. 2002)."

Although the numbers of salmon bycatch and associated impacts of western Alaska stocks would appear relatively low, salmon bycatch is nonetheless a contentious issue given the current state of some of the salmon fisheries. For example, in 2000, "salmon returns throughout the Yukon and Kuskokwim River drainages and the entirety of Norton Sound were less than 50 percent of the 20-year average" (D. Eggers, ADF&G Juneau, personal communication, cited in Witherell *et al.* 2002). These, and correspondingly adverse conditions in the Bristol Bay sockeye fishery, have led to constraints on commercial, recreational, and subsistence harvests, and in 1998, 1999, and 2000, an economic disaster was formally declared for western Alaska based on collapsed salmon runs (Witherell *et al.* 2002). While year-to-year fluctuations are common (and are more so in the GOA than in BSAI fisheries), in recent years chum salmon bycatch in the BSAI has remained fairly stable. However, BSAI chinook bycatch increased in 2001 to about 7 percent over the 1990-2001 annual average (Witherell *et al.* 2002). Given the existing conditions in the salmon fisheries, and the specific importance of salmon to overall subsistence take, the cause of public concern over salmon bycatch in the Alaska groundfish fisheries, even in low numbers, is readily apparent.

Commercial Groundfish Fishing and Subsistence Joint Production Opportunities

Joint production refers to the use of commercial fishing vessels and/or gear in the pursuit of subsistence. Joint production can occur in at least two fundamentally different ways. Subsistence fish can be retained during what are otherwise commercial trips, or separate trips (using the commercial vessel and gear) may be taken that focus on subsistence.

In general, there is a paucity of information on joint production within the groundfish fishery. Below are some general points about the vessels involved, followed by points about the communities involved.

- Some, but not all, vessels in the commercial groundfish fishery are used for subsistence in addition to commercial fishing.

- Depending on the community involved, a greater or lesser proportion of fleet engaged in the local commercial groundfish fishery is a non-resident fleet.

As a general rule, trips specifically dedicated to subsistence are uneconomic for the larger vessels engaged in the groundfish fishery. Larger vessels also tend to fish more away from the community of residence of owner, skipper, and crew, therefore subsistence use is not practical even during what could otherwise be combined commercial/subsistence trips. For the largest vessels participating in the fishery, there is no indication of any subsistence utilization in any form. (For the large vessels that are based in communities where subsistence does take place, dedicated subsistence trips for fishing may be unusual, but it is known from field interviews that sometimes larger vessels are used to make hunting trips with several persons going at once.)

Smaller vessels are most likely to be involved in joint production. The proportion of the total subsistence production for individual communities that result from joint production from these particular vessels during the groundfish fishery is unknown, but as a general rule of thumb, the smaller vessel classes are less likely to be narrowly specialized than the larger vessels. Nearly all of the smaller class vessels that engage in the groundfish fishery are also involved in some combination of (or all of) the salmon, halibut, sablefish, and herring fisheries.

In practical terms, joint production opportunities vary by gear type as well as vessel size. Although quantitative data are slim, knowledge of the industry would suggest that little subsistence takes place using trawl vessels compared to other gear types. Among the fixed gear classes, much more time is directed toward sablefish, salmon, and herring than is devoted to groundfish, therefore the joint production opportunities in this class would remain relatively high independent of the groundfish management alternative chosen.

Commercial vessel owners and crew are not restricted to use of commercial vessels and gear, and in practice the use of specific platforms appears to be fluid. Field observations and discussions would indicate that almost all commercial vessel owners resident in communities where subsistence takes place also own at least one skiff from which they can engage in subsistence pursuits, so even if the larger commercial vessel is not available for any number of reasons, it will not mean the discontinuation of subsistence efforts. Even if a commercial vessel owner does not individually own a skiff, it is a truism of village life that there will always be other vessels owned by sons, fathers, brothers, other kin, or neighbors. It is also important to note that if commercial fishing time goes down (or even joint production opportunities per se), it is entirely possible that subsistence activities will increase, because the relative importance of subsistence in the household economy (e.g., supplying food for the table) will increase, as long as fuel and necessary gear can be obtained.

Short and long-term variation in joint production is not uncommon. Field observations would indicate that different individuals look at the balance between commercial and subsistence catches during times of resource scarcity or other forced decision-making (such as when the price being paid for fish by processors is especially low) in very different ways. From one point of view, if the fishing is poor because few fish are available, the vessel owner should direct effort to the greatest extent possible toward the commercial catch in order to get at least some economic return out of a scarce resource for the family or household economy. From another point of view, if conditions are bad, subsistence fishing should be accomplished first, because subsistence takes care of the basic need to put food on the table in the most direct way possible. Clearly both points of view are held, and both strategies are pursued by different individuals, and this is illustrative of another dimension of the complex relationship between commercial and subsistence pursuits. Poor market conditions also force tough decisions, and different decisions may be influenced by a threshold effect after an individual operation is able to recoup expenses. Again, there are many factors at work in this dynamic decision-making environment and, as a result, similar conditions may result in different outcomes for individual operations, and individual operations may show considerable variability over time.

CDQ-owned vessels that participate in the groundfish fishery largely do not participate in subsistence activities. Although CDQ communities in general have relatively high levels of subsistence engagement, CDQ owned vessels participating in the groundfish fishery may not be based in those communities (i.e., they are an investment that is not directly run out of one of the communities, as is the case for ownership interest in catcher processors). Other CDQ-owned vessels do not participate in the groundfish fishery (or those portions of the groundfish fishery that could change as a result of the alternatives) at all, or at only very low levels. For example, some CDQ owned vessels concentrate nearly exclusively on the salmon fishery, while others focus on halibut and sablefish (blackcod). (A more detailed discussion of CDQ-owned fleet characteristics is provided in Section 3.9.4).

As noted earlier, factors involved in whether or not individuals engage in subsistence pursuits are multiple and complex, and this applies to vessels as well. Some data from ADF&G (and mentioned in the Steller sea lion discussion above) suggest that in at least some instances, level of engagement in subsistence activities declines when individuals are engaged in commercial pursuits. Therefore it may be the case for at least some individuals that if their commercial groundfishing activity declines, their direct participation in subsistence activities may increase. Field interviews and other studies (Kruse *et al.* 1981, Kruse 1982, Schroeder *et al.* 1987) suggest that in other cases, individuals who are the most economically successful in a given community are often also among the highest subsistence producers.[24] This likely results from these individuals having access to more income to purchase better or more efficient equipment (and to be able to afford to engage in activities that require cash outlay for longer periods of time), and the flexibility of schedule that often comes with higher paying employment, among other individual or personal factors. In sum, the factors leading to subsistence participation are many and complex.

There is considerable variation in joint production opportunities by community and region under existing conditions. In the case of Unalaska, none of the large commercial vessels that deliver groundfish to the local processing plants are owned or crewed by residents of the community. There is a small boat fleet from the community that jigs for cod, although the most recent data available suggest that none or very few jig boat owners derive their income exclusively from commercial fishing. The fact that commercial fishing for small boat owners is generally one part of a (variable) multiple income strategy suggests that even when there is a partial reduction in opportunity to fish, there are still incentives to continue to fish.

In terms of the number of participants, this fleet has seen growth and decline in recent years. According to CFEC/ADF&G fish ticket data, three Unalaska/Dutch Harbor jig vessels fished groundfish in 1992, two fished in 1993, and then there was an upsurge in participation with between 13 and 18 vessels reporting per year from 1994 to 1997, inclusive. A decline quickly followed, however, as in 1998, 1999, and 2000, there were 9, 8, and 7 vessels participating each year, respectively. There are also some small boat longline groundfish activity by small boats, but the level of effort in federal waters by local residents within this small boat fleet is difficult to assess with currently available data.

---

[24] This general point is also developed on the ADF&G website Subsistence FAQ at: http://www.subsistence.adfg.state.ak.us.

In Akutan, like Unalaska, the fleet that delivers at the local processing facility is a non-residential fleet. Unlike Unalaska, however, the small boat fleet from the community is comprised nearly exclusively of open-skiff type of vessels that generally do not deliver groundfish to the plant, so the residential fleet from the village/traditional community is essentially not engaged in the commercial groundfish fishery. At present, there are few if any joint production opportunities.

In the case of Sand Point and King Cove, there is a residential fleet that delivers groundfish in significant volume to the plants, in addition to deliveries from non-residential catcher vessels. In 2000, 57 of the 80 total vessels in the Alaska Peninsula and Aleutian Islands region were owned by residents of King Cove and Sand Point (including six of the 10 'ghost' vessels[25]). Looking at the vessel classes involved, it is unlikely, for reasons outlined above, that the four local pot boats (all over 85 ft in length) are even in part subsistence vessels. It is also unlikely that the two "04-Trawl catcher vessel Non-AFA" vessels over 90 ft in length (two in King Cove and one in Sand Point) commonly engage in subsistence (due to high operating costs and an inherent lack of flexibility when compared to smaller vessels), although the third vessel in this class, at 68 ft, is more likely to do so. The rest of the local vessels are of a size that they are likely to engage in subsistence, just as their size typically corresponds to a higher degree of diversity within commercial fisheries, as seen in the information presented in Section 3.9.2.

For Kodiak, similar to Sand Point and King Cove, there is a residential fleet that delivers significant amounts of groundfish to the local processing plants. The City of Kodiak-based vessels account for 95 percent of the groundfish total ex-vessel value of the region, and about 87 percent of all groundfish vessels in the region. Old Harbor and Ouzinkie vessels each account for between one and 2 percent of the total regional catcher vessel ex-vessel value. Old Harbor is home to about 6 percent of the groundfish vessels in the region, and Ouzinkie about 3 percent of these vessels. Port Lions and Larsen Bay each represent less than one percent of value and 2 percent of regional vessels. As a general rule, the larger vessels in the region tend to be disproportionately associated with the community of Kodiak compared to the smaller villages, so some joint production can be assumed to be taking place in these smaller communities as well as among the smaller vessels within the Kodiak fleet.

For southcentral and southeast communities with their diversified groundfish fleets, little is known about current joint production practices, but joint production may be assumed to be occurring. In general, however, while joint production may be relatively widespread, joint production concerns resulting from any of the groundfish management alternatives being contemplated are likely to be concentrated among small vessel owners in a relatively small number of communities. A summary of past/present effects of actions and events on subsistence is presented in Table 3.9-127.

3.9.6 Environmental Justice Existing Conditions

3.9.6.1 Regulatory Context

Concerns regarding environmental equity are generally termed environmental justice. Environmental justice can also be defined as "the determination of equal justice and equal protection under the law for all

[25] One factor to keep in mind is that 'ghost' vessels are so classified because while they made groundfish landings, they did not make enough to put them into a particular class, and therefore they are not likely to be affected by any of the alternatives.

environmental statutes and regulations without discrimination based on race, ethnicity, and /or socioeconomic status" (Bryant 2001). Environmental justice issues encompass a broad range of impacts including those on the natural and physical environment and related social cultural and economic effects. While not a part of NEPA itself, EO 12898 (Environmental Justice, 59 FR 7629 [1994]) requires each federal agency to achieve environmental justice by addressing "disproportionately high and adverse human health and environmental effects on minority populations and low-income populations."

As under NEPA itself, "environmental" effects under EO 12898 are construed to encompass social and economic effects, and these are discussed in some detail in this section. Human health effects, as mentioned in EO 12898, would appear to be less relevant to impacts potentially associated with the various groundfish fishery management alternatives being considered in this Programmatic SEIS. EO 12898 does include language regarding the need to identify differential patterns of subsistence consumption of fish and wildlife (which is done in Section 3.9.5 and noted in summary form in this section), but it goes on to link this data collection with potential human health risks associated with the consumption of pollutant-bearing fish and wildlife. While subsistence in Alaska is associated more strongly with minority (Alaska Native) populations and low-income populations (those in rural areas with fewer commercial economic opportunities) than other populations, there is no indication that any of the alternatives being considered would result in a degradation of resources in a manner such that their consumption would result in a health risk elevated above existing conditions.[26]

In order to determine whether environmental justice concerns exist, the demographics of the relevant area are examined to determine whether minority populations or low-income populations are present and could be disproportionately impacted by the proposed alternatives. The question as to whether a proposed alternative raises environmental justice issues depends to a large degree on the history or circumstances of a particular community or population, as well as the specific ties of that community or population to the resources (or access to resources) that will be changed by the alternative.

---

[26] This is quite a different situation than found in a number of other parts of the United States, where there are health concerns that result from minority populations and low-income populations being more reliant on pollution-bearing subsistence resources than the general population as a whole. This, along with the observation that minority populations and low-income populations were bearing the brunt of locally undesirable land uses - including those that involved direct environmental health concerns - was one of the major equity concerns that sparked the environmental justice movement. Pollution associated with the commercial groundfish fishery is not understood to be of particular concern for subsistence in Alaska, with the possible exception of commercial fishery operations in general being associated with localized environmental degradation in and around commercial fishing harbors. One example of this is seen in the major port of Unalaska where local residents typically avoid use of at least some subsistence resources (such as intertidal invertebrates) in the immediate harbor area due to concerns over contamination from vessels and various shore based commercial/industrial activities (and even earlier military activities) dating back to at least the World War II era. This is clearly a complex and long-standing situation, and no studies on the incremental contribution of environmental contaminants associated specifically with the groundfish fishery (as opposed to all of the other activities that have historically taken place or are currently taking place in this busy harbor) are known to exist, but it is understood that contemporary environmental regulations make current operations much less environmentally problematic than earlier harbor related activities.

Alternatively, in the Alaska (and groundfish fishery) specific context, it could be argued that any of the management alternatives that have the effect of decreasing subsistence resource consumption could result in a degradation of overall health (or other well-being) of human populations engaged in subsistence activities. This argument would be based on the assumption that consumption of wild resources results in positive health benefits in comparison to benefits derived from commercially available foodstuffs (or that participation in subsistence activities has beneficial health effects due to its central sociocultural importance and an associated perception - or psychological reality - of well-being). Available data do not allow a definitive treatment of this issue and, as a result, potential impacts to subsistence are treated in social and economic terms in this section rather than as a human health issue.

There is no standardized methodology for identification or analysis of environmental justice issues. The demographics of the affected area should be examined to determine whether minority or low income populations are present. If so, a determination must be made as to whether the implementation of the alternatives may cause disproportionately high and adverse human health or environmental effects on the minority populations, or low income populations present.

In determining what constitutes a low-income or minority 'population,' CEQ guidance, with specific regard to minority populations, states: "if the minority population percentage of the affected area is meaningfully greater than the minority population percentage in the general population or other appropriate unit of geographical analysis." While no available federal guidance addresses the determination of low-income populations, a similar approach has generally been adopted when preparing NEPA documents (King, 2001). The U.S. EPA has stated that addressing environmental justice concerns is entirely consistent with NEPA and that disproportionately high and adverse human health or environmental effects on minority or low-income populations should be analyzed with the same tools currently intrinsic to the NEPA process. NOAA environmental review procedures[27] state that, unlike NEPA, the trigger for analysis under Executive Order 12898 is not limited to actions that are major or significant, and hence Federal agencies are mandated to identify and address, as appropriate "disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations."

3.9.6.2 Community Variations and Data Limitations

The population structure of the regions varies considerably. As discussed below and elaborated in the detailed groundfish regional and community profiles recently produced for NPFMC (NPFMC 2002d), within Alaska, and particularly in the Aleutian and Kodiak regions, there is a relationship between the percentage of Alaska Native population and commercial fisheries development. Specifically, communities that have developed as large commercial fishing communities have become less Native in composition over time compared to other communities in the region. There are many variables involved, but most communities noted the relationship is quite straightforward. The fishery has also had an impact on the male-female population balance for some of the Alaskan communities that are the focus of intensive groundfish processing. This is due to the fact that processing workers reside within these communities for varying durations, and that this workforce is predominately male. While this type of direct impact on population structure attributable to groundfish is seen in few communities, these tend to be the communities with the highest level of groundfish-related processing activities and the highest engagement in, and dependence upon, the fishery. The differences in the male/female and Native/non-Native population segments are, to a degree, indicative of the type of structural relationship of the directly fishery-related population with the rest of the community. Again, this varies considerably from place to place and is not apparent in the southcentral and southeast Alaska regions in the same way it is in the Alaska Peninsula/Aleutian Islands and Kodiak Island regions.

Interpretation of these data, in terms of engagement with the community, is less straightforward for some regions than for others. As detailed in the regional discussions, and in the community profiles available elsewhere (NPFMC 2002d), communities are engaged in, and dependent upon, the fishery in quite different ways through resident catcher vessel fleets, onshore processing facilities, and locally associated catcher

[27] NOAA *Environmental Review Procedures for Implementing the National Environmental Policy Act* (Issued 06/03/99)

processor (and/or mothership) entities. While no consistent data are available, field observations would tend to indicate that ownership and crew demographics of the residential catcher vessel fleet for the relevant Alaska groundfish communities tend to mirror those of the long-term male residents of the community at large. This situation would also appear to hold true for the smaller vessel catcher processor sectors based in the various Alaska regions. For the larger vessel catcher processor and mothership sectors, those are, to a large degree, associated with the Washington region (with the caveat that ownership patterns have been changing in recent years and the percentage of Alaska-based ownership in general and Alaska CDQ ownership in particular has increased, as discussed at length elsewhere in this document), and crews tend to be drawn from a wide area rather than a particular community. These factors are discussed in a separate section below. For the large processing plants that utilize groundfish, the demographics of the workforce and the relation to the host communities tend to be more complex, have substantial environmental justice implications, and are discussed at length below.

In some Alaska groundfish communities, processing plants tend to be industrial enclaves somewhat separate from the rest of the community, while for others there is no apparent differentiation between the processing workforce and the rest of the regional or local labor pool. A further complication for attribution of socioeconomic impacts to a regional base is the fact that for many workers in many of the sectors, groundfish-related work is performed in a region or community that is separate from where they have a number of other socioeconomic ties. It is not uncommon for fishery-related workers to spend relatively little money in their work region and to send pay home to another community or region. In this sense, regional employment is indicative of a volume of economic activity, if not a specific level of labor activity directly comparable to other industries.

The importance of this flow varies from region to region and from sector to sector, but is most apparent within communities that are most heavily engaged in the processing aspect of the groundfish fishery. For the purposes of this environmental justice analysis, however, these populations will be characterized as being resident in their residential workplace communities, consistent with U.S. Census methodology. One of the current limitations of U.S. Census data, however, is that not all of the 2000 data relevant to this environmental justice analysis have been released. Ethnicity by housing type (e.g., ethnicity by group quarters and non-group quarters), particularly useful for examining resident processing workforce numbers in Alaska coastal communities for this analysis, is not available, so data from the 1990 U.S. Census are presented, keeping with the established practice of using federal census data for environmental justice analysis.

Unfortunately for this analysis, however, the groundfish fishery has changed a great deal since 1990 in many ways, including the size and distribution of the workforce. This being the case, the 1990 census data were supplemented with data gathered from industry sources that characterize their workforce demographics for 2000. These data suggest that the workforce has come to include a much larger minority population component than was the case a decade earlier and reflected in the 1990 census information.

Some caution must be given in the comparison of the two different 1990 and 2000 resident workforce related data types. In order to supplement the dated 1990 U.S. Census information that is being used to infer the structure of the locally present or resident fishery-associated workforce, industry was asked to provide 2000 workforce demographics for their individual groundfish processing operations.[28] These data were not collected using a methodology similar to that used for the U.S. Census data, and this should be taken into account in the interpretation of the information. These data are self-reported and, like other self-reported data, there may be a degree of inherent self-interest bias within the information. Whatever bias exists is considered likely to be relatively small and not sufficient to materially alter the overall assessment of whether or not the local seafood processing workforce represents a population segment that is "meaningfully greater than the minority population percentage in the general population or other appropriate unit of geographical analysis" such as the specific community or region. Further, in each relevant Alaska region, these data are supplemented with age and sex data from the 1990 and 2000 U.S. Census that allow a cross-check on both the gross and relative changes in the industrial population segment in the communities.

The demographic composition of the greater Seattle area is markedly different than that seen in the Alaska groundfish communities, and the same type of demarcation between the industrial fishing operations and the resident population is not apparent. Seattle is, in absolute terms, the community most engaged in the groundfish fishery among many of the important indices of involvement, but it is also the least engaged in terms of the relative importance of the fishery to the overall population and economy of the community (as discussed in detail elsewhere [NPFMC 2002d]). Summary information relevant to environmental justice considerations for Seattle is presented at the end of this section.

The CDQ region presents yet another type of environmental justice context. Environmental justice issues are salient in this region due to the nature of the demographic and economic structure of the region, and the nature of the participation of this region and its communities in the fishery through various mechanisms of the CDQ program. The specific attributes of participation vary as the program has been implemented differently in various subregions by different CDQ groups, but in general this program has been designed to foster economic development in minority (Native Alaskan) and economically underdeveloped communities. As such, any impacts to the CDQ program and its communities are, essentially by definition, potentially environmental justice impacts. The existing conditions in this region and the attributes of the program are discussed in detail in Section 3.9.4.

Another type of environmental justice context concerns subsistence issues. While not only Alaska Natives participate in subsistence activities, areas in which subsistence activities are practiced that may be impacted by groundfish management alternatives are predominately Alaska Native. Therefore, impacts to subsistence are also, in general, potentially environmental justice impacts. Existing conditions for relevant subsistence associated populations are discussed in detail in Section 3.9.5. A summary of past/present effects of actions and events on environmental justice is presented in Table 3.9-127.

---

[28] There has been some question in the past as to whether or not environmental justice provisions applied to non-U.S. citizens, and this has relevance for the analysis, given that a substantial number of resident aliens work in the local seafood processing plants. If it is assumed that EO 12898 is premised on the application of the equal protection clause, then it should not matter whether the affected population consists entirely or primarily of citizens or resident aliens. Further, available guidance for the implementation of EO 12898 recommends the use of U.S. Census data, and the methodology of the Census, i.e., where all persons are counted, argues strongly for the inclusion of foreign nationals in the environmental justice analysis. As noted by the EPA, however, census data alone may not always prove sufficient for a thorough analysis, "in part because the level of aggregation may not offer a fine enough mesh to identify the existence of minority and/or low-income populations." In this specific Programmatic SEIS instance, industry provided data are used to identify such 'pockets' of minority populations within various groundfish communities that are relevant to the analysis of the proposed alternatives.

3.9.6.3 Regional Summaries

Alaska Peninsula/Aleutian Islands region

General Community Population Attributes

Alaska Peninsula/Aleutian Island region communities with the strongest direct engagement in, and dependence upon, the North Pacific groundfish fishery are Unalaska, Akutan, Sand Point, and King Cove.[29] These four communities, and their specific ties to the groundfish fishery, were summarized in Section 3.9.3. In this section, community level information relevant to environmental justice analysis is summarized.

Table 3.9-98 provides ethnicity information from the 2000 census for each of the four communities.[30] As shown, these communities vary widely in their population structure. For example, Unalaska is the largest community, but has the lowest Alaska Native population percentage, and King Cove and Sand Point have a much higher Alaska Native population component than either of the other two communities. (While Akutan has a relatively low Alaska Native population percentage, the Alaska Native population is highly concentrated in one area and generally insulated from commercial groundfish related activity and its associated non-Native population. Thus, the Alaska Native portion of the community at least in some ways bears the most resemblance to "village life" from an earlier era among the four communities.) Unalaska has a far higher white or non-minority population percentage than the other three communities. Asian residents represent the largest population segment in Akutan, and the second largest in Unalaska (behind whites) and in King Cove (behind Alaska Natives), and the third largest in Sand Point (behind Alaska Natives and whites). These communities have quite different histories with respect to the growth of the different population segments present in the community in 2000. Each is summarized briefly below. One important constant across all of these communities is that each is a *minority community* in the sense that minorities make up a majority of the population in each community.

Unalaska may be described as a plural or complex community in terms of the ethnic composition of its population. Although Unalaska was traditionally an Aleut community, the ethnic composition has changed with people moving into the community on both a short-term and long-term basis. Not surprisingly, in the latter half of the 20th century, population fluctuations have coincided with periods of resource exploitation and scarcity.[31]

---

[29] As noted in an earlier section, there are also ties between the fishery to Adak, Chignik, False Pass, and St. Paul. However, these ties are far less pervasive and do not have the historical depth of the ties seen in Unalaska, Akutan, Sand Point, and King Cove. Due to these differences in existing conditions, the communities of Adak, Chignik, False Pass, and St. Paul are not detailed in this section, but each may experience impacts resulting from management actions under the various alternatives, as discussed in Section 4, if not to the degree seen in Unalaska, Akutan, Sand Point, and King Cove.

[30] As a methodological note, community populations vary quite a bit throughout the year as seasonal workers are brought in to the smaller Alaska communities to provide an adequate workforce for peak seafood processing demand. U.S. Census data do not take yearly averages, but rather represent a one time count. During the 1990 census, for example, information for rural Alaska communities was collected during the months of January through April1990 according to the Institute for Social and Economic Research at the University of Alaska. Although these data cannot represent the complexity of groundfish community the population dynamics, they do represent the best available data set that is comparable across communities and regions.

[31] The most dramatic population shift of this century was brought about by World War II. The story of the War, and the implications for the Aleut population of Unalaska and the other Aleut communities of Unalaska Island, is too complex and profound for treatment in this limited community profile. It may be fairly stated that the events associated with World War II, including the

For example, the economic and demographic expansion associated with the king crab boom in the late 1970s and early 1980s brought many non-Aleuts to Unalaska, including Euro-Americans, Filipinos, Vietnamese, Koreans, and Hispanics. The Euro-American population shows a distinct change over the years, comprising around 30 percent of the population in 1970, over 60 percent in 1980 and 1990, and then back to 44 percent in 2000. The growth of Asian/Pacific Islander population (over 30 percent by 2000) is closely associated with the increasingly residential nature of the seafood processing sector workforce.

Apart from the war years (1941 to 1945), prior to the growth of the current commercial-fisheries-based economy Unalaska was an Aleut community. Since this development, however, the change over the period of 1970 to 1990 is striking. In 1970, Aleut individuals made up slightly over 60 percent of the total community population (and Alaska Natives accounted for a total of 63 percent of the population). In 1980, Alaska Natives, including Aleuts, accounted for 15 percent of the population; by 1990, Aleuts comprised only 7 percent of the total community population (with Alaska Natives as a whole accounting for 8 percent of the population). Overall representation was similar in 2000. This population shift is largely attributable to fisheries and fisheries-related economic development and associated immigration.[32]

Akutan is a unique community in terms of its relationship to the Bering Sea groundfish fishery. It is the site of one of the largest shoreplants in the region, but it is also the site of a village that is geographically and socially distinct from the shoreplant. This duality of structure has had marked consequences for the relationship of Akutan to the fishery. One example of this may be found in Akutan's status as a CDQ community. Initially (in 1992), Akutan was (along with Unalaska) deemed not eligible for participation in the CDQ program based upon the fact that the community was home to "previously developed harvesting or processing capability sufficient to support substantial groundfish participation in the BSAI . . .," though they met all other qualifying criteria. The Akutan Traditional Council initiated action to show that the community of Akutan, per se, was separate and distinct from the seafood processing plant some distance away from the residential community site, that interactions between the community and the plant were of a limited nature, and that the plant was not incorporated in the fabric of the community such that little opportunity existed for Akutan residents to participate meaningfully in the Bering Sea pollock fishery. That is, it was argued that the plant was essentially an industrial enclave or worksite separate and distinct from the traditional community of Akutan and that few, if any, Akutan residents worked at the plant).

With the support of the APICDA and others, Akutan was successful in a subsequent attempt to become a CDQ community and obtained CDQ status in 1996. This action highlights the fundamentally different nature of Akutan and Unalaska. Akutan, while deriving economic benefits from the presence of a large shoreplant near the community proper, has not articulated large-scale commercial fishing activity with the daily life of the community as has Unalaska, nor has it developed the type of support economy that is a central part of the socioeconomic structure of Unalaska. While US Census figures show Akutan had a population of 589

Aleut evacuation and the consolidation of the outlying villages, forever changed the community and Aleut sociocultural structure.

[32] The fact that there is a "core" Aleut population of the community with a historical continuity to the past also has implications for contemporary fishery management issues. These include the activities of the Unalaska Native Fishermen's Association and active local involvement in the regional CDQ program (through participation as an ex officio member as well as being actively engaged in group sponsored training programs, among other activities). While neither of these undertakings exclude non-Aleuts, Aleut individuals are disproportionately actively involved (relative to their overall representation in the community population).

in 1990 and 713 in 2000, the Traditional Council considers the *local* resident population of the community to be around 80 persons, with the balance being considered *non-resident employees* of the seafood plant. This definition, obviously, differs from census, state, and electoral definitions of residency, but is reflective of the social reality of Akutan. The residents of the village of Akutan, proper, are almost all Aleut.

Sand Point and King Cove share a more or less common development history, but one quite different from either Unalaska or Akutan. Sand Point was founded in 1898 by a San Francisco fishing company as a trading post and cod fishing station. Aleuts from surrounding villages and Scandinavian fishermen were the first residents of the community. King Cove was founded in 1911 when Pacific American Fisheries built a salmon cannery. Early settlers were Scandinavian, European, and Aleut fishermen. Historically, both of these communities saw a large influx of non-resident fish tenders, seafood processing workers, fishers, and crew members each summer. For the last several decades, both communities were primarily involved in the commercial salmon fisheries of the area, but with the decline of the salmon fishery, plants in both communities have diversified into other species. In more recent years, the processing plants in both communities have become heavily involved in the groundfish fishery, although their structural relationships to the fishery have diverged since the passage of the AFA. As discussed elsewhere (NPFMC 2002d), processing facilities in both communities qualified as AFA entities; however, King Cove qualified for a locally based catcher vessel co-op while Sand Point did not.

Three tables present information on income, employment, and poverty for the relevant groundfish communities of the region based on U.S. Census data. Table 3.9-99 displays basic information on community housing, households, families, and median household and family income. As shown, the income range is large for the communities shown, with the median family income in Akutan being roughly half of that in Unalaska. This does not reflect the entire range for the region, however, as two communities in the region (Atka and Nikolski) have a lower median family income than Akutan.

Table 3.9-100 displays data on employment and poverty[33] information for the relevant communities for 1990 and Table 3.9-101 shows comparable information for 2000. These tables show large differences between 1990 and 2000, and a comparison of the two tables may be used to point out some potentially problematic aspects of the 2000 data.

As shown in Table 3.9-100, in 1990 there was virtually no unemployment in these communities, no doubt due in large to the presence of fishery-related employment opportunities. Percentage of poverty varies between the communities, but these communities do not represent the range of regional variation. In 1990, Atka had the highest unemployment in the region at 25.7 percent, whereas Cold Bay, False Pass, Nelson Lagoon, and Nikolski had no employment as all members of the workforce (a subset of the total population) that were seeking employment were actually employed. This figure is somewhat misleading; in some communities a large portion of the adult population may not be working and not seeking employment. In 1990, Nelson Lagoon was the extreme example of this with 81 percent of the adults not working. In 1990, percent of poverty in the region ranged from 0 percent in Cold Bay to 42 percent in St. George. Data do not

[33]Poverty figures in this section are based on U.S. Census information which, in turn, is based on the federal government's official poverty definition. Families and persons are classified as below poverty if their total family income or unrelated individual income was less than the poverty threshold specified for the applicable family size, age of householder, and number of related children under age 18 present. The poverty thresholds are the same for all parts of the country and are not adjusted for regional, state, or local variations in the cost of living. The poverty thresholds are updated every year to reflect changes in the Consumer Price Index.

vary consistently with the presence or absence of commercial fishery development as might be expected. For example, Atka shows a very high rate of unemployment and percent of adults not working, yet there is a smaller percentage of persons in poverty than in Akutan, a community with an unemployment rate of less that one percent. This is attributable, in part, to the fundamentally different natures of the communities, with Atka being a small village and Akutan being a community with a large processing facility adjacent to the traditional village site. False Pass, Nelson Lagoon, Nikolski, and St. George, none of which had fish processing facilities at the time of the census, all had over 50 percent of the adults in the community not working.

The contrast between these and the other communities is reflective of both lack of economic development in these communities and the nature of the workforce population in communities with shoreplants, where large numbers of processing workers are present, tend not to have non-working adult family members present with them, and tend to be in the community exclusively for employment purposes.

Table 3.9-101 shows a very different picture in 2000 than was seen in 1990, and a working knowledge of the fishing industry would seem to indicate the 2000 data are anomalous. For example, in 2000 the U.S. Census lists a total of 505 unemployed persons in Akutan. Given that the traditional village of Akutan consists of less than 100 persons (including all age groups, not just adults in the labor pool who could qualify as employed or unemployed), the overwhelming majority of persons enumerated as unemployed must have been idled seafood processing workers.

While this unemployment may have been real in the sense that processing workers were present and not actively working when the census was taken, it is most likely an artifact of the timing of the census. Processing workers are not typically present in the community when the plant is idle for any extended period of time. Under normal conditions, there are no unemployed seafood processing workers present in the community (by design). These workers are transported to and from the community by their employer to meet labor demand at the plant. As part of the employment agreement, seafood processors typically provide room and board for workers, so it is uneconomic to have idled workers at the site unless the plant downtime is relatively brief (i.e., the cost of housing and feeding the employees during the idle interval does not exceed transportation, recruiting, training and other costs associated with sending workers out and bringing them back in, including some level of turnover that always occurs in these situations). The same type of data problem may be occurring in Sand Point and Unalaska, but this is not as clear as is the case for Akutan.

It is also important to note that some Alaska Native communities in the region that do not directly participate in the commercial groundfish fishery derive direct benefits from the fishery outside of the CDQ program. Primary examples of this are the smaller communities of the Aleutians East Borough. In this case, CDQ communities receive direct and indirect benefits of non-CDQ community (King Cove and Sand Point) participation in the fishery. Both King Cove and Sand Point are part of the Aleutians East Borough, and revenue that derives from landings in these communities (along with landings in Akutan), significantly benefit smaller Alaska Native communities in the Aleutians East Borough, such as False Pass and Nelson Lagoon. In this way, adverse impacts to the fishery that are seen in King Cove and Sand Point are also seen in False Pass and Nelson Lagoon, and may impact everything from school funding to basic service provision.

Population Attributes of the Resident Groundfish Fishery Workforce

Beyond the overall population, income, and employment figures for the individual communities, it is important for the purposes of environmental justice analysis to examine information on the residential groundfish fishery workforces. It is likely that employment and income losses or gains associated with at least some of the alternatives would be felt among the local seafood processing workers, and these workers do not comprise a representative cross-section of the community demography. One method to examine the relative demographic composition of the local processing workforces is to utilize group quarter housing data from the U.S. Census (keeping with the established practice of using U.S. Census data for environmental justice analysis). The group ethnicity-by-housing type data are drawn from both the 1990 census and the 2000 census (and a subsequent section augments this information with industry-provided figures for 2000, see below). This is supplemented by age and sex data from the 1990 and 2000 U.S. Census to provide a cross check of census (and industry-provided) data and the population structure over this period. (This approach is applied to other regions subsequently discussed as well.)

Tables 3.9-102 and 3.9-103 provide information on group housing and ethnicity for Unalaska for 1990 and 2000, respectively. Group housing in the community is largely associated with the processing workforce. As shown in Table 3.9-102, 52 percent of the population lived in group housing in 1990. Also as shown in that same table, the total minority population proportion was substantially higher in group quarters (49 percent) than in non-group quarters (31 percent). The 2000 figures (Table 3.9-103) show a similar overall split between group quarters (51 percent of community population total) and non-group quarters populations (49 percent of the total), but the minority population distribution between and within housing types changed substantially in the 1990 to 2000 period. For example, "white" residents of Unalaska comprised 54 percent of the group quarters population in 1990, but only 30 percent in 2000 (and declined, to a lesser but still substantial degree, from 71 percent to 59 percent of the population within non-group quarters housing). Although demographic categories changed somewhat between the 1990 and 2000 census, some relatively large changes are readily apparent. For example, in 1990, the "Asian or Pacific Islander" category accounted for 27 percent of group quarters population, but 42 percent by 2000. In general, in 2000 Unalaska had a substantially greater minority population in absolute and relative terms than it did in 1990, and this is readily apparent within the group quarters population that is largely associated with seafood processing workers. In other words, environmental justice is potentially a large concern if there is the potential for processing worker displacement, and one that has grown through time.

With the population growth seen in association with the development of the commercial fishing industry, Unalaska's population has had significantly more men than women. Historically, this has been attributed to the importance of the fishing industry in bringing in transient laborers, most of whom were young males. Table 3.9-104 portrays the changes in proportion of males and females in the population for the years 1970, 1980, 1990, and 2000. Census data from the period 1970-1990 showed a climb in median age from 26.3 years to 30.3 years and then a further jump to 36.5 years in 2000. This is commonly attributed to an increase in relative size of the workforce (both fishery and non-direct fishery-related) in comparison to resident families. (Although some who come to Unalaska for employment opportunities bring children into the community, it is apparent that many do not, which drives up the median age.)

Table 3.9-105 provides information on group housing and ethnicity for Akutan for 1990, and similar information for 2000 is presented in Table 3.9-106. Group housing in the community is almost exclusively associated with the processing workforce. As shown, 85 percent of the population lived in group housing in

1990, which represents the extreme of the four communities considered in this region. In 2000, this figure was over 89 percent. Also as shown, the ethnic composition of the group and non-group housing segments were markedly different, with the non-group housing population being predominately Alaska Native (83 percent and 87 percent in 1990 and 2000, respectively), and the group housing population having little Alaska Native/Native American representation (1 percent in 1990, 7 percent in 2000). Like Unalaska, overall minority population representation was higher in absolute and relative terms in the community as a whole and in both group and non-group quarters in 2000 than in 1990.

Table 3.9-107 shows the population composition of Akutan by sex in 1990 and 2000. These data are clearly indicative of a male-dominated industrial site rather than a typical residential community.

Table 3.9-108 provides information on group housing and ethnicity for King Cove in 1990, and similar information for 2000 is presented in Table 3.9-109. As with the other communities, group housing in the community is largely associated with the processing workforce. As shown, 42 percent of the population lived in group housing in 1990 and 38 percent in 2000. The distribution of ethnicity between housing types is striking. In 1990, the Alaska Natives/Native Americans comprised 67 percent of the non-group quarters population in the community, and the analogous figure for 2000 was 75 percent. For both 1990 and 2000, there was only one Alaska Native/Native American individual living in group quarters in the community (about one-half of one percent of the total group quarters population).

Shifts in ethnic populations are also apparent between 1990 and 2000, with the "Asian" group comprising over 64 percent of the group quarters population in 2000, up substantially from 1990. The "White" component of the population was smaller in absolute and relative terms in 2000 than in 1990 for the community as a whole and in group quarters. Among non-group quarters residents, the number of "White" residents was larger in 2000 than in 1990, but still represented a smaller proportion of the non-group quarters population in 2000 than in 1990. In other words, environmental justice is clearly an issue of potential concern for the community as a whole and for the seafood processing associated group quarters population in particular, and census counts suggest that minority representation has substantially increased over the period 1990 to 2000.

Table 3.9-110 presents information on the male to female ratio for King Cove for 1990 and 2000. The disproportional representation of males within the overall population is indicative of the transient nature of much of the workforce.

Table 3.9-111 provides information on group housing and ethnicity for Sand Point for 1990, and similar information for 2000 is provided in Table 3.9-112. As shown, 21 percent of the population lived in group housing in 1990, which was the lowest figure for the four communities detailed within this region. In 2000 this figure was 36 percent, which was greater than the King Cove figure for that same year. In 2000, no Alaska Natives/Native Americans lived in group quarters in the community, but comprised 66 percent of the population living outside of group quarters. As shown, the ethnic diversity among group quarter residents is, in general, substantially less in 2000 than in 1990, but detailed comparison of individual groups (other than White, Alaska Native/Native American, and Asian) is problematic due to missing data (the "unknown" category). Asians comprised over 60 percent of all persons living in group quarters in 2000 with persons of Hispanic origin accounting for about two-thirds of the remaining 40 percent of group quarter residents.

Table 3.9-113 presents information on age and sex of Sand Point's population for 1990 and 2000. As shown, the significant male-to-female imbalance seen in other large regional groundfish communities is present in Sand Point as well.

Industry Provided Data

Information on 2000 workforce demographics was obtained for four of the six major groundfish shoreplants in the Alaska Peninsula/Aleutian Islands region, as well as one of the two floating processors that are classified as inshore plants. At least some of the entities voluntarily providing these data consider them confidential or proprietary business information, but agreed to provide the information if it was aggregated with data supplied by others such that details about individual operations were not disclosed. As a result of these concerns, communities cannot be discussed individually. It can be stated that the total combined reported processing (and administrative) workforce of 2,364 persons was classified as 22.5 percent white or non-minority, and 77.5 percent minority. Reporting shoreplants ranged from having a three-quarters minority workforce to an over 90 percent minority workforce.

It is worth noting that different firms provided different levels of detail in the breakout of the internal composition of the minority component of their workforce. For some plants, the total minority figure was not disaggregated, and too few plants within this region provided detailed data to allow region-specific discussion. In general, however, all of the shoreplants in this region that provided detailed data have workforces that are 5 percent or less Black or African American and 5 percent or less Alaska Native/Native American (a pattern also seen in the detailed data from Kodiak plants). More variability was seen among other minority population components. The group classified as Asian/Pacific Islander was the largest minority group in two-thirds of the plants in any region reporting detailed data, and the group classified as Hispanic was the largest minority group in the remaining one-third. Two entities provided time series data. One provided data spanning a 10-year period, while the other provided information covering a four-year span. For the former, the minority workforce component increased over time; for the latter no unidirectional trend existed.

Regional Summary

The communities in the region that are most engaged in, and dependent upon, the groundfish fishery are those with populations comprised of more minority residents than non-minority residents. The structure of the minority population component varies from community to community, as does the proportion of the community population that is comprised of Alaska Native residents. Further, the workforce at the processing plants that would likely feel the impacts of the alternatives is overwhelmingly comprised of minority workers. While no systematic quantitative data are known, field observations would suggest that for a very substantial portion of the workforce, English is a second language (this is reinforced by data from local schools such as Unalaska, where 47 percent of the entering kindergarten students in 2000-2001 were English as a second language students) and languages other than English are commonly utilized in the workplace among processing crews. These factors, along with limited opportunity to acquire job skills in other economic sectors, would tend to indicate that these populations would be less able to easily acquire alternative employment outside of the seafood industry if there were widespread job reductions as a result of the alternatives. However, information on the level of job turnover/rates of rehire (discussed elsewhere [NPFMC2002d]) suggests that there is a fair degree of mobility among at least part of this workforce.

Kodiak Island Region

General Community Population Attributes

Within the Kodiak region, the City of Kodiak is the location of virtually all of the direct links with the groundfish fishery. Given these circumstances, it will be the only regional community discussed in detail.[34]

Kodiak is a complex community in terms of the ethnic composition of its population. Sugpiaqs (Koniags) were the original inhabitants of Kodiak Island. Beyond earlier development, fishing and military buildup associated with World War II brought many non-Natives to Kodiak, primarily Caucasians but also a substantial number of non-Native minorities, at least initially associated primarily with fish processing employment. Detailed information on community growth and the relative growth of different population segments is available elsewhere (NPFMC 2002d). The Alaskan Native population has remained at approximately the same percentage since the 1970s, but the white (non-minority) population has declined in terms of percentage over time. Overall, there has thus been a gradual, long-term shift in ethnic composition, with Asian and Pacific Islanders increasing in percentage. Census data from 2000 detailing ethnicity are presented in Table 3.9-114. As shown, the majority of Kodiak's population is comprised of minority residents.

The following two tables present information on income, employment, and poverty for the City of Kodiak and the Kodiak Island Borough and are based on 2000 U.S. Census data. Table 3.9-115 displays basic information on community housing, households, families, and median household and family income. As shown, the City of Kodiak is above the borough income averages. For example, median family income in Kodiak itself is about 3 percent higher than the borough as a whole. Compared to all communities in the region, the City of Kodiak places at the upper end of the range. In 2000 the highest median family income in the region was in the community of Chiniak, with a figure of $75,067, while the lowest figure was $19,167 for Karluk.

Table 3.9-116 displays data on employment and poverty for the City of Kodiak and the Kodiak Island Borough for 2000. As shown, there was very little unemployment in these jurisdictions, presumably due in part to the presence of fishery-related employment opportunities, and also due to the fact that the Kodiak economy is relatively diversified by rural Alaska standards (and particularly in comparison to the Aleutian region communities). The City of Kodiak had the second lowest unemployment of any civilian community in the region (3.6 percent compared to 2.1 percent in Port Lions), whereas the village of Old Harbor had the highest unemployment in the region at 12.5 percent. Proportions of the population considered to be below the poverty threshold varied between the communities, but as was the case in the Aleutian region, this is somewhat misleading. For example, Ouzinkie had the lowest poverty rate (6 percent) of any community in the region in 2000, but at the same time 48 percent of the adults in the community were not working. Old Harbor has the highest poverty rate in the region at 29.5 percent.

[34] Processing data does show that groundfish are also run at Alitak, but this is a relatively specialized operation and very small relative to the aggregated operations associated with the City of Kodiak.

Population Attributes of the Resident Groundfish Fishery Workforce

Table 3.9-117 provides information on group housing and ethnicity for Kodiak for 1990, and similar information for 2000 is presented in Table 3.9-118. Group housing in the community is largely associated with the processing workforce, but not to the nearly exclusive degree seen in the Aleutian communities. The institutional base and range of housing types in Kodiak is more complex. As shown, only 6 percent of the population lived in group housing in 1990, and only about 2 percent in 2000. This is a much lower percentage of population residing in group quarters than in the other communities profiled, and is consistent with a processing workforce more heavily drawn from the local labor pool. In 1990, while there was a significant difference between the group quarter and non-group quarter demographics (with the group quarter population being a higher minority group than the community population as a whole), the differences are not as sharp in general or for particular groups as seen in the Aleutian region communities. A similar pattern is seen in the 2000 data; however, the small numbers of persons involved make conclusions about the proportionality or trends of change between groups somewhat tenuous.

The male to female imbalance is present in the community, as shown in Table 3.9-119, but it is of a lesser magnitude than seen in the Aleutian region groundfish communities. This is consistent with Kodiak's fishery-related workforce being drawn more from the local community labor pool than is the case in the Aleutian communities.

Industry Provided Data

Given the nature of the relationship between the processing workforce and the local communities, industry information comparable to that of the Aleutians region was not systematically collected from Kodiak region entities. The information received was not sufficient to be able to disclose precise community level information due to confidentiality concerns. As a generality, the 2000 data received indicated that at least some shoreplants in this region have workforces with a greater minority population component than the Aleutian regional average (77.5 percent). This is despite the fact that, as a rule of thumb, the Kodiak processing workforce is drawn to a larger degree from a local labor pool than is the case for the Aleutian communities.

As was the case for the Aleutian region, different firms provided different levels of detail in the breakout of the internal composition of the minority component of their workforce. For some plants the total minority figure was not disaggregated, and not enough plants within this region provided detailed data to allow region-specific discussion. However, as mentioned in the Aleutian region discussion, all of the shoreplants in any region that provided detailed data have workforces 5 percent or less Black or African American and 5 percent or less Alaska Native/Native American. For the Kodiak region, the group classified as Asian/Pacific Islander was the largest minority group noted within the limited detailed data received.

Regional Summary

The community in the region that is most engaged in and dependent upon the groundfish fishery (Kodiak) is comprised of more minority residents than non-minority residents. While systematic data do not exist, the data that are available suggest that the workforce at the processing plants that would likely feel the impacts of the alternatives are primarily comprised of minority workers.

Southcentral and Southeast Alaska Regions

Environmental justice is likely to be much less of an issue in the southcentral and southeast Alaska region communities than in the Alaska Peninsula/Aleutian Islands and Kodiak Island regions, for several reasons. Of primary importance among these is the nature of the communities most directly engaged in the commercial groundfish fishery. As described in Section 3.9.3, the communities most engaged in the groundfish fishery in southcentral Alaska, particularly with respect to the processing sector, are largely non-Native communities, and have relatively large populations and diversified economic opportunities, especially compared to the Alaska Peninsula/Aleutian Islands groundfish communities. The same holds true for the southeast Alaska region, with the exception of Yakutat.

A second factor is the relatively low level of processing employment directly attributable to groundfish in these regions that could potentially be at risk under at least some of the groundfish management alternatives. For example, in 2001, there were only an estimated 106 FTE groundfish processing jobs among all of the communities in the entire southeast Alaska region (or about 33 times fewer groundfish processing FTEs than in the Alaska Peninsula/Aleutian Islands region). While the potential loss of these positions would, of course, be of consequence for the individuals and operations involved, the diversity of processing operations, size and diversity of community populations, and the availability of alternative economic opportunities would serve to dampen the environmental justice dimension of any impacts realized at the community or regional level.

Similarly, in 2001 among all of the communities in the southcentral Alaska region, there were an estimated 150 groundfish processing FTEs, or about one-quarter the number found in Kodiak alone. These community and workforce factors, especially in combination, mean that, in general, the type of environmental justice concerns seen in the Alaska Peninsula/Aleutian Islands and Kodiak Island regions are largely absent. Further, environmental justice concerns linked to Steller sea lion and salmon subsistence activities are also largely absent in these two regions. As a result, detailed environmental justice existing conditions information has not been developed for these regions. The regional data presented in Section 3.9.3 are considered sufficient for analytical needs.

Washington Inland Waters Region

General Community Population Attributes

The greater Seattle area is the center for much of the economic activity related to the North Pacific groundfish fishery, but the geographic footprint of those activities is difficult to define. The boundaries cannot be attributed to specific communities or neighborhoods in the same manner as Alaska communities may be linked to the fishery, as discussed in detail elsewhere (NPFMC 2002d). For comparative purposes, and so that the information on the Seattle-based catcher processor sector described below can be compared to the greater Seattle population base, Table 3.9-120 provides ethnicity data for the Seattle-Tacoma Consolidated Metropolitan Statistical Area (CMSA) as defined by the U.S. Bureau of the Census.[35] As

[35] A Consolidated Metropolitan Statistical Area (CMSA) consists of two or more contiguous MSAs The Seattle-Tacoma WA CMSA consists of Seattle, WA PMSA (1) King and Snohomish Counties, and (2) Tacoma (Pierce County). A Metropolitan Statistical Area can be defined as a city of over 50,000 inhabitants together with the county in which it is located and contiguous counties which are economically and socially integrated with the central city. It may also consist of an urbanized area of 50,000 with

shown, unlike the Alaska groundfish communities, the white portion of the population comprises a large majority of the overall population (i.e., racial or ethnic groups classified as minorities are mathematical minorities within the local overall population, unlike the relevant Alaska communities).

Information on household income and employment and poverty information for the Seattle-Tacoma CMSA comparable to that provided for the relevant Alaska groundfish communities is not presented here. These types of data at the CMSA level are not meaningful for this environmental justice analysis due to their high level of aggregation.

Population Attributes of the Resident Groundfish Fishery Workforce

Given the nature of engagement with the fishery, the Washington inland waters region does not have the same type of resident workforce focused in individual communities in a manner comparable to that seen in Alaska communities, as discussed above. Rather, this environmental justice analysis will focus on industry provided sector data as described below.

Industry Provided Data

As noted in the introductory discussion, catcher vessel ownership and crews are assumed to reflect the overall demographic make up of the male working age population in their home communities. Although systematic demographic data were not collected for the groundfish catcher vessel crews in the Washington inland waters region, interviews with local sector association personnel suggest that minority population representation within this sector does not exceed the proportion of minority representation in the general population; therefore, environmental justice is not an issue with respect to potential impacts to this sector.

Shore processing plants are not present in this region, and the mothership sector data cannot be presented due to confidentiality restrictions based on the small number of entities. As a working assumption, it is assumed that the mothership employment structure is similar to that of the catcher processor sector, although the catcher processor sector may have a somewhat higher minority representation in the workforce due to more consistent targeted hiring in rural Alaska.

Information on catcher processor workforce demographics for 2000 was obtained from seven entities that together account for almost all (99 percent) of the non-CDQ target pollock caught by trawl catcher processors in the BSAI as well as 86 percent of the CDQ pollock. (While these entities also catch a significant amount of Pacific cod, catch among catcher processors in the Pacific cod fishery is more dispersed over a larger group of participating entities.) Different firms provided different levels of detail in the breakout of the internal composition of the minority component of their workforce, but the detailed information provided encompassed 1,906 out of the 2,126 persons reported, or 90 percent of the total reported workforce. Table 3.9-121 provides ethnicity information for those entities reporting detailed breakouts.

As shown, the portion of the workforce within the detailed reporting set was 36.9 percent white or non-minority and 63.1 percent minority. Adding the more highly aggregated data does not significantly change the overall minority/non-minority ratio. Within the total set of responding entities, individual entity

a total metropolitan area population of at least 100,000.

workforces ranged from a 36 percent minority workforce to an 85 percent minority workforce. Among entities reporting detailed data, Hispanic was the largest minority component in every entity's minority workforce segment, with one exception (in which case the largest minority segment was Asian/Pacific Islander, and Hispanic was second). Apart from the entity where Asian/Pacific Islander workers were the largest minority worker segment, Asian/Pacific Islanders were the second largest minority group represented for all but one of reporting entities (in which case the second largest group was Alaska Native/Native American).

Regional Summary

For reasons discussed earlier, environmental justice is not a regional or community level issue for North Pacific groundfish management initiatives for the Washington inland waters region or the greater Seattle area. Although quantitative data are not available to confirm this, based on interview data it does not appear to be an issue for the regionally based catcher vessel fleet either. As there are no Alaska groundfish shore-based processing entities in this region, the types of environmental justice issues associated with these workforces seen in some of the Alaska regions are not present in this region. Industry-provided data for the catcher processor sector, however, show that environmental justice is a potential issue among that sector's workforce. While the population of the greater Seattle area was 23 percent minority in 2000, this workforce was 63 percent minority for that same year. If substantial job losses in this sector were to occur under various management alternatives, they would disproportionately accrue to minority populations. As noted elsewhere (NPFMC 2002d), while most of the hiring for catcher processor entities is done out of the greater Seattle area, there are targeted hiring efforts directed at Alaska residents in general and Alaska Native residents in particular. In addition to CDQ-related employment issues associated with this sector and discussed separately, loss of other Alaska Native held jobs in the catcher processor sector is also a potential environmental justice issue, but not for the Washington inland waters region.

Oregon Coast Region

There is no indication from available information that environmental justice will be an issue in the Oregon coast region. No BSAI groundfish processing plants operate in this region, nor are any owned by residents of this region, so populations associated with this sector are not a concern. As detailed elsewhere (Section 3.9.3), this region is engaged in the Alaska groundfish fishery primarily through the catcher vessel sector. While demographic data on catcher vessel owners and crews are not available, discussions with industry sources and familiarity with the fishery would seem to indicate that this group is not disproportionately comprised of individuals from minority populations.

3.9.6.4 Other Alaska Native Specific Environmental Justice Issues: Community Development Quota Regions, Subsistence, and Community Outreach

Two main socioeconomic issue areas discussed elsewhere in this document are central to environmental justice considerations. For reasons noted below, impacts to the CDQ program and its associated communities as well as impacts to subsistence (and the relevant associated communities) are likely to raise environmental justice concerns. In addition to these two issue areas that potentially involve specific impacts to minority populations and low-income populations, addressing environmental justice concerns also involves a proactive dissemination of information to minority populations and low-income populations that may otherwise be under-represented in the public involvement process. To address this type of concern, a concerted effort was made to contact a large number of Alaska Native entities, as summarized below.

The CDQ region of western Alaska is a specific area of concern for environmental justice issues with respect to the potential fishery management alternatives covered by this Programmatic SEIS. The CDQ program was explicitly designed to foster fishery participation among, and to direct fishery benefits toward, minority populations (87 percent of total population in these villages is comprised of Alaska Native residents) and low-income populations in the economically underdeveloped communities in western Alaska. To the extent that the CDQ program has achieved these objectives, negative impacts to the CDQ program and communities are essentially, by definition, environmental justice impacts. CDQ region existing conditions are discussed in Section 3.9.4 and in greater detail elsewhere (NPFMC 2002d).

Subsistence impacts are also potential environmental justice issues, given the disproportionate involvement of Alaska Natives in subsistence activities. Relevant existing conditions information for subsistence is summarized in Section 3.9.5. As noted in that section, there is the potential for subsistence activities to experience impacts associated with various management alternatives in the areas of groundfish subsistence (through direct competition for the resource), subsistence use of Steller sea lions (through indirect impacts to Steller sea lion populations), joint production subsistence opportunities (through curtailment of the ability to effectively utilize commercial vessels or gear for subsistence purposes), and some subsistence salmon fisheries (through at-sea bycatch interception of chinook and chum salmon).

The geographic area of potential impact to subsistence (and therefore the communities potentially involved) varies by type of subsistence activity. Joint production impacts are, by definition, limited to areas that are directly engaged in the commercial fishery. On the other hand, vast tracts of the Interior of Alaska with dozens of villages are engaged in the relevant subsistence salmon fisheries. In addition to impacts to subsistence potentially qualifying as an environmental justice issues as a result of disproportional Alaska Native (minority population) involvement, impacts to subsistence are also likely to be environmental justice impacts. For a number of the relevant communities, subsistence is an important aspect of community economic life where commercial economic opportunities are limited and incomes are relatively low (i.e., low-income populations are involved in subsistence in some areas). Not only would an impact to subsistence potentially be a disproportionate impact to a low-income population, the impact would make a low-income population even worse off in economic terms than under existing conditions. Information on existing conditions in the areas and communities involved in the relevant subsistence activities may be found in Section 3.9.5.

The Executive Order on environmental justice (EO 12898) specifies that it shall apply equally to Native American programs and calls for consultation with Federally-recognized Indian Tribes. In terms of specific outreach to include Alaska Native entities and populations in this Programmatic SEIS process, contacts appropriate for government-to-government consultations (pursuant specifically to EO 13175) were made, and Alaska Native groups were contacted individually over and above the regular scoping process notifications. This was to ensure the opportunity for these entities to provide input and receive information consistent with the notification and disclosure intent of environmental justice concerns. Specific notification of Alaska Native communities and entities was conducted utilizing a contact list developed during the original North Pacific groundfish Programmatic SEIS effort. During that effort, NOAA Fisheries obtained from the Bureau of Indian Affairs a list of all entities that are formally recognized by the federal government as tribal governments in Alaska. A subset of this state-wide list was created by employing (and extending) the CDQ eligibility criteria, including use of a 50-nautical-mile buffer from the coast. Additional entities were added to the list by using this methodology not only in the BSAIs area (like the CDQ program itself), but also by applying it to the entire Alaskan GOA coast as well. All of the approximately 250 entities on the Bureau of Indian Affairs list that fell within this 50-nautical-mile wide coastal swath were placed on the contact list. These entities were contacted regarding the Programmatic SEIS process and public involvement opportunities, and encouraged to begin correspondence with NOAA Fisheries. This targeted process encompasses an area and set of Alaska Native entities and communities in the coastal region larger than those directly involved in the fishery, the CDQ region, or the subsistence activities of concern noted above (with the possible exception of some Interior subsistence salmon communities).

3.9.7 Market Channels and Benefits to U.S. Consumers

3.9.7.1 Groundfish Products and Market Channels

This section first provides a summary of the primary products derived from the Alaska groundfish fisheries and a brief overview of secondary processing and product distribution activities. Next, the difficulties of tracking the movement of groundfish products to their final point of sale are examined. Lastly, available data are used to summarize the product flows and markets for pollock, Pacific cod, sole, and rockfish.

Primary Products

Groundfish harvested in the Alaska fisheries are processed at a variety of inshore facilities and on motherships and catcher processors (Section 3.9.2). The groundfish are made into a wide range of primary products. In this analysis, primary product is defined as the product form after the initial stage of processing.[36] By this definition, all products produced directly from raw fish are considered primary products. These products may be table-ready or final product, but more often they are reprocessed before they are sent to retail markets or foodservice establishments. Secondary processing is defined as any processing that occurs after the primary products have been transferred to a different facility. Secondary processing includes the production of kamaboko from surimi and the production of breaded fish sticks from fillets.

Table 3.9-122 shows the various primary products by weight made from Alaska groundfish during the 1992-2001 period. Table 3.9-123 shows the various primary products by wholesale value for the same period. Atka mackerel (a member of the A-R-S-O species group) is primarily produced as a headed and gutted or whole product. Most flatfish by volume are also headed and gutted, often with the roe left intact. A large percentage of flatfish are frozen whole, while a small percentage, primarily yellowfin sole, are made into kirimi, a steak-like product. Almost all sablefish are produced into head-and-gut product. Most of the product made from Pacific cod is headed and gutted, but a significant proportion is also made into fillets. Comparing products by weight can be misleading. Fillets are typically skinless and boneless product. A 5-pound Pacific cod might yield 1.25 pounds of fillets. The price per pound for fillets is higher than for head-and-gut product, primarily because fillets require less secondary processing. Surimi constitutes the largest portion of pollock

[36] This definition of primary processing differs from definitions used by processors when they report production to NOAA Fisheries in Weekly Processor Reports. In weekly reports processors differentiate primary products, such as fillets or surimi, from ancillary products, such as roe and fish meal.

product, with fillets accounting for the next largest percentage. Pollock roe, which accounts for only 4 percent of total product by weight, is extremely important to processors because of its high price in Japan. Substantial amounts of meal and oil are also produced from pollock, although these are generally ancillary products made from bones, skin, and trimmings.

Overview of Secondary Processing Activities

During the period covered in this analysis (1992-2001), there were no major secondary processors operating in Alaska. Almost all product was shipped out of Alaska in primary form. Recently, Alaska Seafood International Company began operations in a seafood processing facility constructed in Anchorage in 2000 and is preparing table-ready products from a variety of Alaska fish, including some groundfish. The Alaska Industrial Development and Export Authority, a state agency, has invested $50 million in the processing plant and owns the title to the company's buildings and land. To date, the enterprise has sent shipments of processed salmon, halibut and Pacific cod to markets in England and the Lower 48.

Groundfish harvested in Alaska is most often exported as primary product, although some leaves in a raw form, such as whole frozen fish. While most of the groundfish products are exported to Asia and Europe, some are shipped to the Lower 48. How much remain in the U.S. and how much are shipped abroad varies from year to year. Products shipped to the Lower 48 may either be reprocessed (primarily in the Washington inland waters region) or re-sorted and exported as a primary product. Companies such as Icicle and Trident have primary production capacity in Alaska and secondary processing plants in the Puget Sound area. In these cases it would be possible to track how much Alaska product is used in secondary processing facilities and the related number of workers. However, numerous other food manufacturers take primary groundfish product from Alaska to make a variety of table-ready foods and other products. For example, Gorton's has secondary processing facilities that reprocess groundfish products from Alaska and other areas. Data on the number of workers in all such facilities and the percentage of primary product at these facilities that originates in Alaska are not available.

Transportation Facilities

Groundfish are transported from Alaska to domestic ports (primarily in the Washington inland waters region) by a number of different carriers, depending on where the fish is processed. For example, the primary carriers operating in western Alaska include CSX Lines, Coastal Transport, Samson Tug and Barge, and Northland Services. The primary carriers in central Alaska include Totem Ocean Trailer Express as well as those operating in western Alaska.

Groundfish transported from Alaska to foreign ports typically are carried by foreign tramper vessels. Product carried from the Pacific Northwest to foreign ports can be carried by foreign trampers or steamships. In the past, some product transported from the U.S. to foreign ports was carried by American-owned and American-flagged companies, such as American President Lines and Sea Land. However, Sea Land is no longer American-owned or flagged and American President Lines is not American-owned. Such changes in ownership and flagging limit the role domestic companies play in the movement of Alaska groundfish and, therefore, limit the scope of potential impacts on U.S. shipping lines from any changes in the groundfish fisheries.

Data Limitations

Sufficient data are not readily available to analyze the volume or value of groundfish shipments from Alaska (in primary or any other form) to the Lower 48 or to foreign markets. Purchasing detailed shipping data from commercial vendors such as the Port Import Export Report Service was beyond the scope of the project. Other data limitations include aggregation levels too broad for a meaningful analysis, confidentiality constraints and different species and product groupings across data sources. For example, the U.S. Seafood Trade Report tracks annual seafood production and export volumes by fish species. How much cod was actually produced in Alaska can not be determined from a category such as "frozen cod fillets." Commercial Fisheries Entry Commission data provide insights into how much primary product, by species or product type, comes from Alaska. Unfortunately, it is not always possible to combine data from different databases because the categories often differ from one database to the next. NOAA technical memorandums are also available that focus on the production of fish products and exports of edible fishery products. These reports show the volume and value of groundfish products exported each year from the Pacific Northwest. For some species, such as Alaska pollock, it is clear where the product originated, and time-series data are available to chart changes in production and export patterns over time. However, for other species the origin is uncertain.

Market forces and variation in product forms also make it difficult to track the flow of groundfish products to a particular destination. The final destination of a primary or secondary product depends on the quality of the product, food prices and many other factors. Decisions about what to produce and where to ship it are made by fish buyers and brokers and may not be made until a fishing vessel reports the type of species being harvested, as well as the size, quality and other information.

Product Flows and Markets for Selected Groundfish Products

Notwithstanding the data problems described above, it is possible to summarize product flows for major groundfish products. The following sections present case studies of product flows for pollock, Pacific cod, sole and rockfish harvested in the Alaska groundfish fisheries. Using the official data available and anecdotal information, these case studies are intended to provide a general sense of the types of products made from Alaska groundfish and the movement of those products to their final point of sale.

Pollock

The following sections summarize the major markets for pollock and the principal primary and secondary processors, market developments and transportation issues related to pollock.

Major Markets. Roughly two-thirds of the pollock caught in the Alaska groundfish fisheries is made into surimi, a fish paste product that can be used to make kamaboko (a traditional Japanese food) and numerous other products. In the United States surimi is used to make imitation seafood products such as artificial crabmeat. Most of the surimi is produced for Asian markets, with Japan being the single largest market. The United States is by far the leading country providing pollock surimi to the Japanese market (NMFS 2001b). Pollock roe is harvested as an ancillary product during the winter spawning season. The roe is frozen or salted and commands premium prices in Japan. After the roe is stripped from the pollock the fish is further processed into surimi or fillets (NMFS 2001b).

The primary market for pollock fillets is the domestic market. Around 15 percent of the total pollock harvest is made into deep skin blocks (fillets with the skin and fat removed), primarily for U.S. fast food restaurants, including McDonald's, Long John Silver's and Burger King. Most processing for this market occurs at the primary processing level. Approximately 3 to 5 percent of the total pollock harvest results in individually quick frozen blocks for the U.S. foodservice industry. This product serves as a substitute for other whitefish fillets. Most of the remainder of the harvest is typically made into traditional blocks that can be used in the European market. All other pollock products, including minced fish, fish headed and gutted, whole fish and oil, account for just 7 percent of the primary product value. Pollock is a fragile fish that deteriorates rather quickly after harvest, so very little is sold fresh (NMFS 2001b).

The volume of production of surimi, roe and fillets has fluctuated from year to year, reflecting differences in total harvest volume, the mix of products produced by processors, and product utilization rates. Figure 3.9-18 shows the destination of exports of surimi made from pollock in 1995 and 2001. Most of these exports are to Japan, although there is a small but growing amount exported to South Korea. The balance of exports reach select ethnic markets in primarily European countries (NMFS 2001b). Figure 3.9-19 shows that the destination of exported pollock fillets changed considerably between 1995 and 2001.

Principal Primary and Secondary Processors. The most significant primary processors are the inshore plants, motherships, and catcher processors described in the earlier sector analyses (Section 3.9.2). The secondary processors are more difficult to describe. Several companies with ownership positions in primary processing facilities also have secondary processing facilities. At the same time, many other companies with secondary processing facilities have no direct connection with the primary processing facilities.

The only U.S. secondary processing facilities producing surimi products are in Washington State. One facility is owned by Icicle and the other by Trident. Both facilities make surimi products for export and for use by U.S. food manufacturers. The Icicle facility (which produces kamaboko from surimi) is located in Bellingham and has 115 full-time employees. Icicle purchased the *Northern Victor*, a FLP, and expects all surimi used in the Bellingham plant in the future to be made from Alaska pollock (in the past, some surimi produced at the facility was made from locally-harvested hake/whiting).

Market Developments. As noted above, surimi from Alaska is sold primarily to markets in Japan. Surimi made from pollock is considered to be superior to most, if not all, other surimi; there are no close substitutes (NMFS 2001b). Some surimi exported to Japan is made from Pacific whiting harvested off the coast of Oregon and Washington. It is generally acknowledged that the surimi made from Pacific whiting is of lower quality and serves a different niche market (NMFS 2001b). Consequently, pollock surimi exports to Japan are price inelastic – the demand for this surimi does not soften much in response to a modest price increase. The effects of price for intermediate products such as surimi may also be cushioned by supply contracts and vertical integration among surimi processors, wholesalers, and retailers in Japan (NMFS 2001b).

The demand for traditional surimi products, such as kamaboko, may be declining in Japan. One possible reason is that much of the demand comes from older Japanese. The younger generation in Japan and many other Asian countries appears to prefer western foods. On the other hand, surimi can be used in the production of a variety of foods. The net effect of a decline in demand for kamaboko may not necessarily be a decline in overall demand or production of surimi. Instead, the effect could be a shift in how surimi is used and where it is shipped. A fish buyer interviewed for this analysis stated that food manufacturers in the U.S. may find new uses for surimi because it is a good binder in processed foods and retains water.

As recent as the late 1980s, domestic quick service and seafood restaurant chains mainly used Atlantic cod (NMFS 2001b). When Atlantic cod harvests in Canada and the United States declined significantly in the early 1990s, chains such as McDonald's and Long John Silver's moved to the more consistently available Alaska pollock as their primary source of fillets. However, the United States does not supply all the fillets demanded by domestic consumers (NMFS 2001b). The balance is made up from imports of Alaska pollock blocks. China is the biggest supplier of U.S. imports of pollock, followed by Russia. Most of the imports from China are of Alaska pollock harvested in Russian waters by both Russian and foreign fleets. Wholesale prices for U.S. produced single-frozen fillets and fillet blocks peaked in 1999 and have since fallen dramatically. In contrast, prices of imported double-frozen fillets and fillet blocks have been much lower and more stable. Since 1999, prices of U.S. products have fallen to close to the levels of imported products. Contributing to the sharp decline in prices for U.S. product has been a dramatic increase in U.S. imports of pollock, which are primarily frozen fillets and frozen fillet blocks.

Transportation. Primary products from pollock that are produced at sea are offloaded to trampers, which take the products directly to secondary processors in Asia, the Lower 48 (Puget Sound area) or Europe. Primary products produced in shoreside facilities typically are shipped by one of the primary marine carriers to Japan or Puget Sound. Marine shippers have charged the same price to ship products from Dutch Harbor to Japan, whether routed through Seattle or not. The price has been the same for the different routes because of the lower cost of cold storage in the Bellingham and Seattle areas. This fact underscores the significance of factors such as size of inventories and cost of storage in determining product flows from Alaska.

Pacific Cod

The following sections summarize the major markets for Pacific cod and the principal primary and secondary processors and market developments related to Pacific cod.

Major Markets. Pacific cod harvested in the Alaska groundfish fisheries enters an international market, but much of it remains in the United States for use in the foodservice industry. Pacific cod fillets are destined primarily for the domestic market. Foreign consumers, especially China, Japan, and Europe, purchase headed and gutted cod for further processing, including the production of salt cod. Salt cod is very popular in Europe, parts of Africa, and Latin America. Although most of the Pacific cod that becomes salt cod is processed outside the U.S., some U.S. processors are once again producing the product domestically for export, as they have at times in the past.

The production levels, mix of primary products, and amount of product exported from Alaska change from year to year for Pacific cod products. Products from other groundfish species show a similar range of variability in product type and distribution paths. Moreover, the final destination of a given product can change dramatically, making it almost impossible to predict the future market for a given product.

Principal Primary and Secondary Processors. No rules of thumb exist for how much Pacific cod is processed in particular facilities because the amount depends on how much cod was harvested by different gear types. In general, freezer longline vessels produce the highest quality product, which goes to salt cod markets. There is a new secondary processing plant in Seattle for salt cod, and additional product is stored in the Seattle area and shipped east. The majority of this product, however, is destined for overseas markets by way of Korea. Pacific cod processed as head-and-gut product or whole fish is exported to Korea, where it is containerized for shipment to Norway and other countries. This product may or may not be reprocessed in Korea. Some of the product that moves through Korea returns to markets in the United States (especially through Boston), but most goes to the major cod markets in Norway, Spain and Portugal for secondary processing or final consumption. Most product sold in Europe and the United States is boneless. Bone-in product (pin bones in) is sold in European markets on an "order only" basis.

Market Developments. Product flows for Pacific cod have changed dramatically in recent years, following the decline of Atlantic cod harvests in the Barents Sea. For example, buyers from Norway and Portugal are now purchasing Pacific cod from Alaska for the first time. Historically, Pacific cod has been considered an inferior product compared to Atlantic cod, but the lack of Atlantic cod has made Pacific cod more acceptable. As a result, prices for head-and-gut cod products from Alaska have doubled in the last three years, and the demand for these products is also increasing in Japan.

With recent declines in the Alaska crab fishery, other gear types harvesting Alaska cod have included pot vessels. Cod harvested by these fishermen typically is brought to shoreplants, where it is made into fillets or head-and-gut product. Pot vessels have a reputation for harvesting high-quality cod, enabling shoreplants to make a high-value primary product.

Sole and Rockfish

The following sections summarize the major markets for sole and rockfish and the principal primary and secondary processors and market developments related to sole and rockfish. Sole and rockfish are combined in this section because fish buyers and cold storage operators interviewed for this analysis discussed sole and rockfish together.

Major Markets. Approximately 80 to 90 percent of the sole and rockfish harvested in the Alaska groundfish fisheries is shipped to Asia. A portion of this harvest goes from Asia to Europe, and a very small amount is sometimes shipped directly from Alaska to Europe.

Principal Primary and Secondary Processors. Sole and rockfish processed offshore typically are shipped to Asia in headed and gutted or round form. Shore plants produce fillets as well as other products, with some products going to Asia and others remaining in the United States.

The relatively small fillets of sole and rockfish have a high labor cost per pound. This high labor cost makes it more attractive to ship the fish to China, where labor costs tend to be relatively low for secondary processing. Readily available data for sole and rockfish do not indicate the product type or amount exported from Alaska.

Market Developments. A wide range of species of sole and rockfish is harvested in Alaska, some of which are unnamed in the United States. This variety and the lack of name recognition is an issue with U.S. consumers who tend to prefer known products and reinforces the tradition of shipping sole and rockfish products to Asia. Consumers in Asia tend to be less name-sensitive with fish species.

Rockfish from Iceland and Norway has historically been considered superior to most Alaska rockfish. Only select species of rockfish found in Alaska are considered high-quality and easily marketed in countries such as Japan. Very little of the product goes to the Lower 48. Much of the sole and rockfish sold in U.S. East Coast markets, such as New England and Florida, comes from Indonesia. One cold storage manager in Seattle said he expects secondary processing facilities in the United States to handle Alaska sole and rockfish in the future and believes more of this product will move from Alaska to the Lower 48 rather than to Asia.

3.9.7.2 Benefits to U.S. Seafood Consumers

In the past two decades U.S. consumers have been eating more seafood—averaging around 15 pounds per person in the last four years, up from less than 12 pounds prior to1980 (NMFS 2002g). In 2002, the consumption of seafood by U.S. consumers was 4.5 billion pounds — 15.6 pounds per person. Of this, 11 pounds were fresh or frozen fish or shellfish, 4.3 pounds were canned seafood, and 0.3 pounds were cured. The National Fisheries Institute recently ranked the most popular varieties of seafood, with shrimp holding first place for the second straight year at 3.7 pounds per person. Canned tuna held second place. Next came salmon, pollock, catfish and cod. Seafood sales to the domestic foodservice sector have risen every year since 1995 (H.M. Johnson & Associates 2001). Seafood now represents 20 percent of menu entrees at the nation's top 200 restaurant chains (Seafood.com 2001). Much of the increase in the demand for seafood stems from its perceived healthful properties. In recent years, seafood has been credited with having ingredients that reduce heart disease, arthritis and depression and enhance sexual performance (Seafood.com 2001). A major impetus in seafood consumption recently occurred when the American Heart Association recommended that people eat fish twice a week for its health benefits.

Products obtained from the Alaska groundfish fisheries have undoubtedly played a major role in meeting this domestic demand for seafood. However, the data limitations outlined in Section 3.9.6.2 make it difficult to estimate the final domestic market value of Alaska groundfish products. For example, NMFS (2001b) reported that Alaska pollock ranked fourth overall at 1.57 pounds, after tuna, shrimp, and salmon, in per capita consumption in 1999, but it is not possible to accurately determine how much of the pollock that U.S. consumers purchased was produced in the Alaska groundfish fisheries. Still less information is available on the value of Alaska groundfish products as measured by the level of consumer surplus (i.e., the difference between the amount consumers are willing to pay for a good or service and the amount they actually pay) accruing to the American public from the consumption of those products.

Nevertheless, it is known that the market for Alaska pollock fillets and Pacific cod fillets is mostly a domestic market, and the demand within the United States far exceeds the available supply (NMFS 2001b). The Alaska pollock harvest supplies most of the frozen whitefish, fish sticks, fish patties and imitation crab meat (surimi) purchased at stores and restaurants around the United States (Alaska Seafood Marketing Institute undated[a]). The delicate texture, white color and mild flavor of the pollock's flesh have proven ideal for every segment of the foodservice market from fast food to white tablecloth restaurants. What's more, its stable supply enables restaurants to maintain consistent menu pricing throughout the year. Pacific cod is also a popular item in the foodservice sector because of its versatility, abundance and year-round availability (Alaska Seafood Marketing Institute undated[b]). Most of the product is used in finer and casual restaurants, institutions and retail fish markets.

Despite the high demand for certain groundfish products among U.S. consumers, numerous past studies have indicated that the price elasticity of demand for those products, especially fillets, is fairly high (NMFS 2001b). In other words, market price is not appreciably affected by the quantity supplied. This is because the domestic fillet market is competitive in terms of product form (individually quick frozen, block, and twice-frozen), supplying country (Russia and China play major roles), and fillets from other species, including hake and hoki. The U.S. market for all fillets, particularly cod, has also been influenced by the increased production of aquaculture-grown whitefish (NMFS 2001b). The species of greatest significance is catfish, but in recent years there have been increases in both domestically produced and imported tilapia. The domestic production of catfish increased from 208,000 mt in 1993 to 271,000 mt in 2001,virtually all of it consumed domestically. Furthermore, seafood, in general, must compete with other animal protein sources in the American diet such as chicken, pork and beef. Consequently, the per unit price for pollock or Pacific cod fillets would probably rise only if there were a large decrease in the amount of pollock or Pacific cod fillets supplied to the domestic marketplace by U.S. firms.

The most likely result of a decrease in the domestic production of fillets would be a negative effect on the trade balance, as more fillets are imported to offset the reduced supply. For example, a significant share of domestic pollock fillet demand is presently satisfied by imports. U.S. imports of Alaska pollock more than doubled during the 1990s (NMFS 2001b). China, in particular, has emerged as a major supplier of Alaska pollock fillets. Imports of frozen fillets and blocks from China were less than 5,000 mt in 1991 but increased to about 68,000 mt by 2000. The role of China in supplying Alaska pollock fillets to the U.S. market could continue to expand. The "twice-frozen" fillets and blocks from China are generally lower in quality than "single-frozen" U.S. product, but are often substituted for the latter because of their competitive price (NMFS 2001b). If retail market supplies are not expected to change due to ready availability of imports, a given regulatory action may have little or no impact on American consumers. Also, the dollar amount of the consumer surplus associated with the domestic consumption of Alaska groundfish likely represents a small fraction of the total net benefits that U.S. consumers receive from all goods and services they purchase or even from all seafood products they consume.

Seafood products obtained from the Alaska groundfish fisheries are also distributed to U.S. consumers outside of established market channels. Amendment 28 to the Fishery Management Plan for Bering Sea and Aleutian Islands groundfish and Amendment 29 to the Fishery Management Plan for GOA groundfish authorize a voluntary donation program for fish taken as bycatch in the groundfish trawl fisheries off Alaska. The seafood is distributed to economically disadvantaged individuals by tax-exempt organizations through a NOAA Fisheries-authorized distributor. Currently, the authorized distributor is Northwest Food Strategies, a 501(c)) 3 non-profit organization. Northwest Food Strategies accesses seafood products for distribution to the America's Second Harvest network of 200 food banks and food-rescue organizations (Northwest Food Strategies undated). Since it's inception in 1994, Northwest Food Strategies has grown into the leading supplier of seafood to hunger-relief organizations in the country. The fish voluntarily donated by the groundfish fishing industry to Northwest Food Strategies are salmon and halibut that are part of the groundfish fishery prohibited species catch. The salmon and halibut retained and donated under the NOAA Fisheries Prohibited Species Donation Program represent a small, but significant portion of the seafood distributed by Northwest Food Strategies. It is estimated that catcher processor companies donate one million seafood meals annually to provide hunger relief. A summary of past/present effects of actions and events on market channels and benefits to consumers is presented in Table 3.9-126.

3.9.8 The Value of the Bering Sea and Gulf of Alaska Marine Ecosystems (Including Non-Consumptive and Non-Use Benefits)

Examples include the seafood produced in commercial fisheries. In addition, some non-consumptive activities such as those associated with eco-tourism may also produce goods and services with observable prices (e.g., wildlife tours). A marine ecosystem and individual species associated with that ecosystem may provide a range of benefits to humans (NRC 2001). These benefits span a spectrum from direct on-site user benefits to benefits accruing to individuals who do not use the marine ecosystem but who derive value from knowing it is being protected. Direct, on-site uses of the marine environment are typically associated with consumptive activities (commercial and sport fisheries, resource extraction from the sea bed, etc.); however, non-consumptive activities such as tourism, diving, bird and whale watching, and appreciating the general aesthetics of wild areas are also valuable to humans. The benefits of consumptive activities that produce goods and services exchanged in markets are comparatively easy to evaluate, as the goods and services generated have observable prices. Examples include the seafood produced in commercial fisheries. In addition, some non-consumptive activities such as those associated with eco-tourism may also produce goods and services with observable prices (e.g., wildlife tours).

However, marine ecosystems may also provide goods and services that are not exchanged through markets and do not receive market prices (NMFS 2000c). These are referred to by economists as non-market goods and services. Examples include recreational fishing experiences and opportunities for subsistence activities. The values accredited to non-market goods and services, like the values assigned to market goods and services, are variable across a population and may change over time for a given individual. Including non-market goods and services in economic analyses of fishery management decisions is particularly important when considering habitat, ecosystem and many marine mammal issues (NMFS 2000c).

This discussion of the range of possible potential benefits provided by the GOA and Bering Sea marine ecosystems and associated species consists of five subsections. The first subsection outlines the array of economic values that individuals may attribute to environmental assets and amenities. The next three subsections examine the various value categories as they relate to the Bering Sea and GOA ecosystems as a whole and to two components of these ecosystems: groundfish and the Steller sea lion. The fifth section discusses values that lie outside the categories of values subject to economic investigation but that may be relevant to decision-making. These values are presented by their proponents as moral imperatives and, thus, do not lend themselves to analyses of economic tradeoffs. This discussion of the range of possible potential benefits provided by the GOA and Bering Sea marine ecosystems and associated species consists of five subsections.

Giving special consideration to the benefits derived from the Bering Sea and GOA marine ecosystems is consistent with the directive of NEPA to consider the significance of potential effects in terms of their intensity or severity of impact (15 CFR 1508.27). Among the factors listed by NEPA that should be considered in evaluating intensity are the unique characteristics of the geographic area such as proximity to ecologically critical areas (15 CFR 1508.27(b)(3)). The Bering Sea and GOA marine ecosystems are among the most productive in the world, and any modification of these ecosystems may have a dramatic effect on the quality of the human environment. Giving special consideration to the benefits derived from the Bering Sea and GOA marine ecosystems is consistent with the directive of NEPA to consider the significance of potential effects in terms of their intensity or severity of impact (15 CFR 1508.27). Among the factors listed by NEPA that should be considered in evaluating intensity are the unique characteristics of the geographic area such as proximity to ecologically critical areas (15 CFR 1508.27(b)(3)). Alaska's healthy ecosystems are scarce and valuable natural assets (Colt 2001). As human population, economic development and other pressures increase worldwide, the relative scarcity– and hence the value– of these ecosystems is almost certain to increase significantly. The Bering Sea and GOA marine ecosystems are among Alaska's most important ecosystems. They may be most productive marine areas in the world, and any modification of these ecosystems may have a dramatic effect on the quality of the human environment.

Devoting particular attention to the endangered Steller sea lion is also consistent with the directive of NEPA to consider the intensity of potential effects. A second factor that NEPA states should be considered in evaluating intensity is the degree to which an action may adversely affect an endangered or threatened species or its habitat (15 CFR 1508.27(b)(9)). In 2001, NOAA Fisheries prepared a SEIS on Steller sea lion protection measures, together with a biological opinion. The biological opinion concluded that the effects of the BSAI and GOA groundfish fisheries, as modified by the proposed action implemented by the preferred alternative of the SEIS would not likely jeopardize the continued existence of the western population of Steller sea lions and would not likely adversely modify its critical habitat. However, the continuing controversy about potential impacts of the groundfish fisheries on the Steller sea lion and the availability of additional information on the economic value of the Steller sea lion since the SEIS and biological opinion were completed suggest that further analysis of the possible benefits attributed to this particular endangered species is warranted. Furthermore, it is likely that the perceived benefits of preserving the Steller sea lion also apply to other endangered and non-endangered species associated with the Bering Sea and GOA ecosystems (e.g., various species of whales, dolphins, and seabirds).

3.9.8.1 Categories of Economic Values

Resource economists have developed a taxonomy of wildlife and ecosystem preservation values, although they have divergent opinions of the definitions of some benefits. Moreover, categories of benefits within a given list may overlap. Typically, economists divide the total value an environmental asset may generate into use values and non-use values. Use values involve either in situ contact with the environmental asset in question or personal consumption of products or services derived from the asset (Bishop 1987). Use values include consumptive use values, non-consumptive use values, indirect use values, and scientific values (Table 3.9-124). A summary of past/present effects of actions and events on non-consumptive use values is presented in Table 3.9-126.

Consumptive direct use values can be subdivided into commercial value if the purpose of the extractive activity is to sell products to others; recreational value if the purpose is recreational enjoyment; and subsistence value if the purpose is to provide one's family, or others, with food and no remuneration is involved. Extractive activities that are engaged in for their recreational or subsistence value typically are non-market in nature, but exceptions include certain recreational activities such as charter fishing. The non-consumptive direct use benefits derived from observing wildlife may be non-market in nature or may be purchased from commercial ventures such as those associated with eco-tourism. Consumptive direct use values can be subdivided into commercial value if the purpose of the extractive activity is to sell products to others; recreational value if the purpose is recreational enjoyment; and subsistence value if the purpose is to provide one's family, or others, with food and no remuneration is involved. Extractive activities that are engaged in for their recreational or subsistence value typically are not produced and traded in the private enterprise market economy, but exceptions include certain recreational activities such as charter fishing. Similarly, the non-consumptive direct use benefits derived from observing wildlife may or may not be traded in markets, an example of the former being the benefits associated with eco-tourism.

In contrast to use values, non-use values are always non-market in nature. Non-use values, also referred to as passive-use values, may include bequest or existence values (Table 3.9-124). These values do not involve personal consumption of derived products nor in situ contact. They are generated from people's inter-generational altruistic concerns or from the utility people receive from knowing that a particular asset exists or is being preserved (Bishop 1987). Existence value may be highly sensitive to the amount of information acquired, i.e., small changes in information or knowledge about a species may produce large shifts in existence value for that species (Stevens *et al.* 1991). It follows, therefore, that improvements in communication technology may lead to significant increases in existence value. For example, the arrival of the Internet has greatly enhanced the ability of the general public to access, at low cost, information about endangered species and other environmental assets.

Resource economists have taken the decomposition of the basic components of value in a species or ecosystem a step further by incorporating uncertainty into an individual's choice. For example, individuals may be willing to pay a premium for retaining an option for future use of a good or service, although they may not currently use it. This so-called option value exists under conditions of uncertainty about the future demand of an environmental asset. An extension of option value known as quasi-option value represents the value derived from postponing a decision about preserving a species or ecosystem in order to gain more knowledge in the future. The MSA acknowledges the uncertainty inherent in fisheries by stating that the term "conservation and management" refers, in part, to measures designed to assure that "...irreversible or long-term adverse effects on fishery resources and the marine environment are avoided; and there will be a multiplicity of options available with respect to future uses of these resources...." (Section 3(5)).

While it is important to recognize that the opportunity costs of management decisions that result in irreversible species or ecosystem losses may be particularly high, it is also important to note that some individuals may hold a positive value for avoiding losses of part of a species' population even if recovery is fairly rapid (Bishop and Welsh 1992) – witness the opposition by some members of the public to the recent gray whale hunt by the Micah people of the Pacific Northwest, despite the fact that NOAA Fisheries deemed the gray whale (*Eschrichtius robustus*) stock to be in good condition and capable of withstanding a restricted harvest. It is likely that for some opponents to the whale hunt the harvest of even a single whale is one too many because of the value of the special qualities they ascribe to a living whale or because of the sympathy or empathy they hold for animals in general.

3.9.8.2 Possible Economic Values Assigned to the Bering Sea and Gulf of Alaska Ecosystems

In this section, possible economic values ascribed to the Bering Sea and GOA ecosystems as a whole are discussed. To date, there has been no attempt to measure all of these values. A management decision that preserves sufficient area of habitat to conserve the ecosystem of which the endangered Steller sea lion is a part would tend to increase the probability of the species' survival. Consequently, an implicit value of protecting the Bering Sea and GOA ecosystems may be the value that people assign to preservation of the Steller sea lion (Section 3.9.8.4). Of course, preserving habitat would also help safeguard populations of other types of animals, and one would expect this habitat protection to be worth more than just the benefits provided to a single endangered species. Similarly, the value of the Bering Sea and GOA ecosystems is much greater than the value of groundfish fisheries (Section 3.9.8.3).

Due to the interconnectedness of the various elements of an ecosystem and the variety and complexity of ecological outputs, the tools of economic analysis may be of only limited usefulness. Marine ecosystems world-wide provide important services to humans, such as food production, climate regulation and nutrient storage and cycling. These ecosystem benefits may not be independent from one another. Further, the specific functions of the physical, chemical and biological processes occurring in a given ecosystem, and the beneficial outcomes for people that result from these functions, are often poorly understood. These problems, in addition to the lack of market prices, raise formidable challenges to the estimation of benefits.

Nevertheless, it is still possible to broadly characterize in qualitative terms possible benefits of the Bering Sea and GOA ecosystems.

Consumptive Direct Use Value

The Bering Sea is the most productive marine ecosystem off the United States and one of the most productive in the world (NMFS 1998e). The northern GOA is also one of the world's most productive ecosystems (EVOS undated). As would be expected in such productive ecosystems, the consumptive direct uses are highly valued. These uses include harvesting various marine and anadromous species for commercial, recreational and subsistence purposes.

The Bering Sea and GOA ecosystems encompass the harvesting areas, spawning grounds, recruitment areas and/or migration paths of nearly all of the fish, marine mammal and invertebrate species of consumptive value in Alaska. In 1995, seafood as a commodity statewide contributed $1.4 billion to the Gross State Product (4 percent of the total Gross State Product) and generated 7 percent of total employment statewide. The Alaska Sport Fish Harvest Survey shows that more than 432,000 anglers fished about 2.6 million angler-days and harvested almost 3.3 million fish in 2000 (Walker *et al.* 2001). Subsistence fishing and hunting continue to figure prominently in the household economies and social welfare of some Alaskan residents, particularly among those living in small, rural villages (Wolfe and Walker 1987). Of the estimated 43.7 million pounds of wild foods harvested in rural Alaska communities annually, subsistence fisheries contribute about 62 percent – 60 percent from finfish and 2 percent from shellfish. On average, this subsistence fisheries harvest provides about 230 pounds of food per person per year in rural Alaska (Wolfe 2000). Further, subsistence remains the basis for Alaska Native culture and community. In rural Alaska, subsistence activities are often central to many aspects of human existence, from patterns of family life to artistic expression and community religious and celebratory activities. Additional information on subsistence activities in Alaska is provided in Section 3.9.5.The Bering Sea and GOA ecosystems encompass the harvesting areas, spawning grounds, recruitment areas and/or migration paths of nearly all of the fish, marine mammal and invertebrate species of consumptive value in Alaska. In 1995, seafood as a commodity statewide contributed $1.4 billion to the Gross State Product (four percent of the total GSP) and generated seven percent of total employment statewide. Colt (2001) estimates that commercial fishing and fish processing in Alaska has annually generated more than 33,000 full time equivalent jobs and $1 billion in labor income in recent years. The fishing industry is particularly important to rural Alaska. More than 50 percent of limited entry permit holders reside in rural areas of the state (Colt 2001). For many small coastal and river communities, commercial fishing is a major source of income, both to individuals and to local governments.

The Alaska Sport Fish Harvest Survey shows that more than 432,000 anglers fished about 2.6 million angler-days and harvested almost 3.3 million fish in 2000 (Walker *et al.* 2001). In 1993, 70 percent of all Alaska households contained at least one person who had been sport fishing within the past three years (Colt 2001). In that year, residents and nonresidents spent $600 million (in 1998 dollars) in Alaska on goods and services attributable to sport fishing (Colt 2001). Of this total, residents spent $379 million, or 63 percent, and nonresidents spent $221 million. Subsistence fishing and hunting continue to figure prominently in the household economies and social welfare of some Alaskan residents, particularly among those living in small, rural villages (Wolfe and Walker 1987). Of the estimated 43.7 million pounds of wild foods harvested in rural Alaska communities annually, subsistence fisheries contribute about 62 percent – 60 percent from finfish and 2 percent from shellfish. On average, this subsistence fisheries harvest provides about 230 pounds of food per person per year in rural Alaska (Wolfe 2000). Further, subsistence remains the basis for Alaska

Native culture and community. In rural Alaska, subsistence activities are often central to many aspects of human existence, from patterns of family life to artistic expression and community religious and celebratory activities. Additional information on subsistence activities in Alaska is provided in Section 3.9.5.

Non-Consumptive Direct Use Value

The non-consumptive direct use benefits of healthy marine ecosystems are important to many Alaska residents. They may value these ecosystems for recreational, aesthetic, and spiritual reasons. For some individuals, they may be a key benefit to living in the state and integral to a "sense of place." One indication that some Alaskans view relatively pristine ecosystems as a quality of life benefit available in Alaska is their participation in wildlife viewing. For example, a major mail survey of Alaska voters conducted in 1991 found that 14 percent of Alaskans took at least one overnight trip with the primary purpose of viewing wildlife (McCollum and Miller 1994). Colt (2001) estimated that Alaskans took more than 107,000 "person-trips" in 1999 with the main purpose of wildlife viewing. Colt further estimated that residents participating in this activity spent a total of $82.3 million on miscellaneous equipment and an additional $63.4 million on trip-related expenditures.

Non-consumptive direct uses of the marine environment may also be important to visitors to Alaska. For example, an increasing number of tourists are arriving in Alaska aboard cruise ships. The proportion of summer visitors entering Alaska by this mode of access increased from 26 percent in 1989 to 42 percent in 2001 (Northern Economics, Inc. 2002). An integral part of the cruise ship experience is viewing the state's scenic coastal environment. According to one cruise ship line, vessel passengers can "enjoy stunning vistas of snow-capped mountains, majestic blue-ice glaciers, and an abundance of wildlife" (Carnival Cruise Lines undated).

On the other hand, it is uncertain how important a pristine marine ecosystem is to Alaska's tourism industry. To paraphrase one observer, "Do passengers on a cruise ship need know that the food web is intact [in order for Alaska's marine environment to continue to be a major tourist attraction]?" (Colt and Huntington 2002). The speed and height of cruise ships and their distance from shore limit close views of natural features and wildlife. Furthermore, cruise ships provide a range of onboard activities unrelated to a particular location. It is probable that visitor expectations and experiences differ among various groups. For example, the non-consumptive value of the Bering Sea and GOA ecosystems may be substantial only for certain tourists, such as those who purchase kayaking tours, wildlife viewing excursions and similar services that afford individuals a closer look at marine wildlife and other local fauna. At present, information about the expectations or degree of satisfaction of tourists visiting Alaska is limited.

Existence Value

A significant component of the overall benefit of Bering Sea and GOA ecosystems may be from existence (non-use) value. For example, the following excerpt from a recent publication of the World Wildlife Fund and Beringia Conservation Program suggests that the Bering Sea ecosystem may have significant existence value due to its distinctive qualities:

> "*On every scale, in all its complex dynamics, the Bering Sea is one of our planet's most spectacular ecological regions – that rare place where nature's creatures and biological processes are still providing a wealth of benefits that attract and sustain an extraordinarily*

abundant diversity of life (World Wildlife Fund and Beringia Conservation Program undated).”

The abundant waters of the Bering Sea and GOA support the richest assemblages of marine mammals and seabirds in the northern hemisphere (NPFMC 1994). The benthic invertebrate community off Alaska consists of at least 472 species of invertebrates making up the macroinfauna (Low *et al.* undated). More than 100 million birds of over 100 species depend on Alaska marine ecosystems during some part of their life cycle. At least three-fourths of these species breed in Alaska, and the rest are visitors from a wide variety of locations throughout the Pacific Ocean. In addition, the Alaska marine environment has 37 stocks of more than 25 species of marine mammals (Low *et al.* undated).

It is likely that some people derive pleasure from the contemplation of the varied life forms existing in the Bering Sea and GOA ecosystems and would be willing to pay to preserve the structure and integrity of those biological communities even if they never directly experience them. For these individuals, the knowledge that these communities exist, relatively free of human disturbance, is enough.

3.9.8.3 Possible Economic Values Assigned to Groundfish

The most evident economic value of BSAI and GOA groundfish resources are their consumptive direct use value in a commercial context. This value accrues to the different members of society who make a living harvesting, processing and distributing groundfish products and who purchase and consume these products. The economic value firms and communities derived from the commercial harvest and processing of groundfish are described is Sections 3.9.2 through 3.9.4. The value accruing to distributors and consumers of groundfish products is described in Section 3.9.7. The groundfish products produced and consumed are market goods since they are bought and sold in normal commerce and their value is revealed in market prices.

In comparison to the commercial consumptive value of groundfish, the non-commercial consumptive value of these resources is very small. While no groundfish recreational harvest data for the EEZ are compiled, it would not be unreasonable to assert that the total recreational harvest in the BSAI and GOA is trivial. This is so for several reasons.

First, for the vast majority of the geographic area adjacent to the BSAI and GOA EEZ, local human populations are quite small and relatively isolated. In these remote areas of Alaska, most of the non-commercial take of groundfish would more appropriately be regarded as subsistence harvests rather than recreational fishing. In general, groundfish harvests play a minor role in subsistence activities. Additional information on the subsistence use of groundfish is presented in Section 3.9.5.

Second, the physical environment of much of the BSAI and GOA EEZ limits recreational fishing for groundfish to near shore areas in the vicinity of population centers. All such fishing activity would be expected to occur within state waters, and thus, would be managed by the ADF&G.

Third, most of the BSAI and GOA groundfish harvest is composed of species (e.g., pollock) that generally are not regarded as sport fish.

Aside from its consumptive direct use value, groundfish may have an indirect value. For example, juvenile pollock and other groundfish may be important prey for other species that people value, such as the Steller sea lion. Moreover, groundfish may play a crucial role in the overall function and stability of the Bering Sea and GOA marine ecosystems.

3.9.8.4 Possible Economic Values Assigned to the Steller Sea Lion

Consumptive Direct Use Value

Although there are exceptions, endangered species generally have little or no consumptive direct use value because of their low numbers. Commercial hunting of the Steller sea lion, which took large numbers of the animals until as recently as the 1970s, no longer takes place. Steller sea lions were historically a primary source of food for inhabitants of the Aleutian Islands. In addition, clothing, boots, and boat coverings were made from skins. The Subsistence Division of the ADF&G has surveyed subsistence hunters about their Steller sea lion harvests since 1992. According to the ADF&G, statewide subsistence harvests of Steller sea lions have reportedly dropped, from an estimated 549 animals in 1992, to an estimated 178 animals in 1998. Almost all of these harvests are from the western population and the majority are made by Aleut hunters in the Aleutian and Pribilof Islands. Subsistence analysts at ADF&G suggest that the decline in Steller sea lion harvest is connected to (a) increased scarcity and consequent reductions in subsistence harvest success per unit of effort, and (b) conservation related concerns about the health of Steller populations among subsistence hunters (NMFS 2001b). Given the continuing decline of the western population of Steller sea lions, the consumptive value of these animals is likely to remain low. Additional information on the subsistence use of the Steller sea lion is available in Section 3.9.5.

Non-Consumptive Direct Use Value

The rookeries and haulouts of the Steller sea lion are usually located on relatively remote islands. Furthermore, buffer zones have been established near the largest breeding islands, and vessels are not permitted to go closer than three miles to these rookeries. Consequently, the opportunities for people other than scientists to observe a live Steller sea lion in the wild are somewhat limited. However, this species occurs in a number of national parks in Alaska (Kenai Fjords National Park, Glacier Bay National Park and Preserve, and Katmai National Park and Preserve), and a number of private companies offer boat tours in or around the parks that let visitors view Steller sea lions and other types of Alaska wildlife. The non-consumptive value that direct encounters with the Steller sea lion might generate are likely similar to those described by Ching (1994:36) for the Hawaiian monk seal (*Monachus schauinslandi*), another endangered pinniped:

> *"Events like those …are precious indeed as many people are experiencing the joy of watching monk seals in the wild without causing them stress. Something magical happens when people actually get to see an endangered animal in real life. It instills within them a sense of protective enthusiasm, thus strengthening conservation efforts."*

Scientific Value

The Steller sea lion may be perceived by some as having some yet unrealized biomedical value that renders it worth preserving (i.e., the species has a quasi-option value). Several current lines of research indicate that some pinnipeds may be useful in human medicine. To cite some examples, an examination of the physiological factors that render the internal organs of seals resistant to anoxia may improve human organ transplants (Kooyman 1981); studies of the Weddell seal's (*Leptonychotes weddelli*) ability to routinely recover from near total lung collapse during deep dives may prove useful in understanding sudden infant death syndrome (Kooyman 1981); and investigations of what are apparently normal sleep apneas in the northern elephant seal (*Mirounga angustirostris*) may provide insights into similar but more pathological events seen in humans (Castellini 1994). These potential benefits may suggest to some individuals that the Steller sea lion could also have some valuable biomedical use in the future.

Indirect Value

The complexity of ecosystem relationships and interconnectedness of the various elements may cause the removal or disturbance of one part of the ecosystem to affect the functioning of many other components of the ecosystem. For example, the Steller sea lion may be an important component of the food web, serving as prey for larger species. The exact role that the Steller sea lion plays in maintaining the integrity of the GOA and Bering Sea ecosystems is uncertain. Such uncertainty is not unusual; knowledge of ecosystem relationships are often incomplete, and the results of disturbance are thus to some extent unpredictable. To have indirect value the Steller sea lion does not necessarily have to be a "keystone species" on which the persistence of a large number of other species in the ecosystem depends. As Ehrlich and Ehrlich (1981) have noted, the removal of any particular species may in itself not be catastrophic, but its occurrence increases the likelihood that the next extinction could unravel the whole ecosystem.

Existence Value

Non-use values may be the most important benefit derived from some endangered species, simply because species become endangered due to their small populations, which means that many people are unlikely to have seen or had much tangible experience regarding these species. People demonstrate their existence values in the marketplace by donating funds to private organizations that support activities to preserve endangered species.

However, whether people enjoy existence values of resources is not contingent upon whether they donate money to support a cause. The fact that some individuals are willing to donate money is just the most obvious manifestation of these existence values.

The discussion by Metrick and Weitzman (1996) of possible factors that affect the magnitude of existence value can be used as a basis for speculating about the nature and relative magnitude of the existence value of the Steller sea lion. First, the authors note that people often speak of the large amount of attention paid to "charismatic megafauna." Presumably, therefore, the existence value of a species may be a function of its charisma. Metrick and Weitzman were unable to identify a satisfactory measure of charisma in the context of endangered species, but they note that eye-size or eye-body ratio have been suggested. Based on these eye-related criteria the Steller sea lion would be rated as highly charismatic. In any case, Steller sea lions are large mammals, and sea lion pups have a "cute and furry" visage – characteristics that are typical of some high-profile threatened and endangered species that people are willing to protect.

Another factor that may influence the magnitude of existence value is the degree to which a species is considered to be a higher form of life and possibly possess (anthropomorphic) capabilities for feeling, thought and pain (Metrick and Weitzman 1996, Kellert 1986). Certain characteristics of sea lions, such as the maternal care that the female provides for her pup, the playful behavior of young sea lions or the ability of the sea lions to vocalize and communicate with each other, may be perceived by some people as indicators of a higher life form. While none of these attributes proves that the Steller sea lion possesses human-like intelligence or emotions, people may identify with these characteristics and interpret them to mean that sea lions do, in fact, represent a relatively advanced form of life.

Finally, Metrick and Weitzman argue that, since we may have existence value for biodiversity as a whole, some measure of the amount that a species adds to this diversity may play a role in deciding how much people are willing to pay to preserve it. Genetic distinctiveness means the number of genes acquired since the species split off from its nearest common ancestor. For Steller sea lions, the question might be, how genetically distinct are the eastern and western stocks that occur in U.S. waters. NOAA Fisheries recognized the two distinct population segments in 1997 based on geographic distribution, differences in population dynamics and mitochondrial DNA data. Other unique characteristics of the Steller sea lion may also influence people's perceptions that these animals should be valued for their contribution to biodiversity. For example, the Steller sea lion is the largest of the sea lions, with males reaching over 1,700 pounds in weight and 10 ft in length.

An Estimate of the Economic Value of an Expanded Steller Sea Lion Recovery Program

As noted previously, market prices express the value of environmental assets in monetary terms if these assets are bought and sold. However, because other benefits of environmental assets are less readily translated into dollar values, resource economists have developed an array of valuation techniques that do not rely on market data. One such technique is the contingent valuation method (CVM). CVM employs survey techniques to ask people about the values they would place on certain environmental assets or other non-market commodities if markets did exist or if other means of payment were in effect. It is called "contingent" valuation because people are asked to state their ‘willingness to pay', contingent on a specific hypothetical scenario and description of the environmental service.

CVM allows for the estimation of the full range of species and ecosystem preservation values set forth in Table 3.9-124, and it is the only method available for estimating non-use values directly. When individuals are asked in CVM studies to evaluate an environmental asset they make a holistic judgment based on the configuration of benefits they believe will accrue to them (Mitchell and Carson 1989). In other words, the value expressed by a respondent represents the sum of all the types of use and non-use values he or she assigns to the good or service in question. Generally, researchers applying CVM do not attempt to assess each separate type of value. It is also important to note that respondents may make associations among environmental goods that the researcher had not intended. For example, a valuation of a particular species may include implicit valuation of the components of the ecosystem that support that species (Loomis and White 1996).

A recent CVM study provides an empirical point estimate of the total economic value attributable to protection (and enhancement) of the western Steller sea lion stock (Turcin and Giraud 2001; Giraud *et al.* 2002). This study constructed and administered a questionnaire survey that included a closed-ended CVM question formatted similarly to a typical public goods referendum.

Specifically, the survey described a hypothetical expanded Federal Steller sea lion recovery program that would double research funding and increase the restrictions of commercial fishing around the western stock of the Steller sea lion's critical habitat in the GOA, Bering Sea and North Pacific Ocean. The survey noted potential impacts to Alaskan coastal communities that depend on the fishing industry as well as potential benefits from the expanded program. However, the survey explicitly stated that biologists are unsure why the sea lion populations have been declining and gave no guarantee that the expanded program would ensure species recovery.

This information was followed by the question, "If the Expanded Federal Steller Sea Lion Recovery Program was the only issue on the next ballot and it would cost your household $X in additional Federal taxes every year for the next Y year(s), would you vote in favor of it?" The dollar amount and payment duration were filled in by the analysts prior to administering the questionnaire. By varying the printed dollar amount across the sample of respondents, the voter referendum format allowed the analysts to statistically trace out a demand-like relationship between the probability of a "yes" response and the dollar amount. The researchers have not yet investigated temporal elasticity of ‘willingness to pay' estimates, and only a one-year payment duration was analyzed.

The survey was administered to a sample of households in three study areas: 1) the Alaskan boroughs that contain Steller sea lion critical habitat, 2) the entire state of Alaska; and 3) the entire United States. Because the benefits of preserving Federally listed threatened and endangered species are national in scope, both the value per household and number of households to aggregate over should include all U.S. households (Loomis and White 1996).

The Steller sea lion CVM study found that the value of an expanded recovery program for the species in the United States sample was positive and substantial. The estimated mean one-time payment was $100.22 per household. If the average value per household is adjusted to account for non-responses with the assumption that they represented a zero willingness-to-pay, the mean benefit is $61.13. With 101,562,700 households throughout the nation, and $61.13 value per household, willingness-to-pay totals about $6.2 billion for the expanded Federal protection program for the western stock of the Steller sea lion. The 95 percent confidence interval is from $5.8 billion to $16.17 billion. This economic value estimate of an expanded recovery program may be conservative, as the valuation responses were treated as household responses rather than individual responses. Treating the responses as individual responses would increase benefits substantially.

The results of CVM are often highly sensitive to what people believe they are being asked to value, as well as the context that is described in the survey. Given the vague outcome of the Steller sea lion protection program described in the above CVM study, it is somewhat uncertain what respondents were evaluating. A more definitive value of the Steller sea lion might have been obtained if a link had been established between an expanded protection program and a well-defined discrete outcome, such as a specific probability that the western Steller sea lion population would recover.

Economists acknowledge that, in general, questions of validity, bias and reliability persist in the use of CVM to evaluate environmental assets. In 1992, NOAA commissioned a blue ribbon panel to advise the agency on the use of CVM for measuring non-use values (Arrow *et al.* 1993). The panel concluded that CVM studies can produce estimates reliable enough to be the starting point for a judicial or administrative determination of natural resource damages, including loss of non-use values, as long as certain sampling and survey design guidelines are adhered to. It is beyond the scope of this analysis to critique the methodology employed by Turcin and Giraud (2001) and Giraud *et al.* (2002) to evaluate the benefits of an expanded program to preserve the Steller sea lion, but the use by these analysts of a willingness-to-pay and dichotomous choice format is consistent with guidelines set forth by Arrow *et al.* (1993). Nevertheless, it is important to emphasize that CVM is based on asking people questions, as opposed to observing their actual behavior, which is a source of considerable controversy among economists, policy makers, and others. The conceptual, empirical, and practical problems associated with developing dollar estimates of economic value on the basis of how people respond to hypothetical questions about hypothetical market situations are a continuing source of debate.

3.9.8.5 Alternative Value Paradigms

Apart from debates about the technical acceptability of CVM with respect to its validity and reliability, there are criticisms of the economic-utilitarian paradigm underlying the economic valuation of at-risk species and ecosystems. A number of these criticisms contend that economic valuation methods such as CVM are inherently inadequate because they capture only the instrumental value to current members of society. For example, Berrens *et al.* (1998) note that irreversible species or ecosystem losses involve inter-generational equity issues since they constrict the choice sets of future generations. Economic valuations are based on the preferences of the current generation and neglect the ethical issue of the inter-generational allocation of natural endowments. Preserving species where positive net benefits are to be earned is obviously a good idea, but preserving species only when doing so meets economic efficiency criteria may place future generations in a disadvantaged position (Bishop 1993).

Other critics focus on the fact that economic valuations are rooted in anthropocentric or human-centered benefits, that is, these valuations rest on the basic assumption that value derives from what people find useful. However, some would argue that human uses and the values to which they give rise are not deserving of any special consideration when it comes to a decision on whether to preserve a species and its habitat (Albers *et al.* 1996). According to one interpretation of this view, nature has rights; to exploit nature is just as wrong as to exploit people (Nash 1989). Another interpretation is that non-human species are intrinsically valuable, independent of any use they may be to humans (Callicott 1986). The latter conviction may be related to religious principles, such as a belief in the sacredness of all or certain life forms.

All of these moral arguments are inconsistent with the economic paradigm of trade-offs between money and wildlife species or ecosystems because they present individuals with the moral imperative that we ought to preserve plants and animals (Stevens *et al.* 1991). As Costanza *et al.* (1997) and Pearce and Moran (1994) note, concerns about the preferences of future generations or ideas of intrinsic value translate the valuation of environmental assets into a set of dimensions outside the realm of economics.

It is difficult to gauge how prevalent such ethically motivated values are among members of the general public. For example, according to a 1997 public opinion poll conducted in the U.S., only 6 percent of the respondents who advocated an end to the harvest of the Minke whale (*Balaenoptera acutorostrata*) indicated that their opposition to whaling stemmed from animal rights concerns (Aron *et al.* 2000). On the other hand, when a recent Gallup poll asked Americans to indicate the degree to which they agree or disagree with the goals of the animal rights movement, 29 percent expressed strong agreement, 43 percent indicated some agreement and only 25 percent were strongly or somewhat opposed (The Gallup Organization 2000). Additional in-depth public surveys are needed before we can better understand people's motivations for supporting efforts to protect endangered species such as the Steller sea lion and ecosystems such as those of the Bering Sea and GOA.

3.9.9 Socioeconomic Comparative Baseline

3.9.9.1 Harvesting and Processing Sectors

As indicated in Section 3.9.2, the harvesting and processing sectors of the Alaska groundfish fisheries consist f catcher vessels, catcher processors, shoreside processors, stationary floating processors, and motherships. The size, composition, and economic performance of these sectors have been influenced by a variety of factors. Some of these factors are of an economic nature, such as the domestic and foreign demand for seafood products, the costs of harvesting and processing inputs such as fuel and labor, and changes in fishing technology. Foreign and domestic demand, in turn, is a function of such factors as consumer preferences, the supply of competing products, foreign exchange rates, international trade agreements, demographics, and national income levels (Kinoshita *et al.* 1993). For instance, with the large amount of groundfish that is exported from the fisheries off Alaska to Japan, the strength of the Japanese yen relative to the U.S. dollar can be a powerful force in the market for groundfish and other Alaska seafood products.

Changes in the condition of fisheries far removed from Alaska have also had a substantial economic effect on the Alaska groundfish fisheries. For example, the price of Pacific cod products increased in the 1990s due to reduced Atlantic cod harvests from the Barents Sea.

Other factors that have affected Alaska groundfish fisheries are regulatory in nature. In particular, fishery management measures have dramatically affected the economic condition of the Alaska groundfish industry as a whole or segments of that industry. These management measures include those implemented to prevent overfishing of fish stocks and to protect endangered species and marine ecosystems. In 2000, for example, Steller sea lion protection measures resulted in a decrease in pollock harvests during the C/D fishing seasons and a consequent temporary closure of several shoreside processing plants.

Some management measures are designed to allocate the TAC among various user groups. One of the first such measures that significantly shaped Alaska groundfish fisheries was an allocation between the inshore/offshore sectors of the BSAI pollock fishery. In 1992, one half of the pollock reserve (7.5 percent of the TAC) was allocated to communities eligible to participate in the western Alaska CDQ program. The remainder of the TAC was divided among vessels delivering pollock to shoreside processors (inshore sector) and vessels processing pollock at-sea (offshore sector), with the former sector receiving 35 percent of the remaining TAC and the latter receiving 65 percent. The American Fisheries Act of 1998 modified specific allocations of the BSAI pollock quota as follows: 10 percent to the western Alaska CDQ program, with the remainder allocated 50 percent to the inshore sector, 40 percent to the offshore sector, and 10 percent to a newly created mothership sector.

Alaska groundfish fisheries have also been affected by management measures intended to enhance the economic efficiency of fisheries. A primary objective of these measures is to reduce the so-called race for fish. In a race for fish, fishermen are compelled to apply an excessive level of operating inputs (e.g., labor, fuel, time) and capital inputs (e.g., vessel and gear improvements) as they compete with each other for shares of the TAC. Fishery management programs designed to end the race for fish and reduce overcapitalization are said by economists to lead to “rationalization” of fisheries, i.e., toward an allocation of capital and labor between fishing and other industries that maximizes the net value of production from the economy as a whole (Anderson 1977).

Measures intended to attenuate the race for fish and increase economic efficiency include an ITQ program established for the sablefish and halibut longline fishery in 1995, whereby a certain portion of the annual TAC is allocated to individual vessels in the form of quota shares, and a vessel moratorium on new entrants to fisheries in the BSAI and GOA groundfish fisheries imposed in 1996. (A license limitation program that further limited participation in these fisheries was implemented in 2000.)

A more recent economic efficiency-enhancing measure was the AFA. The AFA was implemented in phases beginning in 1999 and continuing into 2000. To immediately decrease the number of participants in the pollock fishery, a buyout of nine catcher (at-sea) processors was supported by federally appropriated funds and a federal loan to the fishing industry. The buyout resulted in the permanent removal of nine large vessels from the catcher processor fleet. In addition, the AFA also established the authority and mechanisms by which the remaining pollock fleet can form fishing cooperatives. Within each cooperative, each member company is contractually allocated a percentage share of the total cooperative allocation based on its historical catch (or processing) levels. In practice, the cooperative system is similar to an ITQ program except that the distribution of quota shares and the system for trading, selling or enforcing them are decided by members of the separate cooperatives. Since the AFA was enacted, the BSAI pollock fleet has grown smaller as vessels with marginal activity reduce their level of participation in the fishery (NMFS 2002a).

It is also important to note that the AFA includes provisions that protect the interests of shoreside processors. Specifically, the AFA and implementing rules require each catcher vessel that joins a cooperative and delivers inshore to bring a share of the total allowable pollock catch (TAC) to that cooperative proportional to its historical catch. The vessels, in aggregate, have to agree to deliver 90 percent of their TAC allocation to the processing firm associated with that cooperative. This requirement sought to address concerns raised by processors that the formation of cooperatives would economically disadvantage them during price negotiations unless they received compensation through a restricted processing class.

In general, not enough time has passed since the full implementation of the provisions of the AFA for all likely impacts to have become manifest (NMFS 2002a). Pollock deliveries to shoreside processors increased substantially due to the AFA reallocation of pollock quota to the inshore sector as well as increases in the overall TAC itself. In addition, processors have benefitted from the slower-paced pollock fishery under cooperatives. With more moderate and regular harvests, both catcher processors and shoreside processors have been able to significantly increase their production of higher value products, such as fillets.

While some shoreside processing plants have reported minor cutbacks in personnel as a result of the slowing down or spreading out of pollock processing activity, for the most part employee levels have stayed almost the same because of the need for a full complement of staff to run the plants (NMFS 2002a). What has changed is that workers are working fewer hours per day and working for longer periods than was the case before the enactment of the AFA.

On the other hand, with the consolidation of the fishing fleet and the elimination of the race for fish in the BSAI pollock fishery, there has been a lessening of seasonal peak demands for associated shoreside services (NMFS 2002a). One consequence of this reduced demand appears to be a decline in the number of shoreside support businesses in some communities (although the range of services available locally does not appear to have changed). Many of the support firms that remain in business report employment reductions, either in the form of having fewer year-round personnel or in cutting back on the number of seasonal hires during peak demand.

3.9.9.2 Regional Engagement and Dependency on Groundfish Fisheries

Baseline engagement and dependency on the groundfish fishery vary widely across Alaska regions, and between Alaska and portions of the Pacific Northwest. Section 3.9.3 presents information on the distribution of the sectors across regions, and comparative information on the population, employment and income, processing, processing ownership, and catcher vessel ownership and activity across and among the regions engaged in the fishery.

The population of the regions varies considerably. In Alaska, the Alaska Peninsula/Aleutian Islands region had a 2000 population of approximately 6,000; the Kodiak Island region had approximately 14,000 residents; and the southcentral and southeast Alaska regions had populations of about 367,000 and 75,000, respectively. In the Pacific Northwest, the Washington inland waters region had about 3.9 million residents and the Oregon coast region had a population of about 105,000. Beyond overall population, the types of communities in the different regions also vary considerably. The Alaska regions contain very small relatively isolated traditional communities, as well as the largest community in the state, Anchorage, which along with its surrounding area contains nearly half of the state's population. In the Pacific Northwest, the regions include the greater Seattle metropolitan area as well as relatively small coastal fishing communities.

The population structure of the regions also varies considerably. As discussed in the individual regional profiles, the fishery has an impact on the male-female population balance for some of the Alaskan communities that are the focus of intensive groundfish processing. This type of direct impact on population structure attributable to groundfish is seen in few communities, but these tend to be the communities with the highest level of groundfish-related processing activities. Within Alaska, particularly in the Aleutian and Kodiak Island regions, there is also a relationship between percentage of Alaska Native population and commercial fisheries development, with communities that have developed as large commercial fishing communities becoming less Native in composition over time compared to other communities in the region. This varies considerably from place to place and is not as apparent in the Alaska southcentral and southeast regions as in the more western regions.

Employment and income (payments to labor) information for the processing sector in each region provides a look at types and levels of economic engagement with the groundfish fishery. During 2001, primary or direct Alaska groundfish processing employment ranged from none in the Oregon coast region to more than 3,500 persons in the Alaska Peninsula/Aleutian Islands region and nearly 3,800 persons in the Washington inland waters region. Interpretation of these data in terms of engagement with the community is less straightforward for some regions than for others. For some, processing plants tend to be industrial enclaves that are somewhat separate from the rest of the community, while for others there is no apparent differentiation between the processing workforce and the rest of the regional or local labor pool. For the Washington inland waters region, Alaskan groundfish processing work is at sea, so in some respects it does not take place in a community at all. In all cases, however, processing employment tends to be seasonal in nature. A further complication for attribution of socioeconomic impacts to a regional base is the fact that many workers in many sectors perform groundfish-related work in a region or community other than the locations where they have other (primary) socioeconomic ties. The importance of associated economic flow varies from region to region and from sector to sector, but it is most apparent for the communities that are most heavily engaged in the processing aspect of the groundfish fishery.

For communities (and boroughs) in the western Alaska regions, a local fish tax is often a significant source of local revenue. For other regions, direct revenue benefits are more closely tied to the state fish tax. Information is provided for each region on shared taxes and the role of state shared fish tax in relation to these other taxes. Again, there is considerable variability from region to region. Also apparent is the regional differentiation in the importance of the relatively new fishery resource landing tax. This source of revenue comes from the offshore sectors of the fishery, is designed to capture some of the economic benefits of offshore activity for adjacent coastal Alaska regions, and is far more important to the revenue structure of the Alaska Peninsula/Aleutian Islands region than for any other region.

Inshore groundfish processing information is presented in Section 3.9.3 for each region to facilitate analysis of the volume and value of the groundfish that are landed in a region. The information is broken out by species, and historical information is provided on utilization rate, product value, and value per ton. When examined on a region-by-region basis, these data point out that the groundfish fishery varies widely from one region to another. For example, in 2001, for the Alaska Peninsula/Aleutian Islands region, local groundfish processing activity is relatively focused on pollock, while in the southeast Alaska region, the fishery is focused much more on the non-pollock, non-cod, non-flatfish, "other" (A-R-S-O) species. Therefore, sharp differences exist in value per ton (about six times greater in the southeast Alaska region) and in volume (greater in the Alaska Peninsula/Aleutian Islands region, which accounts for about 88 percent of the total volume for the state). These differences correspond with differences in a number of other factors, including the extent to which a local labor force is used in processing and the degree to which a local fleet is harvesting the resource (both measures are high in the southeast Alaska region, but low in the Alaska Peninsula/Aleutian Islands region). Ownership patterns also have a large influence on economic flow between regions. For example, the Alaska Peninsula/Aleutian Islands region has the greatest volume and value processed inshore among all the regions, but ownership of shore processing facilities in this region is highly concentrated among individuals and firms located in the Washington inland waters region. The large mobile processors that work the Bering Sea have varying catch and processing locations and at least some ties to adjacent Alaska regions (through CDQ group ownership interest, for example), but ownership again clearly shows predominant ties to the Pacific Northwest. For all types of processors (inshore, mothership, and offshore), processors owned by Washington inland waters region residents accounted for 97 percent of total reported tons and 95 percent estimated wholesale value of all North Pacific groundfish processed in 2001.

Resources from FMP subregions adjacent to the Alaska Peninsula/Aleutian Islands, Kodiak Island, and other Alaska regions are not uniformly harvested by catcher vessels from those regions. Different regions have varying combinations of local harvesting activity, local processing activity, and ownership of both harvesting and processing entities, and all of these have implications for the role of the groundfish fishery in the local socioeconomic context. For example, in terms of groundfish harvest value and volume, the Alaska Peninsula/Aleutian Islands region features a mostly nonresidential fleet, except for some of the smaller vessel classes. While the highest volume and value of groundfish resources harvest occur near this region, the catcher vessels accounting for most of this activity are from elsewhere (primarily the Washington inland waters and Oregon coast regions). As a rule of thumb, the higher the catcher vessel harvest volume in a given area, the less local the fleet tends to be. Regions vary widely in how local the catch effort really is by the local fleet. For example, catcher vessels in the southeast Alaska region have a very high concentration of effort in the Eastern Gulf of Alaska FMP area, while efforts of catcher vessels based in Kodiak are more wide-ranging.

Section 3.9.4 also presents information on how groundfish has fit into overall fishing effort for groundfish catcher vessels over the last several years so that the relative role of groundfish can be seen over time. This information is abstracted for this document and clearly shows that the relative importance illustrates marked differences between regions. For each of the regions a section on community rankings by catcher vessel ownership is provided. While most of the rest of the data are regional in nature, the top communities (to the 95th percentile) for vessel ownership are listed to provide a sense of subregional distribution of engagement with the groundfish fishery from the harvest perspective. Diversity information similar to that presented for catcher vessels is also presented for processors for each of the regions to allow at least a general-level consideration of the relative importance of groundfish. For the larger Bering Sea pollock inshore plants, for example, groundfish accounted for more than 60 percent of total ex-vessel value over the period 1995-1997, while in the southeast Alaska region, analogous value ranged from 10 to 35 percent over the period from 1991to1998.

Beyond the regional differences in baseline conditions brought about by a wide range of factors, communities and regions within Alaska have been affected in a number of distinct ways by the growth of the domestic groundfish fishery itself:

- On a regional basis, and specifically with respect to the high-volume, formerly foreign fleet fisheries, the primary regions that have been affected are the Alaska Peninsula/Aleutian Islands region and the Kodiak Island region.

- Within the Alaska Peninsula/Aleutian Islands region, the growth of the domestic groundfish fishery has caused profound changes in the communities of Unalaska and Akutan. In Unalaska, in recent years, it has provided the mainstay of the fisheries-based portion of the economy and generally reversed the local economic decline that followed the crash of the king crab fishery. Both inshore and offshore sectors have contributed to the local tax base and the economic climate that has fostered the development of a significant support services sector. In Akutan, the groundfish fishery, primarily in the form of a large groundfish-oriented shore plant, has transformed the community from a small primarily Native community to a much larger predominantly non-Native community. The implications of this change should be interpreted with caution, however, as the processor (as an enclave type of development) and the rest of the community remain separate in a number of different ways. Lesser changes have been seen in Sand Point and King Cove, although both have experienced a significant growth in local groundfish processing in recent years. Sand Point's residential catcher vessel fleet has benefitted disproportionately from the development of the groundfish fishery in comparison to other communities in the region. Communities in the Aleutians East Borough with no direct involvement in the groundfish fishery have also benefitted from the borough's fish tax. Other CDQ communities in the region have benefitted in yet other ways.

- In the Kodiak Island region, the City of Kodiak has been the prime beneficiary of the development of the groundfish fishery. It has served as an important buffer for variation in other fisheries, especially after the decline of the locally important shrimp and crab fisheries, as well as the Bering Sea crab fisheries.

- The Alaska southcentral and southeast regions have not seen the level of changes experienced by communities in the Alaska Peninsula/Aleutian Islands region and the Kodiak Island region. The fishing communities in these regions tend to be quite diversified, although groundfish is an important component of this mix for some communities.

- It should also be noted that the development of the domestic groundfish fishery has also been important for regions and communities outside of Alaska, particularly for the Oregon (primarily Newport) catcher vessel sector, and the Washington (primarily Seattle) distant water fleet (catcher vessels, motherships, and catcher processors) and regionally based processing and support entities active in the Alaskan groundfish fishery.

A number of historic trends or patterns in management actions or approaches are also serving to shape the regional comparative baseline:

- Beyond the overall development of the domestic fishery, certain fisheries management changes have had significant impacts on the regions and communities.

- With the Joint Venture era, expertise in the groundfish fishery was gained, and the foundation was laid for more complete domestic development of the fishery.

- Concerns regarding overcapitalization of the fishery and growth of the offshore sector in the late 1980s led to management actions to avoid precluding the participation of different sectors. This, in turn, had a number of impacts in both Alaskan and Pacific Northwest regions. Inshore/Offshore allocative splits changed the fishery in both the Gulf of Alaska and Bering Sea.

- Implementation of IFQ-based management for sablefish profoundly changed that part of the groundfish fishery.

- License limitation served to limit entries into the fishery but did not stabilize ownership patterns.

- The evolution of the CDQ program has served to involve entire regions in the groundfish fishery that were not directly involved in the groundfish fishery prior to implementation of the program.

- The American Fisheries Act (AFA) changed the nature of quota allocations between and among sectors. Co-ops were recently formed both offshore (1999) and onshore (2000), and fishery participants are still adapting to the new context. Significant capital was removed (i.e., vessels retired) from the offshore fleet, the race for fish was essentially eliminated, and new types of operational relationships were formed between processors and their harvesting fleets. Ownership structures changed, with increased American ownership overall, and a specific trend of note has been increased investments in the fishery by CDQ groups. In terms of regional or community-based impacts, the beneficial economic impacts of eliminating the race for fish have accrued to most participants, but perhaps especially to those from the Washington inland waters region, due to the ownership patterns and basic operational structure of the sector. Some adverse support sector impacts have been felt in Unalaska due to lessening of seasonal peak demands. In general, not enough time has passed since the full implementation of the provisions of AFA for all likely impacts to be manifest.

- Management measures directed toward Steller sea lion protection have made a significant impact on the fishery. Some of the more restrictive measures were imposed in 2000, and a full suite of alternative measures were analyzed by NMFS in 2001. Given the recency of these developments and the interactive nature of Steller sea lion-related management changes with other management initiatives, impacts are still unfolding and are expected to vary significantly from community to community and region to region.

In sum, the Alaska groundfish fisheries are taking place in a dynamic socioeconomic context, and one that has proven particularly volatile in the past few years with respect to changes within the groundfish fishery itself, as well as with respect to other fisheries that, in turn, have interacted with the groundfish fisheries . These factors resulted in a baseline or 'status quo' that is by no means a set of static conditions.

3.9.9.3 Community Development Quota

The Community Development Quota (CDQ) program has had a major influence on regional participation in groundfish fisheries. In 1992, the CDQ program was developed to facilitate the participation of Bering Sea and Aleutian Island (BSAI) community residents in the fisheries offshore of communities , as a means to develop a local community infrastructure and increase general community and individual economic and social well-being. The CDQ program was established in perpetuity through the Magnuson-Stevens Act authorized by the U.S. Congress in 1996. The State of Alaska is responsible for the administration and monitoring of the program. The state administers the program jointly through the Alaska Department of Community and Economic Development (the lead agency) and the Alaska Department of Fish and Game.

The CDQ program allocates a portion of the TAC (or GHL, as appropriate) for federally managed BSAI species to eligible communities in western Alaska. Originally involving only the pollock fishery, the program has in recent years expanded to become multi-species in nature. The CDQ program includes such species as pollock, Pacific cod, Atka mackerel, flatfish, sablefish, and other groundfish, along with halibut and crab. Currently, the CDQ program receives allocations of the groundfish TACs that range from 10 percent for pollock to 7.5 percent for most other species. The CDQ program has contributed to infrastructure development projects in the region, as well as loan programs and investment opportunities for local fishermen. In recent years the program has provided more than 1,000 jobs annually for the region's residents, and yearly wages have exceeded $8 million.

Sixty-five Alaska Native Claims Settlement Act (ANCSA) villages near the Bering Sea have established eligibility under federal and state regulations, and these villages formed a total of six non-profit regional groups through which they participate in the program. The six CDQ groups are Aleutian Pribilof Island Community Development Association (APICDA); Bristol Bay Economic Development Corporation (BBEDC); Central Bering Sea Fishermen's Association (CBSFA); Coastal Villages Region Fund (CVRF); Norton Sound Economic Development Corporation (NSEDC); and Yukon Delta Fisheries Development Association (YDFDA). The State of Alaska and the National Marine Fisheries Service periodically allocate percentages of the TAC for each species, based upon evaluation of the Community Development Plans submitted by individual CDQ groups. The groups have established partnerships with fishing corporations. Local hire and reinvestment of proceeds in fishery development projects are a required part of the program.

Since it's inception, the CDQ program has contributed to fisheries infrastructure development. According to the ADCED, approximately 9,000 jobs have been created with wages totaling more than $60 million during the period that the CDQ program has been in operation. As annual royalties grow, the revenue streams have permitted development and accumulation of considerable savings and investment capital within the CDQ groups, for use in a variety of future investments. Data suggest that CDQ groups, when taken as a whole, have retained almost half of their gross revenues in some form of equity, whether infrastructure projects, vessel ownership, or cash. Since 1992, CDQ group's equity growth has averaged 37 percent per annum, or slightly more than $10 million each year. It has been reported by the State of Alaska that, by 1997, CDQ groups had more than 200 people employed in the pollock fishing industry alone, 846 individuals in CDQ training, and a total expenditure of $1,041,309.

3.9.9.4 Subsistence

Ths subsistence use of natural resources by Alaska Native peoples stretches back to prehistoric times. Despite changes in technology and society, subsistence activities continue to be a central element in contemporary village life and culture, providing both physical sustenance and a sense of group identity and individual well-being. Subsistence is also important to many of Alaska's non-Native residents, despite differences in the cultural context of subsistence. Alaska residents involved in subsistence life styles, Native and non-Native alike, may feel the impact of commercial use of the same or interrelated natural resources.

The commercial groundfish fishery overlaps with a number of subsistence resources and activities, such as subsistence use of groundfish, salmon, and Steller sea lions, as well as creating opportunities for joint commercial and subsistence production.

Groundfish subsistence fishing occurs over a very large geographic area, but as detailed in Section 3.9.5.2, the subsistence use of groundfish is low in comparison to other subsistence resources , and in relation to other fish resources in particular. There is little, if any, indication that subsistence groundfish use is experiencing adverse direct impacts under current groundfish management approaches, or would be likely to experience direct impacts under any of the currently contemplated commercial groundfish fishery management alternatives, but a potential exists for joint production type of impacts where commercial and subsistence activities overlap. With available data, it is not possible to differentiate between subsistence use of groundfish retained from commercial catches, and groundfish taken during exclusively subsistence fishing.

As detailed elsewhere in this document, a substantial amount of effort has been devoted to determining the relationship of Steller sea lion population dynamics to commercial groundfish fisheries. Steller sea lions are also a subsistence resource species taken by a number of methods throughout the year. Unlike other subsistence activities that many members of a community participate in, hunting for sea lions is a relatively specialized activity, and a relatively small core of highly productive hunters from a limited number of households account for most of the harvest. For the relatively few recent years for which survey data are available, individuals from 20 to 29 percent of all households in the relevant communities actually hunted sea lion (Wolfe 2001). Once harvested, sea lion is distributed among a much wider range of households (Wolfe and Hutchinson-Scarbrough 1999, Wolfe 2001).

Some changes in harvesting regions and techniques have occurred over recent years. For Kodiak Island communities, the sea lion harvest used to take place at haulouts, and 20 or 30 animals were transported at a time aboard purse seiners. Thus, one or two hunters could supply an entire village. Currently, hunting sea lions involves two or three individuals using skiffs to hunt sea lions swimming in open water. The hauling capacity of such skiffs is one or two animals, and Kodiak hunters prefer to take young adults of medium size rather than large bulls or young pups. Peak months for harvest are October through December (Hayes and Mishler 1991).

Hunting methods vary somewhat in the Aleutians and Pribilof Islands and are documented in Wolfe and Mishler (1995). Pribilof Island residents hunt sea lions almost exclusively from the shore and target swimming juvenile (mid-size) males. Hunters will at times hunt from skiffs in calm weather. Sea lion hunting on St. Paul occurs mainly from September through May. Sea lion hunting on St. George is similar to that of St. Paul, being predominantly shore-based. Harvest occurs mainly from January through May. Sea lion harvest in the Aleutian Chain (Atka, Unalaska, Akutan, and Nikolski) occurs mostly from skiffs in open water, and hunters target both sexes. Aleutian Chain hunters will concentrate effort near haulout locations and take more adult and female animals than do Pribilof Island hunters. Seasonality of sea lion harvest is quite variable and appears to be dependent on sea lion abundance and distribution. For Atka, Akutan, Saint George, and Saint Paul (and perhaps Unalaska and several other communities), Steller sea lions have in the past represented a very significant subsistence resource in terms of relative contribution to overall community subsistence resource consumption but, as discussed in Section 3.9.5.3, the available data lacks precision . What is evident, however, is that the area of heaviest subsistence use of Steller sea lions is in southwestern Alaska and is concentrated in a relatively few communities.

The communities of the Bering Sea and Gulf of Alaska regions engage in a wide range of subsistence activities other than direct groundfish and Steller sea lion harvest, these other activities may be directly or indirectly affected by the existing groundfish fishery (or future management actions). These activities include subsistence salmon fishing (potentially affected by salmon bycatch in the groundfish fishery), as well as a wide range of subsistence activities that are facilitated by engagement in the groundfish fishery, either through joint production (using commercial groundfish vessels or gear for subsistence) or by applying income derived from the commercial fishery towards subsistence pursuits.

Current Alaska groundfish fishery management includes provisions for the minimization of salmon bycatch, but salmon bycatch has remained a concern, particularly with respect to potential ongoing impacts to subsistence salmon fisheries. This issue has also been repeatedly noted in the public comment process for this PSEIS. The species of most concern as bycatch in the groundfish fishery are chinook and chum; of these two, chinook is considered a much larger potential problem. The largest subsistence harvests of chinook salmon in 1999 (the last full year for which data are available) occurred in the Kuskokwim area (77,660 salmon; 50%), followed by Yukon (50,515 salmon; 33%), Bristol Bay (13,009 salmon; 8%); and Northwest (6,242 salmon; 4%). As discussed in Section 3.9.5.4, although the numbers of salmon bycatch by groundfish trawl fisheries and associated impacts to western Alaska stocks under baseline conditions would appear relatively low, salmon bycatch is nonetheless a contentious issue given the current state of some of the salmon fisheries.

Joint production refers to the use of commercial fishing vessels and/or gear in the pursuit of subsistence. Subsistence fish can be retained during what are otherwise commercial trips, or separate trips (using the commercial vessel and gear) exclusively for subsistence fishing. In general, there is a paucity of information on joint production within the groundfish fishery. Some, but not all, vessels in the commercial groundfish fishery are used for subsistence in addition to commercial fishing. As a general rule, trips specifically dedicated to subsistence are uneconomic for the larger vessels engaged in the groundfish fishery. Larger vessels also tend to fish further from the community of residence of owner, skipper, and crew; therefore, subsistence use is not practical even during what could otherwise be combined commercial/subsistence trips.

For the largest vessels participating in the fishery, there is no indication of any subsistence utilization in any form. Smaller vessels are most likely to be involved in joint production. The proportion of the total subsistence production for individual communities that results from joint production from these particular vessels during the groundfish fishery is unknown. As a general rule of thumb, however, the smaller vessel classes are less likely to be narrowly specialized than the larger vessels. In practical terms, joint production opportunities vary by gear type as well as vessel size. Although quantitative data are few, knowledge of the industry would suggest that little subsistence takes place using trawl vessels compared to other gear types. Among the fixed gear classes, much more time is directed toward sablefish, salmon, and herring than to groundfish; therefore, the joint production opportunities in this class would remain relatively high independent of the groundfish management alternative chosen.

3.9.9.5 Environmental Justice

NEPA Compliance with an Executive Order regarding Environmental Justice is a development that has occurred in the last 10 years. Executive Order 12898 (Environmental Justice, 59 Fed. Reg. 7629 [1994]), requires each federal agency to achieve environmental justice by addressing "disproportionately high and adverse human health and environmental effects on minority populations and low-income populations." The population structure of the regions engaged in the groundfish fishery varies considerably. As discussed in Section 3.9.6 and elaborated on in the detailed groundfish regional and community profiles recently produced for the North Pacific Fishery Management Council (NPFMC 2002d), within Alaska, and particularly in the Aleutian and Kodiak Island regions, there is a relationship between the percentage of Alaska Native population and commercial fisheries development. Specifically, communities that have developed as large commercial fishing communities have become less Native in composition over time compared to other communities in the region.

The fishery has also had an impact on the male-female population balance for some of the Alaskan communities that are the focus of intensive groundfish processing. This is because processing workers reside within these communities for varying durations, and this workforce is predominantly male. While this type of direct impact on population structure attributable to groundfish is seen in few communities, these tend to be the communities with the highest level of groundfish-related processing activities and the highest engagement in, and dependence upon, the fishery. The differences in the male/female and Native/non-Native population segments are, to a degree, indicative of the type of structural relationship of the directly fishery-related population with the rest of the community. Again, this varies considerably from place to place and is not as evident in the southcentral and southeast Alaska regions as in the Alaska Peninsula/Aleutian Islands and Kodiak Island regions.

Interpretation of these data, in terms of engagement with the community, is less straightforward for some regions than for others. As detailed in the regional discussions, and in the community profiles available elsewhere (NPFMC 2002d), communities are engaged in, and dependent upon, the fishery in quite different ways through resident catcher vessel fleets, onshore processing facilities, and locally associated catcher processor (and/or mothership) entities. While no consistent data are available, field observations tend to indicate that ownership and crew demographics of the residential catcher vessel fleet for the relevant Alaska groundfish communities mirror those of the long-term male residents of the community at large. This situation would also appear to hold true for the smaller vessel catcher processor sectors based in the various Alaska regions. The larger vessel catcher processor and mothership sectors are, to a large degree, associated with the Washington region (with the caveat that ownership patterns have been changing in recent years and the percentage of Alaska-based ownership in general and Alaska CDQ ownership in particular has increased, as discussed at length elsewhere in this document), and crews tend to be drawn from a wide area rather than a particular community.

For the large groundfish processing plants the demographics of the workforce and the relation to the 'host' communities tend to be more complex, and have substantial environmental justice implications as the large majority of processing workers comprise a minority (although non-Alaska Native) population sector. In some Alaska groundfish communities, processing plants tend to be industrial enclaves somewhat separate from the rest of the community, while for others there is no apparent differentiation between the processing workforce and the rest of the regional or local labor pool.

A further complication for attribution of socioeconomic impacts to a regional base is the fact that for many workers in many of the sectors, groundfish-related work is performed in a region or community that is separate from where they have a other socioeconomic ties.

The demographic composition of the greater Seattle area is markedly different than Alaska groundfish communities, and the same type of demarcation between the industrial fishing operations and the resident population is not apparent. Workers on the larger at-sea operations based out of Seattle, however, tend to be drawn from minority populations.

The CDQ region presents yet another type of environmental justice context. Environmental justice issues are salient in this region due to the nature of the demographic and economic structure of the region, and the nature of the participation of this region and its communities in the fishery through the CDQ program. The specific attributes of participation varies as the program has been implemented differently in various subregions by different CDQ groups, but in general this program has been designed to foster economic development in minority (Alaska Native) and economically underdeveloped communities. As such, any impacts to the CDQ program or its communities are, essentially by definition, potentially environmental justice impacts. The existing conditions in this region and the attributes of the program are discussed in detail in Section 3.9.4.

Another type of environmental justice context concerns subsistence issues. While not only Alaska Natives participate in subsistence activities, areas in which subsistence activities are practiced that may be impacted by groundfish management alternatives are predominantly Alaska Native. Therefore, impacts to subsistence are also, in general, potentially environmental justice impacts. Existing conditions for relevant subsistence-associated populations are discussed in detail in Section 3.9.5.

3.9.9.6 Market Channels and U.S. Consumers of Groundfish Products

There are many factors that have influenced U.S. consumer preferences and the domestic demand for products of the Alaska groundfish fisheries. Health-related issues have been especially significant factors in recent years. Much of the increase in the demand for seafood, in general, stems from its perceived healthful properties. Seafood has recently been credited with having ingredients that reduce heart disease, arthritis, and depression and enhance sexual performance (Seafood.com 2001). A major impetus in seafood consumption occurred in 2000, when the American Heart Association recommended that people eat fish twice a week for its health benefits. Products obtained from the Alaska groundfish fisheries have undoubtedly played a major role in meeting this domestic demand for seafood. For example, it is known that the market for Alaska pollock fillets and Pacific cod fillets is mostly a domestic market, and the demand within the United States far exceeds the available supply (NMFS 2001b).

Despite the high demand for certain groundfish products among U.S. consumers, numerous past studies have indicated that the price elasticity of demand for those products, especially fillets, is fairly high (NMFS 2001b). In other words, market price is not appreciably affected by the quantity supplied. This is because the domestic fillet market is competitive in terms of product form (individually quick frozen, block, and twice-frozen), supplying country (Russia and China play major roles), and fillets from other species, including hake and hoki. The U.S. market for all fillets, particularly cod, has also been influenced by the increased production of aquaculture-grown whitefish (NMFS 2001b). The species of greatest significance is catfish, but in recent years there have been increases in both domestically produced and imported tilapia. Furthermore, seafood, in general, has had to compete with other animal protein sources in the American diet such as chicken, pork, and beef.

3.9.9.7 The Value of the Bering Sea and GOA Marine Ecosystems (Including Non-Consumptive and Non-Use Benefits)

Alaska's healthy ecosystems are valuable natural assets (Colt 2001). As human population, economic development, and other pressures have increase worldwide, such ecosystems grow more scarce, and hence their value increases significantly. The Bering Sea and GOA marine ecosystems are among Alaska's most important ecosystems. U.S. citizens derive a wide range of benefits from these ecosystems, including direct, on-site uses associated with consumptive activities (e.g., commercial and recreational fisheries) and non-consumptive activities (e.g., tourism, bird and whale watching, and simply appreciating the general aesthetics of wild areas). Benefits also accrue to individuals who do not use these marine ecosystems but who derive value from knowing they are being protected (i.e., existence value).

Because the Bering Sea and GOA marine ecosystems are so productive and provide such a wide range of highly-valued goods and services, any major modification of these ecosystems and associated species has likely had a dramatic effect on the quality of the human environment. Details on the baseline for these marine ecosystems are provided in Section 3.10. Moreover, existence value may be highly sensitive to the amount of information acquired, i.e., small changes in information or knowledge about a species may produce large shifts in existence value for that species (Stevens *et al.* 1991). It follows, therefore, that improvements in communication technology have led to significant increases in existence value. For example, the arrival of the internet has greatly enhanced the ability of the general public to access at low cost information about endangered species and other environmental assets, including those that occur in the Bering Sea and GOA.

3.10 Ecosystem

This section discusses the affected environment at the ecosystem level. It provides three kinds of information:

1. It summarizes relevant historical information and recent scientific data on the North Pacific Ocean ecosystem;

2. It discusses interactions among climate, commercial fishing, and ecosystem relationships in the North Pacific Ocean from a multi-species perspective, including climatic processes that may act as forcing agents on the BSAI and GOA ecosystems, producing background changes that are independent of human activities such as commercial fishing; and

3. It reviews indicators of the present status of the BSAI and GOA ecosystems that help to form the baseline for assessing and comparing potential future environmental consequences of the alternatives, including cumulative effects, in Chapter 4.

The section is subdivided as follows:

Section 3.10.1 presents a historical overview of the regional ecosystem, distinguishing the BSAI and GOA where records permit. The overview begins at the environmental reference point of 1740, the year before Vitus Bering's first expedition to Alaska, and continues to the present. It includes observational information from the eighteenth, nineteenth, and early twentieth centuries, as well as data collected after passage of the Magnuson Fishery Conservation and Management Act of 1976 (now the Magnuson-Stevens Fishery Conservation and Management Act, referred to as the MSA).

Section 3.10.2 summarizes interactions among climate, commercial fishing, and ecosystem characteristics in the North Pacific Ocean.

Section 3.10.3 evaluates the current status of the North Pacific Ocean ecosystem using indicators from three broad categories: predator-prey relationships, energy removal and flow, and biodiversity.

The main conclusions of this section are as follows:

1. The North Pacific Ocean ecosystem is within the bounds of natural variability with respect to predator-prey relationships, energy removal and flow, and biodiversity.

2. Fish and wildlife populations within the North Pacific Ocean ecosystem are naturally dynamic: at any point in history, some species are increasing in abundance while others are declining.

3. Climatic forcing agents exert a powerful influence on marine fish and wildlife populations of the BSAI and GOA. Gathering and incorporating knowledge about these forcing agents may increase their predictability and enhance the effectiveness of future fishery and wildlife management.

3.10.1 The North Pacific Ocean Ecosystem from 1740 to Present

This section reviews available historical information on the BSAI and GOA ecosystems and changes since 1740, the environmental reference point for the ecosystem analysis. While much of the earlier information is anecdotal, particularly accounts from the eighteenth and nineteenth centuries, it represents the best available observational data on the North Pacific Ocean ecosystem from those periods. More information on the history of North Pacific Ocean commercial fisheries and their management is presented in Appendix B. Detailed life history information on fish, birds, and marine mammals is presented in the individual species accounts (Sections 3.5 through 3.8).

Establishing an environmental reference point as the starting place for the historical review follows USEPA guidance for the consideration of cumulative effects (USEPA 1999). The historical review serves as the source for information about past external effects, natural and manmade, on the North Pacific Ocean ecosystem. In this case, the environmental reference point is set at 1740 because this was the year preceding Bering's first voyage, with naturalist Georg Wilhelm Steller, to BSAI and GOA waters (Steller 1743).

For this analysis, it is assumed that the BSAI and GOA ecosystems in 1740, one year prior to first contact, represent an ecologically sustainable condition. As defined by USEPA, an ecologically sustainable system "supports biological processes, maintains its level of biological productivity, functions with minimal external management, and repairs itself when stressed" (USEPA 1999). This definition allows the possibility that a sustainable ecosystem may change with respect to the details of its component parts–for example, as populations of individual species cyclically increase and decrease over time–but that the ecosystem-level characteristics with regard to overall productivity and ability to maintain structure and patterns of behavior in the face of disturbance continue without being intensively managed.

3.10.1.1 Eighteenth Century

The first fish and wildlife observations by non-indigenous visitors to what are now called the Bering Sea, Aleutian Islands, and Gulf of Alaska were made by Steller aboard the St. Peter in 1741 during Bering's first voyage to Alaskan waters. Steller's journals (Steller 1743) indicate that marine furbearers, birds, and fishes were abundant and easily observed at the time of first contact. In addition to whales, fishes, and many seabirds and terrestrial birds, Steller described abundant occurrences of four North Pacific marine mammal species: sea otter, sea lion, fur seal, and sea cow (*Hydrodamalis gigas*, a large manatee hunted to extinction by 1768). He collected thousands of botanical specimens and first described hundreds of plant species unknown in Europe. Having learned from indigenous people the value of certain plants (e.g., *Cochlearia officinalis*) in preventing and curing scurvy, Steller was the first European known to administer antiscorbutics to ships' crews, saving many lives.

During the half-century following Bering's first voyage, Russian traders killed large numbers of the abundant marine mammals, as well as arctic and red foxes, river otters, and other mammals for their pelts. The pelts were sold at high prices in Europe and China. Walrus were killed in large numbers for their ivory tusks. Sea otter harvests, which began in 1743, were particularly high, but mercantile records of the period have not been widely published. Some of the most complete records in English can be found in Bancroft (1886); these are summarized in Table 3.10-1.

Intensive harvesting of sea otters in the BSAI and GOA, including the waters of Prince William Sound and Cook Inlet, had been underway for 45 years by the time Gerassim Pribilof first reached the island of St. George, named for his ship, in June 1786. Bancroft described the scene as follows:

> *"The shores of St. George literally swarmed with sea-otters, which undisturbed so far by human beings could be killed as easily as those of Bering Island during the first winter after its discovery. Large numbers of walrus were secured on the ice and upon the adjoining small islands; arctic foxes could be caught by hand, and with the approach of summer the fur-seals made their appearance by thousands (p. 192)."*

Fur seals had been previously harvested from the Commander Islands and elsewhere, with Shelikof having imported 70,000 skins prior to 1780 (Bancroft 1886). However, the Russian acquisitions of St. George and St. Paul, which Pribilof reached in 1787, immediately opened a major new trade in fur seal skins at a time when sea otter populations, having sustained consistently high annual mortality rates for decades, were rapidly declining. Veniaminov (1840) stated that at the time of first contact with the Pribilof Islands in 1786, sea otters were so abundant that their numbers in the water physically impeded access to the islands. Within six years, not a single otter was observed in nearshore waters. Veniaminov unambiguously attributed these declines to direct mortality from fur harvesting. The new, seemingly inexhaustible supply of fur seals from the Pribilofs provided a timely substitute for the declining sea otters. Bancroft (1886) recounted a letter by Shelikof, dated 1789, describing the first fur harvest following Russian occupation of the Pribilofs: "[D]uring the first year the hunters obtained on the newly discovered islands 40,000 fur seal skins, 2,000 sea otters, 400 pounds [14,400 lbs.] of walrus ivory, and more whalebone [baleen] than the ship could carry."

In the late eighteenth century, BSAI and GOA sea otter populations had declined to the point that supplies of pelts were nearly exhausted. At the same time, the growing Russian settlement of coastal Alaska led to an expansion of the furbearer trade to include the trapping of terrestrial mammals such as mink, pine marten, and foxes, while fur seal killings continued in the Pribilofs. Concerns among the established Russian merchants to stabilize and protect their dwindling fur supplies as a growing number of competing rivals entered the market led to organization of the Russian American Company in 1799 (Bancroft 1886).

By the close of the eighteenth century, nearly 60 years of intensive fur harvesting had caused major declines in the marine mammals of the BSAI and GOA, and the Steller sea cow had been gone since 1768, hunted to extinction for meat. It is not known whether these high mortalities led to other changes to the marine ecosystem or how deeply the changes penetrated the food web. Major human impacts to upper trophic levels of the BSAI and GOA ecosystems were occurring as long as 250 years ago.

3.10.1.2 Nineteenth Century

In the early nineteenth century, the fur seal trade dominated Russian mercantile activities in Alaska. Fur seal harvest levels prior to 1817, while unrecorded, were estimated at 90,000-110,000 per year by Veniaminov (1840), who stated that the annual harvest was often undertaken without foresight. In 1803, for example, the accumulated store of fur seal skins in the Pribilofs reached 800,000, more than 700,000 of which were burned or thrown into the sea because of poor market conditions due to the Napoleonic wars.

Quantitative data on annual fur seal harvests in the Pribilof Islands were recorded from 1817 through 1837 (Table 3.10-2). The harvest declined from 60,188 in 1817 to 6,802 in 1837, a decrease by nearly 90 percent over two decades. Veniaminov (1840) wrote:

> *"The cause of the decrease in the number of fur seals is evident, and one can only wonder how they have survived up to the present, considering how mercilessly they have been killed year after year, that they produce but one offspring each year, and that, in addition to known perils encountered in their migrations, [they] must also be subject to some unknown ones (p. 147)."*

As noted in Section 3.10.1.1, Veniaminov stated that at the time of first contact with the Pribilof Islands, sea otters were so abundant that their numbers physically impeded access to the islands; within six years, not a single otter was observed in nearshore waters. Within three decades, by 1811, none was seen in offshore waters of the Pribilofs. In the Unalashka District, over 1,000 sea otters were harvested annually in the late eighteenth and early nineteenth centuries. By 1840, 70 to 150 were taken annually (Veniaminov 1840).

Similarly, Steller sea lions had been killed in great numbers during the latter two decades of the eighteenth century, and this trend continued into the nineteenth century. By 1840, about 2,000, including young, were harvested annually from St. George, and sea lions had been entirely absent from St. Paul for many years (Veniaminov 1840).

Although quantitative data were not available, Veniaminov states that seabird populations, very numerous at the time of first contact, were greatly reduced by 1840, and that only by instituting harvest prohibitions and controls could they be conserved or increased.

Economically important groundfish populations were observed to decline. At Unalashka, several hundred cod were harvested daily during earlier decades, but by 1825 and 1826, no cod were caught. Fluctuations in cod populations are reflected in the Eastern Aleut name for the fish, which translates as "the fish that stops" (Black 1993).

Seasonal migratory fish (e.g., salmon and Dolly Varden) were harvested annually in the hundreds of thousands in the early decades following first contact. By 1840, however, annual salmon harvests at Makushin village had declined from hundreds of thousands to tens of thousands, and Veniaminov observed that:

> *"The same situation obtains everywhere (p. 39)."*

Veniaminov attributed declines in groundfish populations to undersea volcanic activity. In 1825, immediately before a major eruption in the Unimak Range, dying cod and sculpin were observed floating in great numbers on the surface and were absent until after 1827 when a gradual recovery began. He attributed declines in salmon to the pollution of river mouths by refuse disposal and to changes brought by volcanic activity.

Following the purchase of Alaska by the United States in 1867, institution of regulatory controls on resource management began. In 1868, the U.S. Treasury Department sent agents to Alaska to protect fur seals and administer a lease to the Alaska Commercial Company for harvesting seals in the Pribilof Islands. As the Alaska salmon industry developed, government agents collected taxes on processed salmon products (Fredin 1987). Commercial fisheries for salmon and halibut expanded as technologies for large-scale canning, iced storage, and rail trans shipment developed. Salmon canneries were established in Alaska for the first time in 1878 (Cooley 1963).

Commercial fishing in the BSAI and GOA for cod and other groundfish, however, was unregulated and proceeded on a common-pool basis in which fishery resources were available to all participants. During the final three decades of the nineteenth century, expanding commercial groundfish harvests continued on a laissez-faire basis, open to any entrants and without noteworthy federal oversight. Cod stations were established in the late 1880s throughout the Aleutians to exploit the abundant resource, an indication that the cod population had rebounded substantially since Veniaminov's observations in the 1830s (Morgan 1980).

3.10.1.3 Twentieth Century Prior to Magnuson-Stevens Act

During the first three quarters of the twentieth century, the growth of commercial fishing, whaling, and fur seal harvesting put pressures on the North Pacific Ocean ecosystem by targeting important components of the food web, including top predators. A variety of policy instruments were put in place to moderate these pressures. Prior to passage of the MSA in 1976, commercial fishing was conducted in the North Pacific Ocean, including United States territorial waters, by fleets from many nations operating within a complex framework of multilateral and bilateral agreements. Under these agreements, international commercial harvests of groundfish rose to unprecedented volumes after the 1950s. Appendix B summarizes the history of the North Pacific Ocean groundfish fisheries and their management prior to 1976.

Similarly, commercial whaling increased greatly in the North Pacific Ocean region during the first half of the twentieth century, as Atlantic and South Pacific stocks became depleted. In 1946, the International Convention for the Regulation of Whaling, signed by 14 nations including the United States, established the IWC to conserve whale stocks and regulate commercial whaling. Under IWC oversight, commercial whaling in the North Pacific Ocean continued to increase, reaching its maximum level in the 1950s and 1960s. After this, concerns over stock depletions led the IWC to establish increasingly restrictive whaling quotas and to ban all commercial whaling in 1986. Small subsistence quotas for aboriginal peoples, including Alaska Natives, remain in effect and are adjusted periodically in accordance with whale population data. These limited harvests are not thought to affect whale population characteristics. For species-specific information on the life histories and current status of the whales, see Sections 3.8.11-25.

As previously noted, the commercial harvesting of northern fur seals began on the Pribilof Islands in the 1780s and continued through the nineteenth century, with protections starting to be imposed after the acquisition of Alaska by the United States in 1867. From 1786 to 1828, roughly 100,000 northern fur seals per year, primarily pups, were killed (Baird and Hanson 1997). Commercial harvesting during this early period, which included pregnant females, is generally believed to have caused the large reductions in population size observed in the late 1800s and early 1900s. From 1912, pregnant females were excluded from the harvest, and the fur seal population grew through the 1940s. In an effort to move the population toward a level where productivity would be maximized, approximately 300,000 females were killed between 1956 and 1968. The population did not respond as expected at the time, however, and pup production decreased (York and Hartley 1981).

In 1957, the United States, Canada, Japan, and the Soviet Union signed the Interim Convention on the Conservation of North Pacific Fur Seals, which established the North Pacific Fur Seal Commission. The

Interim Convention prohibited the hunting of fur seals at sea, but allowed the annual harvest on the Pribilof Islands to continue under the oversight of the Commission. The annual harvest continued through 1966, when Congress passed the Fur Seal Act prohibiting the taking of fur seals on United States lands and waters, with the exception of Native American subsistence use. The Interim Convention expired in 1984 because it was no longer supported by the United States, which had its own protective laws in place. The northern fur seal is now managed by NOAA Fisheries under the authority of the Marine Mammal Protection Act.

As the ecosystem concept gained currency in the 1960s and later, the ongoing large, international commercial harvests of groundfish, whales, and northern fur seals discussed above were considered likely to produce changes at the ecosystem level (Trites *et al.* 1999). As discussed in Section 3.10.2, the populations of some species in the EBS showed major alterations between the 1950s and the 1980s. Among the best documented were the declines of Steller sea lions (Section 3.8.1) and northern fur seals (Section 3.8.2), and the apparent increase and dominance of groundfish, particularly pollock and large flatfish (Section 3.5.1). Trites *et al.* (1999) proposed two hypotheses to account for these changes. First, the he removal of top predators from the food web through commercial harvesting was proposed as the mechanism for change. Second, a climate-related shift in physical oceanographic characteristics was implicated (for a review of physical oceanographic processes, see Section 3.3).

To test these hypotheses, Trites *et al.* (1999) used two inter-related software packages (Ecopath and Ecosim) to compare quantitatively the EBS ecosystem as it was during the 1950s, before large-scale commercial fisheries were underway, and during the 1980s, after many marine mammal populations had declined. They consolidated the hundreds of species that make up the EBS ecosystem into 25 functional groups. Some ecosystem indices derived from the two models suggested that the EBS ecosystem was more mature (that is, had more fully developed and diverse biological guilds and communities) in the 1950s than in the 1980s. However, the actual condition of the EBS in the 1950s was uncertain because of the relative paucity of data from that time. The ecosystem indices for both the 1950s and 1980s models suggested that the EBS was resilient and resistant to perturbations such as those from the commercial harvests described above. For example, removing whales from the 1950s ecosystem had a positive effect on pollock by reducing competition for food. However, commercial whaling alone was insufficient to explain the 400 percent increase in pollock biomass thought to have occurred between the 1950s and the 1980s. Nor did commercial fisheries account for the observed changes. Indeed, the magnitude of changes that occurred in the biomass estimates of all major groups in the EBS ecosystem could not be explained solely through trophic interactions influenced by commercial harvests. Instead, it was suggested that a climatic regime shift affecting hydrographic features such as the distribution of seawater temperatures was likely to be responsible (Trites *et al.* 1999). These findings are supported by traditional knowledge from many sources. For example, older residents of Sand Point and King Cove noted during the scoping process for this Programmatic SEIS that sudden decreases in marine fish and mammal populations occurred in the late 1940s and mid-1950s. Although they did not mention climate changes, these observations seem consistent with more recent scientific findings linking fish abundance to climatological conditions (e.g., Anderson and Piatt 1999, see Section 3.10.1.5). This is due to the finding that there was a large negative shift in the values of the Pacific Decadal Oscillation Index, which measures changes in North Pacific sea surface temperature variability, from the 1940s to mid-1950s. The negative phase of this index is associated with enhanced coastal productivity along Oregon and Washington and inhibited productivity in Alaska (NPFMC 2002c).

3.10.1.4 Ecosystem Trends under MSA Fishery Management Plans and Amendments

The BSAI and GOA currently support some of the largest and most productive commercial fisheries in the world. Under policies instituted by FMPs and their sequential amendments since passage of the MSA in 1976, the biological and oceanographic dynamics of these regions have been monitored to detect trends and potential sources of problems, such as overfishing or fishery-induced declines in species not targeted by commercial fisheries. The following two subsections summarize information on recent ecosystem trends in the BSAI and GOA management areas, respectively.

Ecosystem Trends in the BSAI Management Area

In a review of fishery trends and potential fishery-related impacts within the BSAI ecosystem, Livingston *et al.* (1999) examined historical biomass trends of three different trophic guilds to see if there was a relationship between fishing or climate and changes in total guild biomass or changes in species composition within guilds. For example, large fishing removals of one guild species might result in increases in other members of that guild as competitive pressures ease. Similarly, if fishing removes large numbers of a prey species important to all members of the guild, an overall decrease in the abundance of all the guild species might be observed, as well as decreased mean size at age of predators relying on that prey. Alternatively, if the factor inducing the observed change is environmental, trends in abundance or in mean size at age that correlate positively or negatively with temperature or other physical oceanographic factors might be seen. Three trophic guilds were examined:

1. offshore fish, mammals, and seabirds that consume small pelagic fish;

2. inshore fish, crabs, and other benthic epifauna that primarily consume infauna; and

3. a ubiquitous group that feeds on crab and fish (Figure 3.10-1).

Despite conservative exploitation rates, a variety of species in diverse trophic groups (e.g., arrowtooth flounder, Greenland turbot, some seabirds, and marine mammals) showed either increasing or decreasing long-term trends in abundance, and both fished and unfished species (pollock, cod, crabs, sea stars, and others) showed cyclic fluctuations in abundance over the two decades from 1979 to 1999. No link was found between species declines and prey abundance. The timing of some species declines, e.g., marine birds, was actually correlated with increases in the adult populations of their main prey species–in this case, pollock. Similarly, the timing of increases in some guild member biomass values did not relate to fishing intensity on other guild members (e.g., skate versus cod). The Livingston *et al.* study, however, did not consider spatial changes in prey abundance or availability that could occur, and these factors cannot be ruled out as potential causal links to changes in predator abundance.

Physical oceanographic factors, particularly northward or southward shifts in regional climatic regimes, were correlated with the recruitment of some guild members (see Sections 3.3.4 and 3.10.1.5), and decreases in individual growth of some species (rock sole) were linked to increases in rock sole biomass. Diversity changes in some trophic guilds were related to increases in a dominant guild member (e.g., pollock in the pelagic fish consumer guild, and rock sole in the benthic infauna consumer guild) rather than to fishing-induced changes in diversity.

The study by Livingston *et al.* (1999) showed a stable trophic level of catch and stable populations overall. The trophic level of the Bering Sea harvest has risen slightly since the early 1950s and appears to have stabilized as of 1994.

Modeling Biological Interactions Among Multiple Species

Livingston and Jurado-Molina (1999) have developed a computer-based model of predator-prey interactions among the dominant groundfish species in the EBS. Three goals have directed the development of this multi-species model: 1) to examine trends in mortality due to predation, 2) to examine the relative importance of predation versus climate in influencing fish recruitment, and 3) to provide a basis for evaluating how future changes in fishing intensity might affect the groundfish community. The model uses information on historical catch estimates and predation among the species to estimate numbers at age and predation mortality of groundfish populations. The following species are modeled as predators: walleye pollock, Pacific cod, Greenland turbot, yellowfin sole, arrowtooth flounder, and northern fur seal. Arrowtooth flounder and northern fur seal are considered "other predators," which means that population and mortality estimates are not made directly for these species. However, it is feasible to estimate the impact of their predation on other species in the model. Prey species are walleye pollock, Pacific cod, Greenland turbot, yellowfin sole, rock sole, and Pacific herring.

Results from the modeling indicate that most predation mortality occurs on juveniles, particularly juvenile walleye pollock. This juvenile mortality varies over time, and recruitment of juveniles into the adult population also varies. Cannibalism by adult pollock explains some of the recruitment variation, but it appears that much of the variability is related to climatic variation (see Section 3.10.1.5). Understanding of predation and climate as structuring forces on groundfish communities will be advanced when multi-species predation models like these are linked to climate models that predict survival rates of larval fish before they are vulnerable to predation.

Output from this predation model can be used to evaluate the multi-species implications of various fishing strategies. One question asked about the BSAI by groundfish stock assessment biologists is: What effects might uneven groundfish harvesting rates have on groundfish community dynamics? For example, some species, such as pollock, are fished up to the recommended level of ABC, while others, such as rock sole and yellowfin sole, are fished at levels below ABC for economic and bycatch reasons. Using a multi-species model, Jurado-Molina and Livingston (2000) examined what could happen over the long-term future to groundfish population size if species were harvested more evenly or were not harvested at all. They compared these projected changes with model predictions based on current groundfish fishing rates. They also compared the results with predictions using single-species models that did not consider predation interactions.

In the scenario where groundfish were fished more evenly (F_{ABC}) than actually occurs under the present harvesting regime (F_{REF}), the single-species models predicted almost the same population changes that the multi-species model did. The biggest differences between multi-species and single-species models were seen in the predictions for prey species biomasses of herring and rock sole, but even these were not very large (Figure 3.10-2).

Small differences in the predictions are the result of evaluating relatively small changes in fishing intensity. Larger differences between single-species models and the multi-species model are seen when the present fishing strategy (F_{REF}) is compared with a no-fishing strategy (Figure 3.10-3). Here, the main reason for the difference is that the multi-species model predicts that predators increase their consumption of prey when there is no fishing. The model results indicate that when pollock fishing is stopped, the largest beneficiary species is pollock itself. This is because adult pollock consume mostly younger (age 0 and age 1) pollock, while other predators tend to consume mostly older (age 1 and older) pollock. In the long-term, consumers of small pollock get the first opportunity to benefit from the increased abundance of juveniles when fishing stops.

In summary, the results of multi-species predator-prey modeling suggest that implementation of a more even harvesting regime would not produce effects much different from changes predicted by single-species models. The largest difference occurs in predictions under a no-fishing scenario, with the multi-species model predicting smaller increases in prey species such as pollock, rock sole, and herring than those predicted by the single-species models. Increases in predator populations, and thus predation mortality, under a no-fishing scenario are the reason for the lower rate of increase in prey populations in the multi-species model.

Multi-species Technological Interactions

Harvesting can have multi-species implications through technological interactions (i.e., co-occurrence of multiple species in a single target species fishery). When specific fisheries are unable to catch their target species exclusively, their fishing effort imposes some mortality on each species that is taken as bycatch. Bycatch of non-target flatfish species is a particularly important characteristic of several EBS target fisheries, including yellowfin sole, rock sole, flathead sole, and Alaska plaice. These species, along with Pacific halibut, occupy similar habitats on the EBS shelf and co-occur to varying degrees in the harvest. Additionally, the retention of Pacific halibut is prohibited in the federally managed groundfish fishery, and quotas of halibut bycatch—not directed target quotas—have been the main factor in restricting the fishery in recent years.

The total trawling effort for all flatfish fisheries combined imposes a variety of fishing mortality rates on the individual flatfish species. This has been evaluated with a multi-species yield-per-recruit model (Spencer *et al.* 1999). One motivation for such modeling is to consider management options that would increase the total flatfish yield, factoring in the bycatch of flatfish in the various fisheries. A main feature of this model is that a catchability coefficient is computed for each species and fishery, based on recent catch and effort data; the distribution of effort among the various EBS trawl fisheries (defined by species catch composition) is based on the same data. The slope of each line in Figure 3.10-4 is the total catchability for a particular species, resulting from all fisheries that harvest the species. For example, the catchability of yellowfin sole is higher than other species because a significant proportion of total trawling effort is directed toward this fishery, and this species has relatively high catchabilities in several fisheries.

Reaching halibut bycatch quotas early has resulted in early closures of the flatfish fisheries, thus resulting in large differences between fishing levels that would attain the ABC at F_{ABC} (triangles in Figure 3.10-4) and recent average F levels (asterisks) for most fisheries. One way to manage these species that are caught together would be to derive biological reference points for the complex as a whole. The $F_{40\%}$ level for the group combined (squares in Figure 3.10-4) would produce higher yields (in the absence of halibut bycatch quotas) than the single-species approach. This approach for managing flatfish as a group, however, would expose the yellowfin sole population to a higher fishing rate than the rate that would be recommended in a single-species management scheme. Therefore, this strategy might not provide optimal protection for yellowfin sole. If the complex were managed to protect the weakest stock (yellowfin sole), the combined flatfish fisheries would be able to increase effort by only a relatively small amount above the current effort levels (to the level of effort that would reach the yellowfin sole ABC at F_{ABC} (triangle in Figure 3.10-4). There is a relatively small difference between the recent average yellowfin sole F and the yellowfin sole $F_{40\%}$, indicating that there would be no significant change from current practice.

The limitation currently imposed on flatfish fisheries by the halibut bycatch quota has motivated fishermen to develop methods of reducing trawling effort that has high catchability on halibut (Gauvin *et al.* 1995) and also to develop fishing gear with lower halibut catchability (i.e., halibut excluder devices). These gear improvements and the already mandated phasing-in of requirements for retaining flatfish bycatch under the improved retention/improved utilization management approach show promise for producing a fishery management system with increased protection for protected species such as halibut and a large reduction in the levels of flatfish discards in flatfish fisheries. Because the gear improvements and improved retention scheme implementation will change the nature of the effort and multi-species catch characteristics of these target fisheries, the impacts of the improvements must be evaluated before multi-species biological reference points can be developed for target flatfish.

Ecosystem Trends in the GOA Management Area

Meuter (1999) examined GOA groundfish communities using groundfish and shrimp trawl data collected over several years from the eastern and western GOA. To identify spatial and temporal patterns in community structure, the data were analyzed for species richness, diversity, total abundance, and indices of species composition in relation to depth, temperature, salinity, sediment composition, geographic location, and time of sampling. The data were then compared to local and larger scale atmospheric and oceanographic changes. In general, species richness and diversity peaked at water depths of about 200–300 m in the GOA. Higher abundance, lower species richness and diversity, and a different species composition of demersal fishes were found in the western GOA as compared to the eastern GOA. Meuter concluded that these large-scale spatial patterns were related to upwelling differences between the two regions.

With respect to long-term trends, the lowest species richness (number of species per haul) was observed in 1984, whereas the lowest species diversity (as measured by the Shannon-Wiener diversity index) was seen in 1996. It is difficult to tell whether these trends are real because of changes in trawl survey techniques and gear usage during the 12-year sample period. General increases in total groundfish biomass were seen from 1984 to 1996 (Figure 3.10-5), coupled with statistically significant changes in species composition (Figure 3.10-6). Community structure in nearshore areas around Kodiak Island changed during this same period, with decreasing populations of shrimp and small forage fish and increasing populations of large, fish-eating species such as Pacific cod and flatfish.

Meuter found that the total biomass of commercially-fished species in shelf and slope areas had increased since 1984, despite a considerable, concurrent increase in harvest effort. At the same time, the abundances of unexploited (or underexploited) species including skate, some shark species, forage species, arrowtooth flounder, and other flatfish had increased (Figure 3.10-7). Populations of an overexploited species, the Pacific ocean perch, had also rebounded from low population levels. The controlling factor for these increases appeared to be environmental, with changes in community species composition in nearshore areas linked to an increase in advection in the Alaska Coastal Current. Meuter concluded that increased flow around the GOA may have enhanced the supply of nutrients and plankton on the shelf and upper slope areas, resulting in higher productivity.

In addition to Meuter's work, studies by Piatt and Anderson (1996), Anderson and Piatt (1999), Orensanz *et al.* (1998), Robards *et al.* (1999) and others, discussed in Section 3.10.1.5, provide evidence that physical oceanographic factors, particularly climate, have a controlling influence on biological community composition in the BSAI and GOA. An important conclusion to be drawn from these studies is that any effects of human activities on the marine environment should be considered in the context of the powerful physical forces that appear to be driving the BSAI and GOA ecosystems.

3.10.1.5 Climate-Implicated Changes in the North Pacific Ocean Ecosystem

Evidence from observations during the past two decades and the results of modeling studies using historical and recent data from the North Pacific Ocean suggest that physical oceanographic processes, particularly climatic regime shifts, might be driving ecosystem-level changes that have been observed in the BSAI and GOA. These physical oceanographic processes are reviewed in Section 3.3. Commercial fishing has not been largely implicated in BSAI and GOA ecosystem changes, but studies of other ecosystems with much larger fishing pressures indicate that fishing, in combination with climate change, can alter ecosystem species composition and productivity (Jennings and Kaiser 1998, Livingston and Tjelmeland 2000).

During 1997 and 1998, a period of warmer-than-usual ambient air temperatures (Hare and Mantua 2000), a number of unusual species occurrences were observed in the BSAI and GOA, including the following examples:

- In 1998, several warm-water fish species, including Pacific barracuda (*Sphyraena argentea*), were observed and/or caught in the GOA. Ocean sunfish (*Mola mola*) and chub mackerel (*Scomber japonicus*), occasionally recorded in southeast Alaskan waters, were documented there in unusually large numbers. Similarly, Pacific sleeper sharks (*Somniosus pacificus*) were caught (and released) in higher than normal levels in Cook Inlet, and salmon sharks (*Lamna ditropis*) were taken in fairly large numbers off Afognak Island (Kevin Brennan, ADF&G, personal communication).

- Spiny dogfish (*Squalus acanthias*) substantially increased in the Kodiak area and in Prince William Sound (Bill Bechtol and Dave Jackson, ADF&G, personal communication). In 1998, this species' inclusion in collection tows increased by more than 40 percent. A corresponding increase in spiny dogfish has been observed in the International Pacific Halibut Commission's GOA halibut longline bycatch surveys (Lee Hulbert, NMFS, personal communication).

- Individuals of several marine mammal species were seen at unusual times and/or places during 1998, including a Pacific white-sided dolphin (*Lagenorhynchus obliquidens*) near Haines and a northern right whale (*Eubalaena glacialis*) off Kodiak Island.

- Unusual bird sightings in the GOA included a gray-tailed tattler (*Heteroscelus brevipes*) south of the Kenai Peninsula and a mallard (*Anas platyrhynchos*) several miles offshore in the open ocean. Common murre (*Uria aalge*) die-offs were reported in Cook Inlet, Kodiak, the eastern Aleutians, Resurrection Bay, and the EBS.

- Three northern elephant seals (*Mirounga angustirostris)* were spotted in nearshore waters around Unalaska during late June and early July, whereas they are usually found farther offshore and at a different time of year.

- There were poor returns of chinook (*Oncorhynchus tshawytscha*) and sockeye (*Oncorhynchus nerka*) salmon to Bristol Bay during both years.

Research on climate shifts as a forcing agent on species and community structure of the North Pacific Ocean can be found in Francis and Hare (1994), Klyashtorin (1998), McGowan *et al.* (1998), Hollowed *et al.* (1998), and Hare and Mantua (2000). The approach used in these studies assesses correlations between past climatic patterns and changes in biomass or recruitment rate for particular marine species. Because cause-and-effect relationships between temporal and spatial patterns of climate change and corresponding patterns of change in biological populations have not been proven for the BSAI and GOA, the correlations must be considered circumstantial. But there are reasons to expect that causal links do exist. For example, stronger recruitment would be expected under more favorable climatic conditions, because more juveniles would be likely to survive to adulthood, whereas harsh conditions would result in weak recruitment because fewer juveniles would survive. In both cases, the recruitment patterns would be reflected in the strength or weakness of the affected age groups within future fisheries.

Francis and Hare (1994) analyzed historical data supporting a climate shift that caused a precipitous decline in the sardine (*Sardinops sagax*) population off Monterey, California in the 1950s. Although it had been widely concluded that this decline resulted solely from overfishing, the data indicate instead that a change in sea surface temperature was closely correlated with the sardines' disappearance, and this related closely to patterns of sardine numbers in marine sediments off Southern California. Consequently, both climate and fishing are now recognized to be implicated in the sardine population decline.

Francis and Hare (1994) related the intensity of the Aleutian low pressure system (Aleutian low), a weather pattern, with production of salmon and zooplankton. Winter ambient air temperatures at Kodiak and the North Pacific Index, an index tracking the intensity of the Aleutian low during the winter, were used as indicators of climatic severity. Strong correlations were found between long-term climatic trends and Alaskan salmon production. Annual weather patterns were found to be closely correlated with changes in zooplankton populations.

For the northeastern North Pacific Ocean, McGowan *et al.* (1998) showed that interannual climatic variations linked to the ENSO and decadal-scale climate shifts can be detected in physical oceanographic data. For instance, the depth of the mixed layer in the California Current and GOA became shallower over time, whereas the mixed-layer depth in the Central Pacific deepened during the same period. This was not, however, reflected in the mass flow of the California Current. Greater depth of the mixed layer during elevated sea surface temperature events was correlated with decreased nutrient availability, plankton abundance, and shifts in community structure. These researchers concluded that climatic events such as ENSO are correlated with changes in biological populations associated with the California Current. Biological processes in the GOA appear to be more strongly influenced by variations in the Aleutian low.

According to McGowan *et al.* (1998), climate-related changes in the biological communities of the California Current system ranged from declines in kelp forests to shifts in the total abundance and dominance of various zooplankton species. Some fish and invertebrate populations declined, and the distributional ranges of species shifted northward. In addition, seabird and marine mammal reproduction were apparently affected by ENSO conditions. Interdecadal changes in community structure also occurred, with intertidal communities becoming dominated by northward-moving southern species and changes in species proportions occurring in most other sectors of the ecosystem.

Interdecadal shifts observed in the northeastern North Pacific Ocean ecosystem have been of the opposite sign from those in the California Current system, with increases in zooplankton biomass and salmon landings observed in the GOA (McGowan *et al.* 1998, Francis and Hare 1994). These shifts have corresponded to the intensity and location of the winter mean Aleutian low, which changes on an interdecadal time scale.

Klyashtorin (1998) linked catch dynamics of Japanese sardines, California sardines, Peruvian sardines, Pacific salmon, Alaska pollock, and Chilean jack mackerel in the Pacific with an atmospheric circulation index that shows trends similar to the North Pacific Index used by other researchers. Other species, such as Pacific herring and Peruvian anchovy, are negatively associated with this index.

Hollowed *et al.* (1998) analyzed oceanographic and climatic data from the eastern North Pacific Ocean and compared those data with information on recruitment for 23 species of groundfish and five non-salmonid species and with catch data for salmon. The fish recruitment data were compared to environmental factors over various time scales and with varying time lags. Hollowed *et al.* (1998) found that, for species such as pollock, cod, and hake, recruitment was generally stronger during ENSO events. Whereas salmon and large-mouthed flatfish such as arrowtooth flounder, Greenland turbot, and Pacific halibut responded more strongly to longer-term events such as decadal-scale climatic regime shifts. Because both ENSO and decadal-scale ecosystem shifts are environmentally controlled, the results of this analysis support climate change as an important controlling factor in ecosystem dynamics.

There is considerable evidence that decadal and basin-scale climatic variability (Section 3.3.4) can affect fish production and ecosystem dynamics. Sudden basin-wide shifts in climatic regime have been observed in the North Pacific Ocean (Mantua *et al.* 1997), apparently due to changes in atmospheric forcing. Eastward- and northward-propagating storm systems dominate the wind stress on surface waters for short periods (less than one month), mixing the upper layers and altering sea surface temperatures (Bond *et al.* 1994). Because fish are very sensitive to ambient water temperature, even changes in surface temperature, if sufficiently frequent or prolonged, can alter fish distribution and reproductive success as well as recruitment (the number of juveniles that survive to enter the adult, reproducing portion of the population).

In a long-term trends analysis by computer, Ingraham and Ebbesmeyer (Ingraham *et al.* 1998) used the OSCURS model to simulate wind-driven surface drift trajectories initiated during winter months (December through February) for the period 1946 to present. The model-generated endpoints of the 3-month drift trajectories shifted in a bimodal pattern to the north and south around the mean. The winter flow during each year was persistent enough to result in a large displacement of surface mixed-layer water. The displacement also varied in a decadal pattern. Using the rule that the present mode is maintained until three concurrent years of the opposite mode occur, four alternating large-scale movements in surface waters were suggested: a southward mode from 1946 to 1956, a northward mode from 1957 to 1963, a southward mode from 1964 to 1974, and a northward mode from 1975 to 1994. As more northern surface water shifts southward, colder conditions prevail farther south, and as southward water moves northward, warmer conditions prevail farther north, both potentially affecting fish distribution and population dynamics.

Real-world evidence that atmospheric forcing alters sea surface temperatures comes from two principal sources: shorter-term ENSO events and longer-term Pacific Decadal Oscillations (Mantua *et al.* 1997). Temperature anomalies in the BSAI and GOA indicate a relatively warm period in the late 1950s, followed by cooling especially in the early 1970s, followed by a rapid temperature increase in the latter part of that decade. Since 1983, the BSAI and GOA have undergone different temperature changes. Sea surface temperatures in the BSAI have been below normal, whereas those in the GOA have been generally above normal. Consequently, the temperature difference between the two bodies of water has jumped from about 1.1°C to about 1.9°C (U.S. GLOBEC 1996).

Subsurface temperatures, potentially an even more important influence on biological processes, have been documented to change in response to climatic drivers. There was a warming trend in subsurface temperatures in the coastal GOA from the early 1970s into the 1980s similar to that observed in GOA sea surface waters (U.S. GLOBEC 1996).

In addition, seawater temperature changes in response to ENSO events occurred, especially at depth, in 1977, 1982, 1983, 1987, and in the 1990s. The 1997-1998 ENSO event, one of the strongest recorded in the twentieth century, substantially changed the distribution of fish stocks off California, Oregon, Washington, and Alaska. The longer-term impacts of the 1997-1998 ENSO event remain to be seen. Francis *et al.* (1998) reviewed the documented ecological effects of this most recent regime shift through lower, secondary, and top trophic levels of the North Pacific Ocean marine ecosystem. Some of the following impacts on higher trophic levels are based on this review:

- Parker *et al.* (1995) demonstrated marked similarities between time series of the lunar nodal tidal cycle and recruitment patterns of Pacific halibut.

- Hollowed and Wooster (1995) examined time series of marine fish recruitment and observed that some marine fish stocks exhibited an apparent preference (measured by the probability of strong year and average production of recruits during the period) for a given climate regime.

- Hare and Francis (1995) found a striking similarity between large-scale atmospheric conditions and salmon production in Alaska.

- Quinn and Niebauer (1995) studied the Bering Sea pollock population and found that high recruitment coincided with years of warm ocean conditions (above normal air and bottom temperatures and reduced ice cover). This fit was improved by accounting for density-dependent processes.

Additional evidence of marine ecosystem impacts linked to climatic forcing comes from Piatt and Anderson (1996), who provided evidence of possible changes in prey abundance due to decadal-scale climate shifts. These authors examined relationships between significant declines in marine birds in the northern GOA during the past 20 years and found that statistically significant declines in common murre populations occurred from the mid- to late 1970s into the early 1990s. They also found a substantial alteration in the diet composition of five seabird species collected in the GOA from 1975 to 1978 and from 1988 to 1991, changing from a capelin-dominated diet in the late 1970s to a diet in which capelin was virtually absent in the later period.

The effects of ten-year regime shifts on the inshore GOA were analyzed using data from 1953 to 1997 (Anderson and Piatt 1999). Three taxonomic groups dominated (approximately 90 percent) the biomass of commercial catches during this period: shrimp, cod and pollock, and flatfish. When the Aleutian low was weak, resulting in colder water, shrimp dominated the catches. When the Aleutian low was strong, water temperatures were higher, and biomass the catches were dominated by cod, pollock, and flatfish. Similar results were reported in very nearshore areas of lower Cook Inlet (Robards *et al.* 1999).

Few patterns were seen in the less-common species over the course of the study. Generally, the transitions in dominance lagged behind the shift in water temperature, strengthening the argument that the forcing agent was environmental. However, different species responded to the temperature shift with differing time lags. This was most evident for species at higher trophic levels, which are typically longer-lived and take longer to exhibit the effects of changes. The evidence suggests that the inshore community was reorganized following the 1977 climate regime shift. Although large fisheries for pandalid shrimp may have hastened the decline for some stocks (Orensanz *et al.* 1998), unfished or lightly fished shrimp stocks showed declines. Both Orensanz *et al.* (1998) and Anderson and Piatt (1999) concluded that the large geographic scale of the changes across so many taxa is a strong argument that climate change is responsible.

Other studies have linked production, recruitment, or biomass changes in the BSAI with climatic factors. For example, a climate regime shift that might have occurred around 1990 has been implicated in a large increase in gelatinous zooplankton in the BSAI (Brodeur *et al.* 1999). Recruitment in both crabs and groundfish in the BSAI has been linked to climatic factors (Zheng and Kruse 1998, Rosenkranz *et al.* 1998, Hollowed *et al.* 1998, Hare and Mantua 2000).

There are indications from several studies that the BSAI ecosystem responds to decadal oscillations and atmospheric forcing, and that the 1976-1977 regime shift had pronounced effects. A peak in chlorophyll concentrations in the late 1970s was closely correlated with an increase in summer mixed-layer stability documented at that time (Sugimoto and Tadokoro 1997). Also, on a decadal time scale, chlorophyll concentrations in the summer were positively correlated with winter wind speeds, indicating a positive response of BSAI phytoplankton to stronger Aleutian lows (Sugimoto and Tadokoro 1997).

Evidence of biological responses to decadal-scale climate changes are also found in the coincidence of global fishery expansions or collapses of similar species complexes. Sudden climate shifts in 1923, 1947, and 1976 in the North Pacific Ocean substantially altered marine ecosystems off Japan, Hawaii, Alaska, California, and Peru. Sardine stocks off Japan, California, and Peru exhibited shifts in abundance that appear to be synchronized with shifts in climate (Kawasaki 1991). These historical 60-year cycles are seen in paleo-oceanographic records of scales of anchovies, sardines, and hake as well. Other examples are salmon stocks in the GOA and the California Current whose cycles are out of phase. When salmon stocks do well in the GOA, they do poorly in the California Current and vice-versa (Hare and Francis 1995, Mantua *et al.* 1997).

In addition to decadal-scale shifts, interannual events such as the ENSO can have significant impacts on fish distribution and survival, and can affect reproduction, recruitment, and other processes in ways that are not yet understood. This is particularly true for higher-latitude regions such as the northern California Current and GOA. As noted above, the 1997-1998 ENSO event significantly changed the distribution of fish stocks off California, Oregon, Washington, and Alaska. A change that has persisted to the present. Predicting the implications of this trend for future fishery management is problematic, in part because ENSO signals propagate from the tropics to high latitudes through the ocean as well as through the atmosphere, and it is difficult to separate these two modes of influence. Information on the dynamics of North Pacific Ocean climate and how this is linked to equatorial ENSO events is not adequate to adjust fisheries predictions for such abrupt, far-reaching, and persistent changes. Warm ocean conditions observed in the California Current during the present regime may be due, in large part, to the increased frequency of ENSO-like conditions.

In conclusion, evidence from past and present observations and modeling studies at the community and ecosystem levels for the BSAI and GOA suggest that climate-driven processes are responsible for a large proportion of the multi-species and ecosystem-level changes that have been documented. Modeling studies have been a valuable tool for elucidating the possible long-term implications of various fishing strategies. As with all computer-based models, these have been sensitive to unproven assumptions about recruitment and its relationship to climate. As the preceding discussion suggests, the models could be improved by incorporating components that include climatic effects on species, particularly with respect to recruitment. However, this approach has not been widely applied yet to species in the BSAI and GOA ecosystems.

3.10.2 Interactions Among Climate, Commercial Fishing, and Ecosystem Characteristics in the North Pacific Ocean

As the preceding discussions show, groundfish fishery management in the BSAI and GOA is implemented in a dynamic environment where both commercial fishing and climate-driven physical oceanographic processes interact in complex ways to affect the marine ecosystem. To characterize these interactions, it is necessary to distinguish, where feasible, the separate effects of fishing and climate on biological populations. The following discussion reviews current knowledge regarding these effects and their relationship to ecosystem characteristics.

Three processes underlie the population structure of species in marine ecosystems: competition, predation, and environmental factors. Natural variations in the recruitment, survival, and growth of fish stocks are consequences of these processes. The first process, competition, is a basic concept underlying many ecological theories (e.g., Hairston *et al.* 1960, Welden and Slauson 1986, Yodzis 1978, 1994). It requires an assumption that species in an ecosystem are limited in their access to critical resources such as food, space, reproductive mates, and time for important activities. Predation is important, because it changes prey density, thereby directly or indirectly affecting populations throughout the ecosystem. Finally, environmental factors, particularly climatic processes, are thought to be major agents of change in North Pacific Ocean ecosystems. Climate has the potential to influence the important biological processes of reproduction, growth, consumption and predation, movement, and, ultimately, the survival of marine organisms.

Against this complex and dynamic natural background, human activities such as commercial fishing can influence the structure and function of marine ecosystems. Like competition, predation, and climate change, the effects of commercial fishing can extend over a range of temporal, spatial, and population scales. Large-scale commercial fishing has the potential to influence ecosystems in several ways. It may alter the amount and flow of energy in an ecosystem by removing energy and altering energetic pathways though the return of discards and fish processing offal back into the sea. The recipients, locations, and forms of this returned biomass may differ from those in an unfished system. In addition, the selective removal of species has the potential to change predator-prey relationships and community structures. Fishing gear may alter bottom habitat and damage benthic organisms and communities.

Both climate and commercial fishing activity currently influence the structure and function of the North Pacific Ocean ecosystem (Francis *et al.* 1999). Since climate change and commercial fishing can co-vary, it may be difficult to distinguish the impacts of the two (e.g., Trites *et al.* 1999). The primary way in which complex scientific knowledge is integrated to further the understanding of the influence of natural and human-related processes on marine ecosystems is through the use of models. Models can be as simple as conceptual diagrams that show a picture of how we think a certain ecosystem process operates, or they can be very complicated, with quantitative descriptions of the relationships between various factors and species growth, recruitment, movement, or survival. Reviews of the status of models that have been developed to understand the effects of climate and fishing on ecosystems have been produced by Livingston (1997) and Hollowed *et al.* (2000a). These reviews outline the types of models presently being used and the state of our ability to understand and predict the effects of the two important factors of climate and fishing in marine ecosystems by using models.

Most models that consider more than one species link the species together through knowledge about their feeding (trophic) interactions. Once the trophic linkages among species are understood, questions about impacts of predators and prey on one another (Yodzis 1994), or how natural or human-induced habitat changes affect the food-web structure (Yodzis 1996), can be addressed with a variety of multi-species or ecosystem models. Another model type, called a technical interaction model, may consider the simultaneous capture of groups of species by a particular fishery or type of fishing gear.

With the exception of information on forage fish, which—unlike many marine species—are preyed on as adults and not just mainly as juveniles, most scientific advice from multi-species models is not presently being used in making short-term management decisions. These models are mainly useful for trying to understand the possible medium- (6 to 10 years) and longer-term implications of various management strategies on the ecosystem.

However, long-term predictions from single-species, multi-species, and ecosystem-level models remain uncertain, because the predictions rely heavily on assumptions about recruitment, particularly for predators (Gislason 1991 and 1993), which may be strongly influenced by environmental variation. Limitations still exist regarding the ability to predict both future changes in climate and recruitment rates resulting from a particular climate state.

Therefore, as noted by Parkes (2000) and Hall (1999a), predator-prey models are not considered reliable enough to provide directly applicable management advice at the present time. Hall (1999b) notes that ecosystem-based management advice should move toward setting single-species biological reference points for non-target species, developing single-species reference points for localized regions (i.e., spatially explicit management), and using measures of system-level properties (e.g., species diversity, trophic level of the catch, biomass-size distributions) to derive ecosystem-level reference points.

Food web models of the BSAI, specifically, the EBS shelf, ecosystem have been developed for the 1950s and 1980s (Trites *et al.* 1999). These models use the Ecopath strategy for evaluating mass-balance in marine ecosystems. Ecopath uses estimates of biomass, consumption, diet, and turnover rates of populations or groups of populations to evaluate energy flow and mass-balance in a particular ecosystem (Christensen 1990).

Ecopath creates static biomass flow models of ecosystems and represents a snapshot of the ecosystem for a given time period. Species in these models are linked, so that the biomass transfer resulting from processes such as fecundity, mortality, production, respiration, and predation are in equilibrium (balanced). These types of models provide a way to identify large-scale views of ecosystems and to highlight data gaps (Christensen 1990, 1992, 1994; Pauly and Christensen 1995).

An examination of energy flow within the ecosystem is instructive, although one must be careful in interpreting the inevitable differences among the flow estimates. For instance, although the magnitude of biomass flow from prey to tertiary consumers (e.g., juvenile pollock to seabird predators) is modest relative to that between primary producers and primary consumers (e.g., phytoplankton to crustaceans), it may nonetheless play a significant role in the dynamics of the food web (P. Yodzis, University of Guelph, Ontario, Canada, personal communication). Further, if a food web is composed of few, highly connected species in a trophic sense, removal of a predator may yield a larger ecosystem perturbation than a similar removal from an ecosystem with weaker trophic links among many predators and prey (e.g., Pimm 1982).

The Ecopath models for the Bering Sea were initially developed to see if impacts of intensive whale harvesting that occurred in the 1950s and 1960s were sufficient to explain the ecosystem structural changes that were observed in the 1980s, discussed in Section 3.10.1.3. The primary removal of energy in both decades was by harvesting whales and pelagic fishes in the 1950s, and pollock in the 1980s. The production estimate for the 1950s simulation showed baleen whales as the dominant ecosystem component. These whales were classed as a midlevel consumer with a trophic level slightly higher than pollock, due to their consumption of squid. The dominant component in the 1980s simulation was pollock, the dominant fishery. There was a slight drop in trophic level of the catch between the two periods, but this was acknowledged to be an artifact of the volume of squid assumed in the diet of the baleen whales. Without this assumption, there was little change in trophic level of harvest. Trophic level of the catch actually incr eased from the 1950s to the 1980s, if only fish harvests are considered. This would suggest that harvesting in the Bering Sea at present is at a level that has been sustained over long periods. A further result of this simulation was that whale harvests required an estimated 47 percent of net primary production in the Bering Sea in the 1950s. Fisheries of the 1980s, dominated by pollock, required only 6.1 percent of primary production.

Measures of ecosystem maturity show some differences between the two Bering Sea models. The ratio of primary production to respiration, net system production, and the ratio of biomass to throughput indicate a more mature ecosystem state in the 1950s compared with the 1980s. This is due to the assumption that benthic infauna biomass was lower in the 1980s. However, benthic infaunal surveys used to estimate biomass for the two models used different methods and may not be comparable.

Trophic pyramids are similar for the two time periods, and both indicate that biomass and energy flow were distributed fairly well throughout the system. The steep-sided shape of the pyramids indicates that there is a lot of energy flow at lower trophic levels. One system maturity index, the ratio of primary production to total biomass, actually indicates a more mature system in the 1980s relative to the 1950s. However, this was due to assumptions about the change in primary production between the two time periods, for which there is conflicting evidence. Conclusions about system maturity will be premature until trends in primary production and benthic infauna biomass are better understood.

The Bering Sea appears to be more mature than other modeled ecosystems, particularly with regard to total system throughput, which measures the sum of all energy flows in the system. It has ecosystem measures that indicate it has significant strength in reserve, which makes it more resilient or resistant to perturbations compared with other ecosystems.

Ecosim, a forward-looking simulation coupled to Ecopath, was used to project the results of various scenarios. The model was run in either an equilibrium or dynamic mode. The equilibrium mode assumed that the total biomass of the ecosystem remained stable, and as the biomass of one component declined, others were required to increase to balance it. Dynamic models do not have this requirement.

The equilibrium mode of Ecosim was used to examine the results of changes in a species' abundance on interacting groups. The results of the equilibrium model suggest that changes in baleen whale numbers could significantly affect pollock populations, and that increases in sperm whale numbers could yield decreases in the numbers of Steller sea lions through competition. Reducing pelagic fish numbers reduces the numbers of seabirds that feed on them, as well as numbers of Steller sea lions and large flatfish. Increasing fishing pressure on pollock would have little effect on their biomass, and increasing fishing pressure on large flatfish would result in increased Steller sea lion populations through the removal of a competitor.

In a different approach, the dynamic mode of Ecosim was used to look at possible mechanisms involved in the historical marine biomass changes seen between the 1950s and the 1980s. Scenarios used for the dynamic model were a regime shift that resulted in changes in primary production; a commercial fishery simulation to see if fishing whale could account for the observed changes; three pollock fishing scenarios that project into the future; and scenarios which varied the fishery mortalities on pollock and pelagic fishes.

These simulations suggested that commercial harvesting of fish and whales had little likelihood of producing the changes seen in actual pollock populations since the 1950s. The effect of increasing primary production provided a much more realistic change in the pollock population. While most groupings showed increases, Steller sea lions did not.

There are substantial uncertainties about the abundance of small pelagic fish in both time periods and the abundance of pollock in the 1950s model. Low abundance of pollock and higher abundance of small pelagic fish in the 1950s was assumed. However, although non-standardized surveys by the Soviets during the 1950s showed apparently lower pollock abundance, their research on diet composition of groundfish indicated that pollock was a primary prey item of many species. It is possible that pollock may have been more abundant in the 1950s than has been assumed. Further model testing with this change in assumptions should be done.

Another dynamic simulation showed that, contrary to what might be expected, stopping the commercial pollock harvest had a slight negative effect on Steller sea lions. This is because two of the Steller sea lion prey items, small pelagic fish and juvenile pollock, declined when adult pollock increased. Adult pollock are cannibalistic and compete with small pelagic fish for large zooplankton prey in this model. More recent versions of the model, which changed the assumptions regarding recruitment now show that juvenile pollock actually increase under this scenario, but that Steller sea lions still show a slight negative effect. This is presumably because of the assumption of the dominance of small pelagic fish as a prey item of Steller sea lions. Small pelagic fish still decline under the assumption of increasing pollock, because adult pollock compete with them for large zooplankton prey.

In conclusion, these model simulations indicate uncertainty about the biomass of lower trophic level species in the two time periods. It appears that climate-related shifts in lower trophic level production could partly explain the ecosystem changes that occurred between the 1950s and the 1980s. However, the model only captures predation-related recruitment variability and cannot show climate-related variability in recruitment, which is probably much larger. More detailed scenarios that examine the spatial availability of prey will have to be performed to improve our understanding of the complex interaction between fishery removals and predator-prey interactions.

3.10.3 Current North Pacific Ocean Ecosystem Status and Sustainability

In order to examine North Pacific Ocean ecosystem status and sustainability, we need to identify key ecosystem components and processes that characterize an ecosystem. We must identify features of these components and processes that may indicate whether Alaskan groundfish fisheries have had impacts on the BSAI and GOA ecosystems. The first step in this identification of key components and processes is to examine the definition of ecosystems.

A review of the literature shows that there are numerous definitions of what constitutes an ecosystem. One of the earliest definitions, by Tansley (1935), includes all of the organisms and all the physical factors, what he termed the habitat factors in the widest sense. These linked biological-physical systems are what he termed an ecosystem. It was clear from the definition that although most focus tended to be on the organisms in the system, those organisms could not be separated from their physical environment. Similarly, Botkin (1990) defined an ecosystem as a set of interacting species and their local, non-biological environment, functioning together to sustain life. Large marine ecosystems have been defined as regions characterized by distinct bathymetry, hydrography, productivity, and trophically dependent populations (Sherman and Alexander 1986). Odum's (1977) definition of an ecosystem also recognizes that the biological and physical aspects form a functional unit that has some characteristic trophic structure and material cycles (i.e., how energy or mass moves among the groups). Central to these definitions is the relationship of the organisms to the physical environment and the concept of trophically-dependent or interacting species or groups.

The main ecosystem components and processes that are important to evaluate in order to determine ecosystem impacts of human activities are still the subject of a great deal of research and debate. There are two fairly different scientific views of ecosystems. The functional view was expressed by Odum (1972) and the more hierarchical view was recognized by O'Neill *et al.* (1986). In Odum's functional view of ecosystems, the functional elements consist of:

- Energy flow circuits.
- Food chains (trophic relationships).
- Diversity patterns in space and time.
- Nutrient cycles.
- Development and evolution.
- Control (maintenance of a steady state at the system level by the use of feedback control mechanisms).

Functional components in this view are elements and molecules involved in material cycles (e.g., carbon, nitrogen, carbon dioxide, water); organic compounds that link living and non-living ecosystem components (proteins, carbohydrates, etc.); climate regime (temperature, rainfall, etc.); producers (mainly green plants), consumers (mainly animals that consume other animals or organic matter); and decomposers (mainly bacteria) that break down organic matter and release substances that can be used by producers. This view of ecosystems places energetics as the central focus. It deals with cyclic causal pathways and feedbacks that are often unobservable, but essential to ecosystem maintenance. In its extreme form, energy flow and nutrient cycling are more important than the living entities performing the function. This view tends to ignore the role of species in the system and makes it difficult to detect total ecosystem changes. Therefore, ecosystem study at this level of organization tends to be model-dominated.

Another dominant form of studying ecosystems is the population-community approach, in which ecosystems are considered as networks of interacting populations of different species. The abiotic environment is viewed as more of an external influence on the biological system and is not seen as an integral part of it. This level of study is observation-dominated, since most field research is focused at the population-community level. This view has limitations, in that it is difficult to infer ecosystem properties from species properties, although an exception might be the use of indicator or key species. The isolation of organisms from their biotic and abiotic environment in this approach can also make it difficult to understand ecosystem dynamics.

These two somewhat dichotomous views of ecosystems can be reconciled somewhat by recognizing that species serve important functional roles in ecosystems. An integrated view of the population-community level of study and the process-functional approach recognizes that ecosystems consist of sets of biological communities in which populations of organisms serve various functional roles (O'Neill *et al.* 1986). This view of ecosystems links the community-population studies that have been a dominant research focus with the process-functional approach that is typical of Odum's ecosystem definition, where the focus is more on flows of energy or matter.

Given these views of ecosystems, it seems an evaluation of North Pacific Ocean ecosystems should include key ecosystem processes or functions outlined by Odum, such as trophic relationships, diversity patterns, energy flow, and the role of the physical environment in influencing the dynamics, as well as information about species and communities. Because ecosystem features may be difficult to observe at the broad functional level that Odum describes, we should consider important observable processes at the species or community level that can provide an indication of changes that might be occurring at the ecosystem level.

Costanza (1992) prescribes three types of measures that might indicate overall ecosystem "health." These measures are vigor (a measure of system activity, metabolism, or primary productivity), organization (includes diversity and connectivity), and resilience (ability of a system to maintain structure and patterns of behavior in the face of disturbance). He suggests network analysis and simulation modeling to develop these measures. However, as was noted in Section 3.10.2, simulation models are not well developed in this regard, and we may need to rely more heavily on indicators that are direct measures of small pieces of the system in order to evaluate the present status of North Pacific Ocean ecosystems. Therefore, we will focus more on species- and community-level measures that indicate changes in trophic relationships, diversity patterns, energy flow, and the role of the physical environment in influencing these changes.

Because of the need for further validation of predator-prey and ecosystem models, there has been a large effort to develop indicators of ecosystem change based on more observable aspects of ecosystems and factors influencing them, such as fishing and climate. The Ecosystem Considerations Chapter of the Groundfish Stock Assessment and Fishery Evaluations Reports (NPFMC 2002) provides a compendium of status and trends of various ecosystem components and present status of knowledge with regard to human and climate-induced factors that might be influencing these components. Key indicators of ecosystem change with regard to trophic relationships, diversity patterns, and energy flow can be derived from these species- and community-level measures.

As noted above, commercial fishing can influence ecosystems by altering predator-prey relationships, not only by removing key species but also through the introduction of non-indigenous species; by adding or removing energy and redirecting pathways of energy flow through fish removals and the return of discarded biomass to the sea; and by altering biodiversity as measured in a variety of ways, including species-level diversity, functional diversity, and genetic diversity. Any fisheries management policy that allows commercial fishing will create the potential for such effects to a greater or lesser degree. Since passage of the MSA in 1976, fisheries management policy in the BSAI and GOA has been implemented against the background of a relatively mature and resilient ecosystem that has exhibited changes in species composition, guild and community structure, production, recruitment, geographic distribution, and biomass. As discussed in Sections 3.10.1.5 and 3.10.2, the factors driving these ecosystem changes remain speculative, but decadal-scale climate shifts and interannual climatic variations linked to the ENSO phenomenon have been suggested as forcing agents (McGowan *et al.* 1998). For example, increases in zooplankton biomass and in salmon landings documented in the GOA have been correlated with the intensity and location of the winter mean Aleutian low pressure system, which changes on an interdecadal time scale (Francis and Hare 1994, McGowan *et al.* 1998, Orensanz 1998, Anderson and Piatt 1999, Robards *et al.* 1999). Beyond such correlations with climatic indices, cause-and-effect relationships between climate and ecosystem changes have not been proven, but climate-related changes in physical oceanographic factors such as temperature, salinity, current patterns, upwellings, sediment composition, and nutrient supply have been implicated (e.g., Meuter 1999).

Changes in BSAI and specifically in EBS species composition within guilds and in total guild biomass have been examined to determine if they might be correlated with fishing pressure on predator-prey cycles. Livingston *et al.* (1999) found that long-term increases and decreases in the abundance of selected invertebrate, fish, bird, and marine mammal species did not show positive correlations with prey abundance, and that cyclic fluctuations in abundance occurred in both fished and unfished species. Furthermore, these workers found that changes in species diversity within guilds related to increases in a dominant guild member (e.g., pollock, rock sole) rather than to decreases in abundance caused by fishing pressure. The authors concluded that the EBS ecosystem shows two indicators of stability. First, the trophic level of the harvest, after rising slightly since the 1950s, appears to be stable as of 1994, suggesting that present harvest levels are sustainable. Second, the fish populations examined are stable, i.e., fluctuate normally without showing prolonged trends in a particular direction. This conclusion is supported by modeling results indicating that the Bering Sea ecosystem is more stable, i.e., more resilient or resistant to perturbations, than other modeled ecosystems. That the system is more mature, i.e., biomass and energy flow are distributed more evenly at various trophic levels than in other modeled ecosystems.

Commercial fishing can remove predators, prey, or competitors, thus altering predator-prey dynamics in the food web. Fishing can selectively remove fish-eating predators, then move down the food web and begin removing the next trophic level down, such as plankton-feeding fish. This process is known as fishing down the food web. Trophic level of the fish and invertebrate catch from the BSAI and GOA was estimated from the 1960s to the present (Queirolo *et al.* 1995, Livingston *et al.* 1999) to determine whether such fishing-down effects were occurring. Trophic level of the catch in both management areas has been relatively high and stable over the last 30 or more years. There is no evidence from the present fishery management regime that this fishing-down-the-food-web process has occurred.

Fisheries can have direct impacts on top predators such as sharks, seabirds, and marine mammals that are not part of the directed fishery but may be caught as bycatch. Sections 3.5.3, 3.7, and 3.8, respectively, describe the present-day baseline effects of the groundfish fishery bycatch on these top predator groups. Historical whaling has resulted in low present-day abundance of whale species in the North Pacific. Shark bycatch rates are variable by region, and present-day groundfish fishery impacts are unknown. There is no evidence that present levels of seabird and mammal bycatch in groundfish fisheries are an important source of mortality for most species.

Groundfish fisheries, through selective targeting or bycatch, can remove prey and thus negatively affect other ecosystem components that rely on those prey. Recent concerns have focused on the availability of pelagic prey in the North Pacific Ocean ecosystems in this regard. Thus, measures of the availability of pelagic prey such as walleye pollock, Atka mackerel, Pacific herring, and forage species are an indicator of possible groundfish fishery impacts on predator-prey relationships. See Sections 3.5.1, 3.5.2, and 3.5.4, respectively, for details about the present baseline for these species. Studies of pelagic forage availability show BSAI pollock and Atka mackerel above MSST, GOA pollock at low abundance levels, and BSAI herring as stable. Biomass estimates for forage species are not available, but bycatch estimates in the groundfish fisheries are above average, and relative abundance indices from bottom trawl surveys indicate possible increases in eulachon and capelin in the GOA (NPFMC 2002).

Also of concern with respect to predator-prey relationships is the effect that fisheries may have on prey availability at various spatial and temporal scales. Although prey availability might be high when viewed at the global or stock level, there is potential for localized prey depletion by groundfish fisheries. Previous analyses showed the potential of this effect for walleye pollock and Atka mackerel, and seasonal/spatial allocations of pollock and Atka mackerel catches have reduced the potential for this possible fishery impact in the present-day baseline. Seasonal and temporal catch allocations of pollock and Atka mackerel, along with SSL closures, have spread out fishing removals in space and time, although recent results show BSAI pollock fisheries increasing catch in northern fur seal foraging habitat.

Studies of predator-prey relationships in the BSAI and GOA regions, primarily in the EBS, suggest that there has not been clear evidence of fishing-related species fluctuations through food-web effects. Recent work done primarily in Port Valdez/Prince William Sound shows that biological introductions of non-indigenous species have occurred, although these introductions cannot be ascribed to a particular vessel type, such as oil tankers or fishing vessels (Hines *et al.* 2000). There have been 24 species of non-indigenous species of plants and animals documented in Alaskan waters, primarily in shallow-water marine and estuarine ecosystems, with 15 species recorded in Prince William Sound. One example of a likely introduction is the predatory seastar *Asterias amurensis*, which is found in other areas of Alaska but has not previously been found in Cook Inlet. Although these predators have the potential to produce a major impact on benthic communities, impacts from these introductions have not yet been observed in Alaskan waters. It is possible that most of these introductions were from tanker vessels or other large ships that have large volumes of ballast-water exchange. However, exchange via fishery vessels that take on ballast from areas where invasive species have already been established and that transit in inshore Alaskan waters has been identified as a threat in a recently developed State of Alaska Aquatic Nuisance Species Management Plan (Fay 2002). Therefore, it is concluded to be a conditionally significant adverse effect of fishing in the ecosystem baseline.

High-volume fishing and fish processing may alter the amount and flow of energy in an ecosystem by removing energy (i.e., large numbers of fish) and by altering pathways of energy flow through the return of discards and offal to the sea. Results of mass-balance modeling by Trites *et al.* (1999) to investigate this question with respect to the EBS suggest that biomass and energy flow are evenly distributed throughout the system, and that the EBS is more mature, i.e., less disturbed (Odum 1985), than comparable shelf ecosystems. The annual total catch biomass in the EBS is estimated at about one percent of the total system biomass, excluding dead organic material. There is no indication that the annual removal of this small biomass percentage alters the amount and flow of energy sufficiently to affect ecosystem stability.

Annual surplus production is a real property of a population that can be measured or estimated.
Surplus production is defined as population growth plus recruitment minus natural mortality (Ricker 1978). It is "surplus" only in the narrow technical sense that it is production not required to maintain the population at current abundance. Annual surplus production can be either positive or negative. When the population is lower than its carrying capacity, expected surplus production is positive, i.e., the population tends to increase towards its carrying capacity. At some fraction of the carrying capacity between zero and 100 percent expected surplus production reaches a maximum. These relatively simple ecological concepts underpin MSY-based harvest policies. Whether maximum surplus production occurs at 50 percent of carrying capacity or some other level is a question best addressed with empirical studies of populations living in real ecosystems. Studies such as Myers et al. (1994) support the use of F40% as a risk-averse approach to MSY management, which would be expected to reduce the spawning population to 35-45 percent of carrying capacity. The percent reduction of juvenile fish not targeted by the fishery is likely to be much smaller (<20 percent reduction from carrying capacity) and may even increase under MSY-based harvest policies. Since juvenile fish are often targeted by other top predators such as seabirds and pinnipeds, predators that depend on the same prey populations as fisheries would not be impacted to the degree implied by a 60 percent reduction in the spawning population.

From the perspective of systems theory, all carbon sequestered in the living organisms of an ecosystem must end up somewhere, either by being recycled, exported to other ecosystems, or deposited in the sediments. In the Eastern Bering Sea, predation by top predators accounts for a relatively small fraction of the total natural mortality of populations targeted by fisheries (Aydin et al. 2002). Disease, parasitism, and all the other hazards of longevity apparently account for most mortality, though these sources of mortality are poorly understood. Fish that die without being consumed by predators are a small fraction of the total carbon recycled into the system by decomposers. The fact that ecosystems by definition do not produce a surplus of carbon (or biomass) does not invalidate the logic behind MSY management.

The foregoing discussion has treated ecosystems as equilibrium systems that return to a stable steady state in the absence of disturbance. This static view of ecosystems is no longer prevalent. Recent research has shown the ecosystems are highly dynamic in response to decadal-scale environmental forcing. There may be unknown biological thresholds that once crossed can move the ecosystem to a new state. While it is appropriate to use single-species steady-state models to approximate overall harvest rates, a fully developed harvest policy must be robust to potential ecosystem variation not anticipated by simple equilibrium models. Several such safeguards are built in to North Pacific harvest policies. The harvest control rules for Tier 3 can be used as an example. First, the F40% harvest rate, for which FABC can never exceed, is well below

F35%, which is used as an estimate of FMSY. Second, instead of a constant F40% harvest strategy, the maximum permissible harvest rate is reduced progressively if the stock declines below B40%. For important prey species of Steller sea lions (Atka mackerel, Pacific cod and walleye pollock), harvest rates in the directed fisheries are reduced to zero at 20 percent of unfished stock size.

When a fishery occurs on prey population that is important to a top predator, a potential exists for competition to occur. Predicting how populations of top predators will respond to a reduction in prey availability is extremely difficult. Linkages between species in an ecosystem are complex and non-linear. Top predators have the ability to adapt to changing conditions by changing their foraging strategies. They can allocate more time to foraging, switch to other prey, switch to more abundant smaller fish of the same species. In some cases, fisheries may make prey more available to top predators, for example, by discard of bycatch.

Based on simple mass-balance ecosystem models (i.e. Ecopath), a numerical response of top predators to reductions in prey abundance would be expected. When a predator is obligate on a single prey species, predator abundance would decline at the same rate as prey abundance. In this extreme case, a 60% reduction in the abundance of prey would produce a 60% reduction in the abundance of the predator. However, most top predators consume a variety of species, and can switch other forage species when one becomes scarce. Diet diversity and the ability to substitute one prey species with another would tend to result in predictions from mass-balance models of a smaller percent reduction in top predator abundance. If other prey species increase in abundance due to competitive release when a fishery reduces the abundance of a target species, some top predators may increase in abundance. These directional changes in the abundance of top predators are based on general properties of simple ecosystem models that lack spatial structure. Predators forage in space, and may require a density of prey above a threshold to forage successfully. Although aggregate biomass models do not show these kinds of spatial effects, they are an important consideration.

When fish are discarded and processed wastes are returned to the sea, energy is redirected to different parts of the marine ecosystem relative to the natural state. Queirolo *et al.* (1995), working before present stricter retention requirements for pollock and cod were mandated, estimated that the total production of discarded fish and processing wastes in the BSAI and GOA ecosystems was about one percent of the unused detritus already going to the bottom. With the new retention requirements now in effect, this estimate would be substantially smaller. These authors found no changes in scavenger populations relating to changes in discard or offal production, and found the annual consumptive capacity of scavenging birds, groundfish, and crabs in the EBS to be over 10 times larger than the total production of discards and offal in the BSAI and GOA. Pathways of energy flow within the BSAI and GOA ecosystems, therefore, are apparently not redirected in any significant way by discarded fish bycatch and processing wastes that are returned to the sea.

Fishing gear can inflict unobserved mortality on target and non-target organisms that can be another source of energy redirection in the ecosystem. In particular, bottom gear can inflict mortality or make benthic organisms more available to predators. Loss of biological and physical structural habitat can lead to increased mortality of marine fish and invertebrates that rely on those structures for refuge from predation. See Sections 3.6.4 and 3.6.5 for a more complete description of fishing gear effects on bottom habitat. Consequently, an indicator of the potential for bottom gear to redirect energy in this fashion is the amount of bottom gear effort in the North Pacific Ocean. Present-day trends in bottom gear effort show there has been a decline in this effort over the last ten or more years (NPFMC 2002).

Biological diversity, the third index of ecosystem health in addition to predator-prey relationships and energetics, is measured in several ways. Species diversity can change if fishing removes all individuals belonging to a single species from the system. Comparative abundance, another measure of biodiversity, can change if fishing alters the numbers of individual representatives of one or more species relative to a defined baseline condition. Functional or trophic diversity can change if a member of a trophic guild is removed; this automatically alters species diversity, changes the way biomass is distributed within the trophic guild, and can affect the functional contribution of the trophic guild to the total ecosystem. The selective removal of organisms that share a particular characteristic, e.g., rapid growth, can alter genetic diversity. Removal of spawning aggregations has the potential to alter genetic diversity if the particular aggregation of fish removed from the system is genetically different from other aggregations.

Assessments of species diversity are lacking for the BSAI and GOA. This is a data gap that must be corrected so that a baseline for species diversity can be established for each of these ecosystems. Without such a baseline, it will not be possible to reliably quantify potential changes in species diversity under any future management regime. Although no fishing-related species removals have been documented under fisheries management policies in effect during the past 30 years, elasmobranchs (sharks, skates, and rays) are particularly susceptible to removal, and benthic invertebrate species diversity could be affected by bottom trawling. Because comparatively little is known about the taxonomic structure of benthic communities of the BSAI and GOA, the potential cumulative effect of trawling and other fishing-related activities on the species diversity of these communities cannot be quantified. Population levels of target and prohibited species show that virtually all of them are above MSST, with the exception of some Bering Sea crab populations (Section 3.5.2.4). Bottom trawl surveys provide an index of abundance for many non-target fish species, and although abundance changes have been observed (NPFMC 2002), there is no evidence in the baseline for fishing effects leading to species extinction. Trends in the number of ESA-listed species might also be an indicator of species diversity changes, but these numbers have been relatively constant, and fishery management actions have been taken to mitigate the effects of fishing on these species (Section 3.4). Area closures provide protection against species extinctions, and the amount of area closed to fishing is another measure of protection of species diversity. The amount of area closed to fishing has been increasing in the baseline and thus has provided an unknown, but presumably increasing, degree of protection against decline in species diversity (Section 3.6). The past/present effects of fishery management policies and of external actions and events on the BSAI and GOA ecosystems are summarized in Table 3.10-3.

With respect to trophic guild diversity, Livingston *et al.* (1999) investigated the variability and evenness of biomass levels in guilds of the EBS. They found no evidence that groundfish fisheries had caused declines in trophic guild diversity for the groups studied. Changes in guild biomass diversity were observed when a dominant guild component (e.g., pollock) changed in abundance, but these changes were related primarily to recruitment rather than to fishing, and there appeared to be no significant loss of functional (trophic) diversity. Bottom gear effort, which is an indicator of benthic community guild disturbance, has been decreasing (NPFMC 2002). HAPC biota (Section 3.6.2), a group of benthic organisms that might be considered a structural habitat guild, do not show fishing-related declines, and some groups (sponge, sea anemone, and sea pens) show increasing or relatively high abundance indices in recent bottom trawl surveys of the BSAI and GOA (NPFMC 2002), as discussed in more detail in Section 3.6. However, corals, which are a very long-lived component of the HAPC biota functional guild, are not well assessed in the baseline. Furthermore, present closed areas do not have much overlap with known coral distributions. Consequently, there is a potential for a conditionally significant adverse impact of fishing on structural diversity through effects of bottom gear on corals.

Genetic diversity has not been systematically studied under the current fisheries management regime, and this is another data gap that prevents establishment of a baseline against which future assessments might be gauged to determine if significant changes have occurred. If a fishery concentrates on certain spawning aggregations or on older (larger) age classes of a target species that tend to have greater genetic diversity (dating from an earlier period when fishing was less intensive), then genetic diversity will tend to decline in fished versus unfished systems. It is possible that genetic diversity has already declined in the BSAI and GOA ecosystems, but this cannot be known in the absence of a baseline. Even in heavily fished systems such as the North Sea, however, there is little evidence that selection for body length in cod has reduced genetic diversity after 40 years of intensive fishing. Genetic assessments of North Pacific pollock populations and subpopulations conducted by Bailey *et al.* (1999) have indicated genetic variations among different stocks. These studies, however, have not found genetic variability across time within the same stocks that might indicate effects from commercial fishing. There has been heavy exploitation of certain spawning aggregations historically (e.g., Bogoslof pollock), but present-day spatial-temporal management of the groundfish fishery has tended to reduce fishing pressure on spawning aggregations. It is unknown whether commercial fishing has altered the genetic diversity of stocks with distinct genetic components at finer spatial scales than the present groundfish fishery management regions.

In conclusion, the BSAI and GOA groundfish fishery management areas generally exhibit sustainable ecosystem-level characteristics with regard to overall productivity and the ability to maintain structural and functional patterns in the face of disturbance. Decadal-scale climate shifts and interannual climatic variations linked to the ENSO phenomenon have been suggested as forcing agents for ecosystem changes (McGowan *et al.* 1998). The evidence discussed here suggests that against the background of climatic variation, fishery-related effects on ecosystem parameters, while present to varying extents, have not been large, and that the contribution of the fishing side may be relatively small in comparison to the climatic drivers.

Chapter 4

This page intentionally left blank

Chapter 4 Environmental and Economic Consequences

This Programmatic Supplemental Environmental Impact Statement (SEIS) has so far presented the preliminary information necessary to analyze the potential impacts resulting from implementation of any of the five policy alternatives (Alternatives 1-4, plus the North Pacific Fishing Management Council's [NPFMC] Preferred Alternative). We have explained the purpose and need for federal action (Chapter 1) and reviewed both the legal context of federal fisheries management in Alaska and the tools managers use to satisfy those legal requirements (Chapter 2); also in Chapter 2, we defined the alternatives presented in this document and the Fishery Management Plan (FMP) bookends created to illustrate the range of management measures that might be used to implement a given policy alternative; and, in Chapter 3, we defined the environmental and economic baseline conditions against which the impacts of the alternatives can be measured.

We now turn to the work of analyzing the possible impacts of the alternatives. Chapter 4 presents our analysis of the FMP bookends and the environmental and economic impacts that might reasonably be expected to follow from implementation of the suite of management measures contained in each FMP bookend. The analyses contained in this chapter will thus allow readers to evaluate the relative effectiveness of the policy alternatives in meeting the legal, environmental, and economic demands of the federal groundfish fisheries off Alaska.

Analysis of the impacts of management policies requires knowledge of potential actions that could be taken to implement the policy. Policies are, by definition, a high-level, overall statement or plan embracing the general goals and procedures of a government body. In the United States (U.S.), policies usually reflect the values and wisdom of the citizens, as expressed by laws and agencies of the nation. Policy goals and objectives are often used to frame the policy and make the statement clearer and easier to understand. Still, determination of the effects of a policy on the human environment is difficult to comprehend and analyze without some indication of how the policy might be implemented.

This chapter evaluates a number of example FMPs intended to illustrate a particular policy as defined by the alternatives described in Section 2.6. In evaluating example FMPS, we will be able to better understand the current management policy governing federal management of the groundfish fisheries off Alaska, as well as the trade-offs of changing existing policy to reflect a new management approach. Since we had no proposed alternative management policies or alternative FMPs to consider at the outset of the Programmatic SEIS process, National Marine Fisheries Service (NMFS or national Oceanic and Atmospheric Administration [NOAA] Fisheries) has relied heavily on comments received during the public scoping process and on the 2001 Draft Alaska Groundfish Fisheries Programmatic SEIS in crafting the alternatives. Additionally, NOAA Fisheries consulted frequently with the NPFMC in developing the alternatives by relying on their expertise and judgement.

Significant changes to the structure and organization of this chapter have been made in response to public comments on the 2001 Draft Programmatic SEIS. As we explained in Chapter 2, we have restructured the policy alternatives to better reflect a multi-species, ecosystem management approach. Each of the policy alternatives (Alternatives 1 through 4) now represents a different management approach, ranging from a more aggressive harvest strategy (Alternative 2) to a very restricted harvest strategy where fishing is only authorized with proof that no adverse impacts will occur (Alternative 4). Two intermediate policy alternatives are presented: Alternative 1, which would continue the current risk-averse policy, and Alternative 3, which would adopt a more precautionary policy. Each policy alternative contains a suite of policy goals and objectives, each addressing to various degrees the important components of the Bering Sea/Aleutian Islands (BSAI) and Gulf of Alaska (GOA) marine ecosystems.

To help both the decision-maker and the public understand what a policy means and what environmental consequences may occur, we have defined example FMPs to illustrate each policy. These example FMPs contain a number of FMP components that were identified by the public as important features of any fishery management program. The best example of the current management policy are the current BSAI and GOA groundfish FMPs. For Alternatives 2 through 4, we define two example FMPs, each comprised of a different combination of management tools and tool applications. Each of these example FMPs contain concepts or specific suggestions obtained from NPFMC and the public. From an overall programmatic perspective, the actual characterization of the example FMPs and their effects is not as important as what is learned about the environmental trade-offs one can expect when considering alternative management policies governing the Alaska groundfish fisheries. Understanding these general environmental trade-offs will enable NPFMC, NOAA Fisheries, and the public to collectively shape future management policy and identify potential alterations to the existing management program.

The example FMPs also satisfy another purpose. NOAA Fisheries has determined that providing a management framework can help guide and communicate the direction of future actions. This is accomplished by including, as an element of the preferred alternative, two example FMPs that serve as "bookends" to a range of management actions, recognizing their inherent environmental consequences. Each example FMP will be analyzed separately and will proxy a range of future management actions. The bookend framework, comprised of two example FMPs, will indicate the range of environmental effects of that policy. The FMP bookends are not intended to be stand-alone alternatives. The FMP bookends are examples of management plans that are driven wholly by the policy statements. They illustrate different ways the groundfish fisheries can be managed and the range of environmental effects that can be expected from the implementation of a policy alternative. An FMP framework will be included in NPFMC's and NOAA Fisheries' final decision, and will be used to define a range of management actions that will be pursued following completion of the Programmatic SEIS. This alternative structure recognizes that the resource being managed, as well as the marine ecosystem, is quite dynamic in nature and only partially understood. Providing a range of management tools and their potential effects for each policy alternative is an attempt to take into account the dynamic nature of the fisheries as a whole and to provide enough management program flexibility in each alternative to allow decisions based on the best available science.

Analyzing such a complex set of alternatives is difficult. Presenting our analysis in a single chapter of the Programmatic SEIS also has its challenges. This is first provided in Section 4.1, which describes the methods used to evaluate the alternatives and their associated FMP bookends. This section defines the term significance; describes how data gaps and incomplete information are treated; defines what is meant by direct, indirect, and cumulative effects; and provides a technical description of the multi-species model and its assumptions. Section 4.2 describes the concept of the FMP bookends and provides a detailed summary of each of the example FMP components used as proxies for a policy alternative. Section 4.3 provides the public with a qualitative examination of each FMP component and discusses the range of management measures that could later serve as plan amendments. In this qualitative assessment section, the public is provided with a general review of the likely environmental effects that could be expected from each of the measures, across example FMPs (Figure 4.0-1; illustrating the "row look"). Section 4.3 is intended to provide the public with information on what could be expected from each management tool (in relative isolation from other plan components), across a range of environmental effects categories, as well as an indication on how well these management tools may meet a particular set of policy objectives.

The Programmatic SEIS continues in Section 4.4 by reviewing the statements defining the current environmental baseline to which all the alternatives and their associated example FMPs will be compared. These baseline statements, developed in Chapter 3, provide an important reference point for this Programmatic SEIS. Sections 4.5 through 4.8 analyze Alternatives 1 through 4 by examining their associated example FMPs as proxies. Each FMP is analyzed as a whole (Figure 4.0-2; illustrating the "column look") so as to represent the entire FMP and all of its components. This is a marked departure from the 2001 Draft Programmatic SEIS document and is included as a result of considerable public input. Another difference between this and the 2001 Draft Programmatic SEIS is that this chapter is organized around alternatives, rather than by resource categories. Many members of the public recommended this organization as an improvement over the earlier draft.

Section 4.9 presents a policy analysis of each of the alternatives using the potential impacts of the example FMPs as a guide. Evaluation of each alternative is provided in terms of satisfying the Magnuson-Stevens Fishery Conservation and Management Act (MSA), Marine Mammal Protection Act (MMPA), Endangered Species Act (ESA), and other applicable federal laws. Section 4.10 concludes this chapter by providing the public with an overall comparison of the alternatives at the policy level.

At this point, we feel obliged to beg the reader's continuing patience. The following analyses are unavoidably lengthy. We have tried to err on the side of inclusiveness, rather than run the risk of omitting any information or analysis that might aid decision-makers and the public in evaluating the relative merits of the alternatives. Also, the description of modeling methods in Section 4.1.5 contains highly technical information and mathematical equations that we have seen fit to include in the text rather than consign to an appendix. Although we do not expect that all readers will want to follow these equations variable by variable, we have placed the methods description prominently to allow public scrutiny of the scientific rigor with which the analyses have been conducted. Yet, however lengthy, detailed, and technical the analyses, we have tried our best where possible to keep the information accessible to the reader.

4.1 Methodology

Alternatives are analyzed in the Programmatic SEIS to determine their environmental impacts. As previously described at the beginning of this chapter, each alternative is analyzed first at the FMP level, and later at the policy level. The FMP-level analysis examined both individual components as well as all of the components together, using the example FMPs, to determine the significance and intensity of impacts. A number of analytical models were used to conduct this analysis.

Section 4.1.1 discusses the significance thresholds used to analyze the impacts of the alternative, and Section 4.1.2 explains how data gaps and incomplete information were treated in this document. Section 4.1.3 describes the methodology for the direct and indirect effect analysis, and Section 4.1.4 describes methodology for the cumulative impact assessment. Section 4.1.5 describes the multi-species model, Section 4.1.6 describes the habitat model, and Section 4.1.7 describes the sector model used to estimate socioeconomic effects.

4.1.1 Determining Significance of Potential Consequences

The National Environmental Policy Act (NEPA) requires that an Environmental Impact Statement (EIS) include

> *... the environmental impacts of the alternatives including the proposed action, any adverse environmental effects which cannot be avoided should the proposal be implemented, the relationship between short-term uses of man's environment and the maintenance and enhancement of long-term productivity, and any irreversible or irretrievable commitments of resources which would be involved in the proposal should it be implemented (40 Code of Federal Regulations [CFR] 1502.16).*

The EIS analysis must also identify whether or not an adverse environmental effect is significant. Significance is determined by considering the contexts (geographic, temporal, societal) in which the action will occur, and the intensity of the action. The evaluation of intensity should include consideration of the magnitude of the impact, the degree of certainty in the evaluation, the cumulative impact of the action as related to other actions, the degree of controversy over the action, and violations with other laws.

In this Programmatic SEIS, significance thresholds have been determined for each resource category (target species, socioeconomic effects, ecosystem, etc.). In some instances, although the significance threshold remains the same, the qualifier "conditional" is assigned. This indicates that a significant impact is assumed, based on credible scientific information and professional judgement, but that more complete information is needed for certainty. The following impact ratings may be used for each resource category:

Significantly adverse (S-): Significant adverse effect in relation to the reference point, based on ample information and data and the professional judgement of the analysts who addressed the topic.

Conditionally significant adverse (CS-): Conditionally significant adverse effect in relation to the reference point. This determination is lacking in quantitative data or information; however, the professional judgement of the analysts is that the alternative will cause a decline in the reference point condition.

Insignificant impact (I): Insignificant effect in relation to the reference point; this determination is based on information and data, along with the professional judgement of the analysts, that suggest that the effects will not cause a significant change to the reference point condition.

Conditionally significant beneficial (CS+): Conditionally significant beneficial effect in relation to the reference point. This determination is lacking in quantitative data and information; however, the professional judgement of the analysts is that the alternative will cause an improvement in the reference point condition.

Significantly beneficial (S+): Significant beneficial effect in relation to the reference point, based on ample information and data and the professional judgement of the analysts who addressed the topic.

Unknown (U): Unknown effect in relation to the reference point; this determination is characterized by the absence of information or data sufficient to adequately assess the significance of the impacts, either because the impact is impossible to predict, or because insufficient information is available to determine a reference point for the resource, species, or issue.

These ratings are applied to resource-specific impact indicators in the following resource categories: target species, prohibited species, other species, forage fish species, non-specified species, habitat, seabirds, marine mammals, socioeconomic effects, and ecosystem effects. The specific application for each is described below.

4.1.1.1 Target Species, Prohibited Species, Other Species, Forage Fish Species, Non-Specified Species

The significance of the impacts on target species, prohibited species, forage fish species, other species, and non-specified species was evaluated with respect to five effects: 1) fishing mortality, 2) change in biomass level, 3) spatial/temporal concentration of the catch, 4) prey availability, and 5) habitat suitability. The significance of these effects was evaluated as to whether the impacts, within the current fishery management regime, may be reasonably expected to jeopardize the sustainability of each target species or species group.

Target species are unique in that thresholds for overfishing and stock size have been developed (Amendment 56/56 to the BSAI and GOA FMPs) that relate to sustainability of the stock. As such, these thresholds are used to evaluate the significance of the effects of the example FMPs relative to their impacts on the sustainability of the target species. Fishing mortality rates that exceed the overfishing mortality rate are considered to jeopardize the capacity of the stock to produce maximum sustainable yield (MSY) on a continuing basis and adversely impact the sustainability of the stock. A related measure of this potential is indicated by change in biomass levels. The significance of effects of the current spatial/temporal concentration of the catch, and the level of prey availability and habitat suitability for target species is evaluated with respect to each stock's current size relative to its maximum stock size threshold (MSST). An action that jeopardizes the stock's ability to sustain itself at or above its MSST is considered to adversely affect the sustainability of the stock.

The significance of the five selected effects is evaluated according to the specific criteria for the impact ratings (Tables 4.1-1, 4.1-2, and 4.1-3). Species or species complexes that fall within Tiers 1 though 5 have estimates of the current fishing mortality rates and are evaluated with respect to exceeding the overfishing mortality rate (fishing mortality effect). Species or species complexes that fall within Tiers 1, 2, or 3 have reliable estimates of MSST and are evaluated for the effects of spatial/temporal concentration of the catch, prey availability, and habitat suitability. Species or species complexes that fall within Tiers 4, 5, or 6 do not have reliable estimates of MSST and therefore cannot be evaluated for the significance of these effects. This inability to evaluate the significance of the effects also occurs for the forage, prohibited, and non-specified species. Since several species or species complexes do not have estimates of abundances-at-age, in this version of the model their abundance levels simply reflect the most recent estimate. For these groups, analysis of the effects of the example FMPs was limited to catch projections and likely consequences given patterns in related fauna.

4.1.1.2 Habitat

The potential effects of the groundfish fisheries on habitat that were used to compare the alternatives include mortality of, and damage to, living habitat, changes to benthic community diversity, and changes to the geographic diversity of impacts and protection. Specific impacts of groundfish fisheries on habitat are very difficult to predict. Evaluation of effects requires detailed information on the distribution and abundance of habitat types, the life history of living habitat, habitat recovery rates, and the natural disturbance regime. This information is generally incomplete.

Qualitative judgments as to the significance of effects were made after considering information on 1) bycatch of living habitat derived from the multi-species projection model; 2) the results of a habitat impacts model for estimates of the equilibrium levels of living habitat in fishable and currently fished areas; 3) estimates of the amount of area by habitat type and geographic zone closed year round to bottom trawling for all species; and 4) evaluation of the spatial distribution of bottom trawl closures relative to fishing intensity and habitat types. The evaluation criteria are described in Table 4.1-4. Significance determination in this analysis differs from the more commonly used approach in scientific research. Typically, the null hypothesis of no effect is tested rigorously and only rejected if there is a very low probability of it being true (Type I error). Scientists are trained to minimize the chance of a Type I error. In this Programmatic SEIS analysis, however, rigorous tests of available data to reject the hypothesis of no fishing effects were not relied upon to determine significance. This was done for two reasons. First, there was little information available to detect fishing effects, so rigorous statistical testing for a Type I error could not be performed. Second, it was believed that a more appropriate approach for this Programmatic SEIS was to decrease making a Type II error (accepting a hypothesis of no effect to habitat when an effect to habitat does actually exist. Reducing the probability of making a Type II error is more precautionary and is more responsive to both essential fish habitat (EFH) mandates and public comments received on the 2001 Draft Programmatic SEIS.

During the course of preparing the revised draft Alaska Groundfish Fisheries Programmatic SEIS, comments and questions were raised about the purpose and scope of the Programmatic SEIS and the agency's EFH EIS that is currently being prepared on a separate schedule. In response to these questions and to clarify the purpose and need, the following summary compares the two analyses.

<u>The Alaska Groundfish Programmatic SEIS and its Relationship to the Ongoing EFH EIS</u>

The EFH EIS and Groundfish Programmatic SEIS have different scopes and areas of focus.

EFH EIS. The analyses within the EFH EIS consider adverse effects of fishing on benthic marine habitat from the perspective of managed fish species that are dependent on certain qualities and features of that habitat. As such, the scope of this work is more narrow than a consideration of these changes at the scale of entire marine ecosystems (as pursued in the Programmatic SEIS.)

Programmatic SEIS. The analyses within the Programmatic SEIS consider adverse effects of fishing on benthic marine habitat from the perspective of ecosystem structure and function, as well as managed fish species. As such, the scope of this work is broader than a consideration of these changes on commercially important and functionally dependent fish species.

These differences are reflected in the issues, criteria, and assessments made in each EIS. To a lesser extent, the information available for analysis in each EIS is different because the Draft Programmatic SEIS was written and released prior to the EFH EIS. The principal differences between the scope, alternatives, and purpose and need of the two documents are summarized in Table 4.1-1.

Table 4.1-1 Major differences between the Alaska Groundfish Fisheries Programmatic Supplemental Environmental Impact Statement and the Essential Fish Habitat Environmental Impact Statement.

	Programmatic Supplemental Environmental Impact Statement (SEIS)	Essential Fish Habitat (EFH) Environmental Impact Statement (EIS)
Purpose and need	Programmatic review of Bering Sea and Aleutian Islands (BSAI) and Gulf of Alaska (GOA) groundfish Fishery Management Plans (FMPs) and their effects on the marine ecosystem.	Review of alternatives for identifying EFH, identifying habitat areas of particular concern (HAPCs), and minimizing adverse effects of fishing on EFH for groundfish, crabs, salmon, and scallops.
Action	Broad scope: Reauthorization of all groundfish fisheries under Magnuson-Stevens Act (MSA), Endangered Species Act (ESA), Marine Mammal Protection Act (MMPA), and other applicable law; set policy.	Narrower scope: Consider revising EFH designations and adopting mitigation measures to reduce the effects of fishing on EFH.
Alternatives	Broad multi-objective policies.	Alternative EFH designations, approaches to identifying HAPCs and mitigation measures.
Source of closed areas used in analysis	Based on public comments on 2001 draft Programmatic SEIS, EFH Committee (Fall 2002) concepts, internal analysis.	EFH Committee (finalized by North Pacific Fisheries Management Council in April 2003).
Legal authority	Under MSA, agency can take action to protect habitat even if not specified as EFH.	Under MSA, agency must minimize to the extent practicable adverse effects of fishing on EFH.

The different analyses used to assess the effects of fishing on habitat in the Programmatic SEIS and the EFH EIS are outlined in Table 4.1-2. While the Programmatic SEIS looks only at bottom trawl impact, the EFH EIS examines trawl, dredge, pot, and longline gear. Another difference is that the Programmatic SEIS usually cited results using the upper recovery value for soft bottom habitats (15 years, higher effects), while the EFH analysis uses a central value (5.5 years). However, both EISs acknowledge that impacts to benthic habitat occur in areas of high fishing intensity regardless of the recovery rate assumed in the analysis. The same quantitative model relating fishing effort to habitat impact is used in both EISs and the results are highly comparable with only subtle differences, which have little effect on the ratings or discussion in the two EISs.

Table 4.1-2 Differences in data and methods for habitat effect analysis and evaluation issues.

	Programmatic supplemental Environmental Impact statement (SEIS)	Essential Fish Habitat (EFH) Environmental Impact Statement (EIS)
Input data source	Bottom trawl only.	Trawl, dredge, pot, longline.
Years	1997-2001.	1998-2002.
Fishery class	Trawl.	By target species and gear.
Living substrate recovery time (soft bottom)	2 and 15 years, 200 years for coral.	3.8, 5.5, and 10 years.
Habitat issues	Living habitat mortality/damage, including coral benthic community and geographic impact diversity.	Prey availability, epibenthic structure, coral.
Managed fish habitat issues	Habitat suitability.	Spawning/breeding, feeding, growth to maturity.

The Programmatic SEIS baseline evaluation identifies areas of high impact on living substrates and noted the estimated high potential impact level to living benthic structure and the size of affected areas. The analysis also considers the likelihood that those areas represent a unique habitat for managed fish species as determined by geography and oceanography, and is not equivalent to all other habitat in the same classification. The analysis concludes that, coupled with historical impacts, impacts to long-lived, slow-growing species (i.e., coral) could cause long-term damage and possibly irreversible loss of living habitat, especially in the Aleutian Islands. The baseline condition of benthic habitat is, therefore, rated as conditionally significant adverse. For purposes of making policy decisions, it is important that any potential significant adverse effects, even if conditional, be presented to decision-makers and the public so that consideration can be given to these effects when developing management measures in the future.

The EFH EIS describes the same areas of high impact to habitat features identified in the Programmatic SEIS, but goes on to evaluate the expected effects of such reductions in habitat quality on the welfare of each managed species. Those evaluations include areas occupied by each species, available information on their use of the habitat, and the stock history of each species. The Programmatic SEIS analysis evaluates impacts to the habitat itself, focusing on habitat features that might provide functions to managed species and speculating that linkages to productivity exist. Considering the paucity of information on habitat function for species life history stages and the broader scope of the Programmatic SEIS, the Programmatic SEIS does not depend on finding proof of such linkages. The EFH EIS examines the likelihood of significant linkages between habitat effects and the welfare of each managed species to determine whether the effects of fishing on EFH of managed species are more than minimal and not temporary. The purposes and methods of analysis used in the EFH EIS are discussed in more detail in Appendix B of the EFH EIS.

While the Programmatic SEIS baseline evaluation identifies areas of concern regarding of the current state of habitat effects from fishing, the EFH EIS was designed to specifically address criteria set forth in the EFH final rule. While identifying areas of concern was one step in the EFH EIS, the ultimate purpose of the EFH EIS is to evaluate whether the effects of fishing has had negative effects on the EFH of managed species that was more than minimal and not temporary. Specific meaning of these terms are discussed in Appendix B of the EFH EIS.

The approach and methodology employed to assess the impacts on target groundfish species in the Programmatic SEIS and EFH EIS are similar. For each species in each EIS, a knowledgeable scientist was designated to perform an evaluation of whether the alternatives affected the welfare of each species in question relative to a number of key issues. In the Programmatic SEIS, the key issues are 1) fishing mortality; 2) change in biomass level; 3) spatial/temporal concentration of the catch; 4) prey availability; and 5) habitat suitability. The key issues analyzed in the EFH EIS are 1) stock biomass; 2) spatial/temporal concentration of the catch; 3) spawning/breeding; 4) feeding; and 5) growth to maturity. These issues are evaluated relative to the status quo fishery, or baseline condition, as well as to the alternatives developed under each EIS. Criteria are established for each issue to assist the analysts in making conclusions. The primary consideration in these evaluations revolve around the ability of the stock to maintain its health and support a sustainable fishery.

In the National Standard Guidelines to the MSA, sustainability is defined relative to a MSST, where stocks below the MSST are considered sufficiently small as to require an appropriate rate of rebuilding. This concept of sustainability is used in the Programmatic SEIS and EFH EIS to maintain consistency with the National Standard Guidelines. For Tier 3 fish stocks, estimated recruitments from the late 1970s to the present are used in defining MSST proxies. These estimated recruitments thus cover a range of recent history when impacts to the stock from fishing practices would be expected. Additionally, 10 year projections are made to assess whether the stock would be likely to fall below their MSST level under the status quo harvesting policy. In the EFH EIS, these projections are not available for the remaining mitigation alternatives. However, because each of the mitigation alternatives represents a more conservative harvest policy than the status quo alternative, a finding of stock status above the MSST under the status quo alternative could reasonably be expected to hold under the remaining alternatives.

It should be noted that the MSST criterion is not the only metric used for the evaluation. For some stocks, information is known about habitat associations and how these may be impacted under various harvesting regimes, from both previous studies and from the results of the Fujioka-Rose model. This information is presented in the narrative of the EFH EIS as part of the more focused look at the linkages between habitat impacts and sustainability. Additionally, for stocks in Tiers 4 through 6, MSST is not available, and an evaluation is based on professional judgment using the best available scientific information and evidence.

4.1.1.3 Seabirds

Significance criteria for seabirds are based on whether the proposed action would be likely to result in population level effects, defined as changes in the population trend outside the range of natural fluctuations. The projection model was used for predictions of fishing effort under the different FMP bookends, especially with respect to different gear types. The analysis also includes other factors such as spatial/temporal restrictions and potential gear modifications for seabird avoidance. However, because there are a large number of unpredictable variables and gaps in our knowledge about particular species and ecosystem effects, it is impossible to ascertain significance on a strictly quantitative basis. Conclusions are based on professional judgement of pertinent data and literature review.

Except for the supplemental food provided by the fisheries in the form of offal, the effects of the fisheries are all considered adverse to individual birds. Low levels of incidental take of seabirds are better for conservation purposes than high levels of take, but no amount of incidental take can be considered beneficial to a seabird population. The significance ratings for incidental take are, therefore, either insignificant or adverse. Although the number of seabirds that would be expected to be taken under the alternative FMPs varies considerably, this difference is not discernible by looking at a shared insignificant rating. The same type of situation applies to fishery-induced changes in benthic habitat important to benthic-feeding seabirds, so there is no beneficial rating for this effect. Effects of the fishery on food availability could be adverse, insignificant, or beneficial. If there is a plausible mechanism and a reasonable set of conditions under which an effect may occur under a given FMP, the significance rating may be labeled conditional. If there is a plausible mechanism for an effect, but not enough data to assess whether it occurs or whether the FMP would create the conditions under which it would occur, the significance rating may be unknown. The evaluation criteria are described in Table 4.1-5.

Species were grouped according to the similarity of their response to the groundfish fishery and/or similarity in their management status. Two species were analyzed on their own and the rest were discussed in five groups. The species categories and the main reason for their distinctions are listed below:

- Short-tailed albatross (listed as "endangered" under the ESA and have played a central role in the development of seabird protection measures).
- Laysan and black-footed albatross (do not breed in Alaska, conservation concerns regarding incidental take in fisheries).
- Shearwaters (do not breed in Alaska, most abundant seabird in Alaska in summer).
- Northern fulmars (the most frequently taken species in every groundfish gear type).
- Species of Management Concern (a U.S. Fish and Wildlife Service [USFWS] designation for species that may be susceptible to listing under the ESA, including red-legged kittiwakes, marbled murrelets, and Kittlitz's murrelets).
- Other piscivorous (fish-eating) species (most alcids, gulls, and cormorants).
- Other planktivorous species (storm-petrels and auklets).
- Spectacled and Steller's eiders (benthic feeding sea ducks listed as threatened under the ESA).

4.1.1.4 Marine Mammals

The standard for determining significance for effects on marine mammals is whether the impact would be expected to be detectable at the population level. Individual effects categories do not have to cause a measurable population decline or increase to be labeled significant, but data and/or plausible arguments must exist to determine that the action would have more than a negligible impact on the reproduction and/or survival of a species group in a way that could affect the population.

For each category of effects, it was determined wether the alternative fishing regime would result in significant adverse, insignificant, significant beneficial, or unknown effects on marine mammals. In addition, effects may be classified as conditionally significant, if significant effects could be expected under a plausible set of conditions. The intent of the conditional label is to imply uncertainty about whether an alternative FMP would actually result in conditions that led to a significant impact. When the conditional label is applied, a plausible mechanism for the impact and the conditions under which a significant impact would be realized is stated. In cases where data are lacking to rank an effect according to the significance criteria, the effect was determined to be unknown.

The expected effects of each alternative were compared to the baseline conditions to determine the relative significance of the impacts of the alternatives on marine mammals. The significant criteria are described in Table 4.1-6.

4.1.1.5 Socioeconomic Effects

In the socioeconomic impact analysis, the term significant for an expected change in a quantitative indicator means a 20 percent or more change (either plus or minus) relative to the comparative baseline. If the expected change is less than 20 percent, the change is not considered to be significant. The same threshold is roughly used to roughly assess changes in qualitative indicators (e.g., fishing vessel safety). However, whereas changes in quantitative indicators are based on model projections, predicted changes in qualitative indicators are based on the judgement of the socioeconomic analysts.

4.1.1.6 Ecosystem

Significance thresholds for determining the ecosystem-level impacts of fishing would involve both population-level thresholds that have already been established for species in the system (MSST for target species, fishing-induced population impacts sufficient to lead to listing under the ESA, and fishing-induced impacts that prevent recovery of a species already listed under ESA, for nontarget species) and community- or ecosystem-level attributes that are outside of the range of natural variability for the system (Table 4.1-7). These community or ecosystem-level attributes are more difficult to measure directly, and the range of natural variability of those attributes is not well known. We may also lack sufficient data on population status of target or non-target species to determine whether they are above or below MSST or ESA-related thresholds. Thus, indicators of the strength of fishing impacts on the system will also be used to evaluate the degree to which any of the alternatives may be having a significant ecosystem impact.

For each of the alternatives, the possible impacts on 1) predator/prey relationships, including introduction of non-native species; 2) energy flow and redirection (through fishing removals and return of discards to the sea); and 3) diversity will be addressed.

4.1.2 Data Gaps and Incomplete Information

The Council on Environmental Quality (CEQ) guidelines require that

> *When an agency is evaluating reasonably foreseeable significant adverse effects on the human environment in an environmental impact statement and there is incomplete or*

unavailable information, the agency shall always make clear that such information is lacking (40 CFR 1502.22).

The regulations instruct that where the information is relevant, but "the overall costs of obtaining it are exorbitant or the means to obtain it are not known" (40 CFR 1502.22), the following should be included in the EIS:

- A statement that such information is unavailable.
- A statement of the relevance of the information to evaluate reasonably foreseeable significant adverse impacts.
- A summary of existing information that is relevant to evaluating the adverse impacts.
- The agency's evaluation of adverse impacts based on generally-accepted scientific methods.

In the analysis, this Programmatic SEIS identifies those areas where information is unavailable to support a thorough evaluation of the environmental consequences of the alternatives. Efforts have been made to obtain all relevant information; however, some data gaps still exist at this time due to several reasons, such as the costs of obtaining the missing data are exorbitant, the data will take several years to obtain, or the means to obtain the data are unknown. Limited resources to collect and analyze baseline information due to limited funding is problematic. NOAA Fisheries receives a certain level of funding, of which a certain amount is set aside for research on Alaska fisheries issues. The amount set aside for research (including data collection) is fully committed, and NOAA Fisheries cannot expend funds it does not have. Therefore, the cost of research needed to fill in current data gaps in addition to currently funded research is exorbitant. Examples of existing data gaps include the uncertainty of survey biomass estimates for many species, which in some cases would require the initiation of species-specific surveys to improve estimates; research needed to assess the use of existing and proposed refugia to improve reproductive success; and life history studies needed to elevate groundfish species in Tiers 4 through 6 into Tiers 1 through 3. NOAA Fisheries' Stock Assessment Improvement Initiative explicitly addresses these needs, and expanded stock assessment funds have been requested in NMFS proposed budgets. Where data gaps still exist, the Programmatic SEIS provided the information listed above, according to the CEQ guidelines.

As outlined in Section 4.1.1, the impact ratings used in this analysis include three categories that indicate a lack of complete data: unknown, conditionally significant adverse, and conditionally significant beneficial. In cases where these ratings are used, a discussion is included about the nature of the unavailable information and its relevance to this analysis. In cases where a conditional qualifier is used, the analysts, using credible scientific methods, have based their assessment on existing information and specific assumptions based on professional judgement in order to evaluate the reasonably foreseeable adverse or beneficial impacts. Where an unknown significance rating is used, not enough baseline information exists to evaluate the impact of the alternatives.

Section 5.1 catalogs the information that is unknown or unavailable for all resource categories. The section discusses ongoing and proposed research relating to the North Pacific groundfish fisheries, and lists the known data gaps for each resource category. Additionally, the specific research initiatives recommended in the various alternative policies are also identified.

4.1.3 Direct and Indirect Analysis

4.1.3.1 Target Species, Prohibited Species, Other Species, Forage Fish Species, Non-Specified Species

The impacts on target species, prohibited species, other species, forage fish species, and non-specified species were evaluated with respect to five effects: 1) fishing mortality; 2) change in biomass level; 3) spatial/temporal concentration of the catch; 4) prey availability; and 5) habitat suitability. Fishing mortality, biomass changes, and spatial/temporal concentration of the catch are considered direct effects, and prey availability and habitat suitability are considered indirect effects. The significance of these effects was evaluated according to whether they might be reasonably expected to jeopardize the sustainability of each species group within the current fishery management regime. Under FMP 1, all target species are managed within the definitions of Amendments 56/56 to the BSAI and GOA FMPs, which set the overfishing levels and the maximum permissible acceptable biological catch for six tier designations as described in Appendix B. Under FMP 1, only one stock is designated as falling within Tier 1 (eastern Bering Sea [EBS] pollock), and no stocks fall within Tier 2. Of the 21 BSAI target groundfish categories, 11 species are managed under Tier 3, no species are under Tier 4, eight species or species complexes are under Tier 5, and one species group (squid) is under Tier 6. Of the 16 GOA target groundfish categories, eight species are managed under Tier 3, seven species or species complexes are under either Tiers 4 or 5, and one species (Atka mackerel) is under Tier 6. The significance of the effects of the current fishing mortality levels is evaluated with respect to the overfishing mortality rates as set forth in Amendments 56/56.

As a means of evaluating the intensity (significance) of the effects on target species prohibited species, other species, forage fish species, and non-specified species under the alternatives, a system was developed whereby the significance of the five selected effects was evaluated. Additional details for each species or species complex are given in the specific section for that species or species complex. The system consists of four rankings of significance, including significant negative, unknown, insignificant, and significant positive. Recognizing that such general terminology is inherently subjective, we applied criteria where possible to define the terms and rankings. Where metrics were not available, descriptions of the impacts within the text are relied upon to justify the significance evaluation.

For the target species, the multi-species, multi-fisheries simulation projection model provided fundamental dynamics to the model behavior. That is, as the biomass of an FMP species changed in the future, the constraint (via acceptable biological catch/total allowable catch [ABC/TAC] control) also changed. The outputs from the model were primarily intended to reflect these dynamics and the interactions with the species composition of the different fisheries.

4.1.3.2 Habitat

This analysis focuses on the following question: do the alternative management policies result in conditions that offer protection to and minimization of adverse impacts to habitat? For Alaska groundfish, this includes the habitat for all target groundfish species, non-target species, prohibited species, other species, and their prey. When viewed in aggregate, across all species, habitat includes all pelagic and benthic habitat in the Alaska Exclusive Economic Zone (EEZ). However, the focus of this analysis is benthic habitat, which is generally believed to be at greater risk to the impacts of fishing than non-benthic habitat in the water column. In addition, much of the analysis focuses on the impacts of bottom trawling. It is recognized that fixed gear (longlines, pots, and jigs) or pelagic trawl gear that comes in contact with the sea floor can disturb benthic habitat. In some types of habitat, fixed gear may cause an impact due to its ability to be more easily fished on rougher substrates (e.g., boulders with coral) than bottom trawl gear. However, most scientific studies of gear impacts have dealt with bottom trawls and dredging because this gear is the most controversial (Auster and Langton 1999, Jennings and Kaiser 1998, Hall 1999b, NRC 2002).

The impacts of bottom trawling on benthic habitat are described in Section 3.6.4. In general, relative to unfished habitat, areas fished with bottom trawls are expected to have reduced habitat complexity, reduced species diversity, and changes in species composition. The level of habitat complexity depends on the structural components of the living and non-living benthic environment. Habitat complexity is reduced when epifauna that form structures are removed or damaged, Sedimentary bedforms are smoothed, and infauna that form burrows and pits are removed. Worldwide studies of the effects of bottom trawling have generally found that trawling reduces habitat complexity (Auster and Langton 1999). These findings have been confirmed by studies conducted in Alaska (Freese *et al.* 1999, McConnaughey *et al.* 2000). The extent of the impacts depends on many factors, such as habitat type, natural disturbance, recovery rates, and the intensity and spatial distribution of bottom trawling.

Evaluating habitat impacts in marine fisheries is not a well developed field. There are few, if any, known applicable analytical methods for evaluating habitat. During the preparation of the Programmatic SEIS, we developed methods to evaluate impacts of fisheries on benthic habitat. Specific impacts on habitat, as noted above in Section 4.1.1.2, are difficult to predict, however, because the information needed to do so is generally incomplete for Alaskan waters. It may never be possible to fully and quantitatively account for all factors involved in determining how an ecosystem will respond to fishing activities. We have analyzed the direct and indirect effects identified in Table 4.1-4 by using, to varying degrees, four primary sources of information:

1. Estimates of the bycatch of living habitat derived from the multi-species projection model described in Section 4.1.5.

2. The results of a habitat impacts model (Fujioka 2002, Rose 2002) for estimates of the equilibrium levels of biostructure.

3. Estimates of the amount of area by habitat type and geographic zone closed year round to bottom trawling for all species.

4. Evaluation of the spatial distribution of bottom trawl closures relative to fishing intensity and habitat types.

We want to emphasize that while the multi-species model, habitat impacts model, and estimates of the amount of area by habitat type closed year round were used initially, these information sources later became peripheral to the habitat impacts analysis. The multi-species projection model was used by Programmatic SEIS analysts as a tool to determine impacts of the alternatives in future years. These data were obtained from the NMFS Observer Program. For the most part, we found that future projections of living habitat bycatch using these data and multi-species model results did not prove useful in analyzing habitat impacts as compared to target species and other fish species impacts. For example, the NMFS Observer Program aggregates all coral species into a single category. While these data are useful in documenting that these benthic organisms are taken as bycatch in various groundfish fisheries, problems arise due to the wide variety of coral species and the vulnerability of hard versus soft corals to different gear types. Differences in recovery rates among species make assessing fishing impacts on these species difficult. All corals likely provide an important biostructure component to habitat for some of the managed species.

In order to run the habitat impact model described by Fujioka (2002; see Section 4.1.6) for the various alternatives, reliable catch and effort projections are needed. For example, for FMPs where the illustrated closure scheme differs substantially from the baseline in the location and amount of areal closures and/or fishing effort (example FMP 2.1, FMP 3.2 and FMP 4.1), the resolution of the data needed to run the model was not available.

Estimates of the amount of area by habitat type and geographic zone closed year round to bottom trawling for all species refers to some simple calculations of the amount of area closed to bottom trawling. While we present these data in the Programmatic SEIS for information purposes, this information was used sparingly to rate the alternatives in terms of habitat impacts.

As a result of these data limitations, our analysis relied most heavily on a comparison of maps of fishing intensity (presented by C. Rose [2002] at the Effects of Fishing Symposium) and closure area illustrations developed by the project team. This qualitative approach was an important part of the Programmatic SEIS analysis. Analysts would have liked to have conducted a more quantitative analysis of the spatial distribution of proposed closures relative to fishing intensity; however, there was only sufficient time to apply the data quantitatively to the status quo FMPs (e.g., FMP 1), and we used our best professional judgment in evaluating the other alternatives.

This analysis does not include impacts of trawling on non-living habitat, such as boulders, cobbles and sandwaves, which can be disturbed by bottom trawls (Auster and Langton 1999). In most cases, the structural integrity, and hence the complexity of the habitat, would not be greatly reduced, but when nonliving substrates are disturbed, the organisms living on them may die or be damaged.

Living Habitat – Direct Mortality of Benthic Organisms

Living habitat includes organisms that provide high microhabitat complexity and serves as cover for fish and their prey. Living habitats include: corals, sponges, anemones, sea whips, sea pens, and tunicates. Criteria to determine acceptable levels of mortality to living habitat have not been established. Such criteria would need to consider fishing induced mortality relative to such characteristics as natural mortality, fecundity, abundance, growth rates, and recruitment. Many deep water areas are characterized as stable environments dominated by long-lived species. In such areas, the impacts of fishing can be substantial and long-term (Auster and Langton 1999). Species such as red tree coral (Primnoa) are very long lived (more than 100 years old) and slow growing, and the habitat they provide does not easily recover if damaged by fishing (Risk *et al.*1998, Andrews *et al.* 1999, Krieger and Wing 2000). Recent studies indicate long recovery rates for deep water sponges that have been damaged or removed by trawling (Freese 2003). A potential quantifiable measure of the expected impact to such habitat are estimates of their living habitat bycatch derived from the multi-species projection model described in Section 4.1.5. Observer data from 1999 to 2001 provides information to estimate baseline levels of this bycatch (Tables 4.1-8 and 4.1-9). For the most part, we found that projections of bycatch of living habitat from the multi-species projection did not provide realistic data to rate the alternatives. Thus, we relied more heavily on application of the habitat impacts model (see Section 4.1.6) as the tool to assess changes to direct mortality of benthic organisms.

There is also unobserved mortality and damage to living habitat that would not be reflected as bycatch (Freese *et al.* 1999, Krieger and Wing 2000, Freese 2003). Assuming that most living habitat caught as bycatch dies, then observed bycatch is a minimum estimate of fishing-induced mortality. We caution about comparing bycatch across gear types and fisheries. For example, if a particular fishery tends to catch more living habitat, this could indicate more impact for that fishery. However, there is little or no information to compare impacts between different gear types. Additionally, one gear type may be particularly efficient at catching and retaining an organism relative to the impact it has on living habitat, while another gear type may not retain the organism while causing a different level of impact. Such variability makes assessing fishing impacts very challenging and, as a result, this has been prioritized for research.

Benthic Community Diversity and Geographic Diversity of Impacts

Areas that are closed to fishing can protect living habitats from damage by fishing activities. In addition, closed areas can allow recovery of habitats already impacted by fishing. Ideally, placement of the closed areas would occur across a range of vulnerable, representative habitat types (National Research Council [NRC] 2002). Areas only seasonally closed to particular fisheries provide little protection to benthic habitat. For example, in the current BSAI and GOA FMPs, seasonal closures to Pacific cod, Atka mackerel, and pollock fishing exist in areas of sea lion foraging. These closures, however, provide little protection to benthic habitat because they are either fished seasonally and/or allow fisheries for other species. Thus, they address sea lion concerns, but fail to address the need to fully protect benthic habitat. Only year-round closures for all species are considered to provide protection to benthic habitat.

Simple calculations of the amount of area by habitat type and geographic zone closed to bottom trawling may provide some data to rate the alternatives. However these data do not provide information on the spatial distribution of closures relative to fishing intensity. Area calculations are mostly provided for information purposes.

Consideration must also be given to the geographic distribution of fishing intensity relative to closures. For instance, if closures are placed primarily in areas where there is little or no fishing then there will be little benefit to habitat over baseline levels. In contrast, if closures are placed primarily in fished areas that have high fish density and the displaced fishing effort moves to areas of low fish density, the result may be more habitat damage because greater effort may be required to catch the same amount of fish. Consideration of the geographic distribution of impact levels allows the habitat unit's distance and direction from other habitat, geographic, and oceanographic features to be accounted for.

We were able to apply the habitat impacts models to the status quo FMP (FMP 1) to quantitatively assess these direct effects. However, for the other alternatives we had to rely on a more qualitative approach. Thus, we used maps of baseline fishing intensity (Rose and Jorgenson 2002), and mapped alternative-specific closure areas to assess changes to benthic community diversity and geographic diversity of impacts.

Given that little is known about the habitat requirements of target, prey, or predator species in the BSAI and GOA and the location of specific habitats in these regions, managers must ask what is the best strategy for distributing fishing impacts over the potential fishing grounds? Should effort be distributed uniformly over the fishing grounds, or should effort be concentrated in certain areas while leaving other areas unfished? If so, how large and in what orientation should the fished or unfished areas be? One may theorize that vast expanses of contiguous fishing effort or impact levels should be avoided. The evaluation of fishing impacts of example FMPs in this Programmatic SEIS operates under the following assertions and assumptions:

1. Knowledge about habitat value and its distribution is of low resolution based on gross bathymetric information, such as shelf, slope, gullies, or large scale geographic or oceanographic features, and we assume that such features capture benthic habitat.

2. Relative to habitat distribution, spatially diverse or patchy fishing impacts are preferable to uniformly distributed impacts (Duplisea *et al.* 2002). Thus, one of the criteria used to evaluate the alternatives will be the spatial and geographic diversity of fishing impacts. The patchiness of fishing effort may be enhanced by having some areas not fished dispersed within historically fished areas. This patchiness promotes habitat diversity.

3. Geographic diversity of impacts and protection is obtained by having a consistent pattern of varying levels of impact within a habitat type. This would be achieved most simply by establishing long-term closure areas over a portion of each habitat type within fished areas. Totally encompassing the habitat type or the cluster of historical fishing intensity within a closure, would not achieve a diverse impact.

4. Bathymetric features such as gullies, banks, shelf, slope, and slope/gully intersections represent individual general habitat types. In addition, clusters of fishing intensity represent an area of unique habitat, perhaps defined only in part by benthic habitat. In the GOA, the spatial resolution of these habitat types is on a much finer scale than the fairly uniform bathymetry of the Bering Sea. Habitat types in the Aleutian Islands are not as easily classified or distinguished, and are on an even finer spatial resolution.

4.1.3.3 Seabirds

Because of differences in foraging behavior, abundance, and distribution, some seabird species are more likely to be directly or indirectly affected by the groundfish fishery than others. Direct effects are those that take place at the same time and place as the fishing activity. Indirect effects are removed in time and/or space from the initial action. The mechanisms and history of direct and indirect effects of fisheries on seabirds are described in Section 3.7.1, along with other natural and human-caused influences on these effects. Details on the extent of each type of effect for each species, to the extent that they are known, are presented in the species accounts of Section 3.7.

For purposes of this chapter, some types of potential effects offer clearer comparisons of the alternatives than others. For seabirds, one direct effect (mortality) and two indirect effects (prey availability and benthic habitat) were analyzed to make the distinction between alternatives. Data on incidental seabird take come from the North Pacific Groundfish Observer Program and include birds that are killed or seriously injured in fishing gear or by striking the vessel or its rigging. Both indirect effects involve changes in the food supply of birds, but the mechanisms are different. Prey availability involves the removal of prey and competitors for that prey from the water column. Benthic habitat describes changes in the physical and biotic structure of the ocean bottom that potentially affect the capacity of that habitat to support the food web important to seabirds. Consumption of fishery wastes has implications for both incidental take (attracting birds and resulting in increased vessel interactions) and food availability. Since incidental take is addressed in different ways by the different alternatives, and the production of fishery wastes is closely linked to overall TAC, consumption of fishery wastes will be incorporated into the analysis of effects on prey availability, which is related to fishing effort. The effects on benthic habitat are analyzed separately because they are more defined in space, and the alternatives vary considerably and specifically with fishing area closures.

Other potential effects, such as oil spills, plastic pollution, and introduction of nest predators, are the result of vessel traffic rather than fishing effort. An oil spill from a shipwrecked fishing vessel or the accidental release of rats from a ship to a seabird colony could have very substantial repercussions for one or more seabird species. However, the magnitude of the effect will depend on a host of variables that cannot be predicted. In addition, the risks of these types of events occurring are not necessarily proportional to fishing effort. Even the closure of the fishery would not eliminate these risks because the fishing and processing vessels would likely be used in other fisheries or brought to port where they may actually increase the risk of an effect (i.e., introduction of nest predators). Because these types of effects do not lend themselves to distinguishing between the alternatives, they will not be analyzed in the direct/indirect effects of each FMP. However, they are important to the overall effects of the fishery and are included as part of the baseline condition and as contributions to the cumulative effects.

Significance criteria were based on whether the proposed action would be likely to result in population-level effects, which are defined as changes in the population trend outside the range of natural fluctuations (see Section 4.1.1 for further details). The projection model was used for predictions of fishing effort under the different FMP bookends, especially with respect to different gear types. The analysis includes other factors such as spatial/temporal restrictions and potential gear modifications for seabird avoidance. However, because there are a large number of unpredictable variables and gaps in our knowledge about the natural history and populations of particular species, as well as many kinds of ecosystem effects, it was not possible to ascertain significance on a strictly quantitative basis. Conclusions are based on professional judgements of pertinent data, literature review, and the likelihood of certain conditions occurring.

4.1.3.4 Marine Mammals

Effects of the groundfish fishery management alternatives on marine mammals will be examined by focusing analyses around four core questions, which were modified from Lowry (1982):

- Is the alternative management regime consistent with efforts to avoid direct interactions with marine mammals (incidental take and entanglement in marine debris)?
- Does the alternative management regime result in harvests of fish species that are of particular importance to marine mammals as prey, at levels that could compromise foraging success (harvest of prey species)?
- Does the alternative management regime result in temporal or spatial concentration of fishing effort in areas used for foraging by marine mammals (spatial/temporal concentration of removals with some likelihood of localized depletion)?

- Does the alternative management regime modify marine mammal or forage behavior to the extent that population-level impacts could occur (disturbance)?

The existing environmental conditions under and independent of the 2002 fishery management measures were used as the baseline for comparing the alternatives with respect to effects on marine mammals, using the above questions to determine impacts. The expected effects of each alternative were compared to the effects as they exist under the baseline conditions to determine the relative significance of the impacts on marine mammals.

Direct Effect – Incidental Take/Entanglement in Marine Debris (Question 1)

Groundfish fisheries directly affect marine mammals when animals are incidentally caught or become entangled in fishing gear. When animals are incidentally taken or entangled, serious injury or mortality may or may not result. Some species are more susceptible than others to interactions with fishing gear, depending on the extent of spatial overlap with the fisheries and on the animals ability to detect and avoid gear. Fishery/marine mammal encounters that result in high levels of mortality and serious injury may have the potential to cause population-level effects. The level of incidental take and entanglement that results in population-level effects will vary according to the status and trajectory of each stock.

The MMPA requires that take of ESA- or MMPA-listed marine mammals incidental to commercial fisheries be authorized under a 101 (5)(E) permit upon determination that the incidental mortality and serious injury from these fisheries will have a negligible impact on the species or stock. For most activities, a negligible impact is defined as having a duration and intensity which results in an insignificant effect on the population. For fishing activities, the intensity of the effect is a more important consideration than the duration of the effect. If an impact is expected to cause no more than a ten percent delay in recovery of an ESA- or MMPA-listed species, then the impact is deemed negligible and will thus be insignificant. If incidental take and entanglement in fishing gear is expected to occur at a level which would delay recovery of a stock by more than ten percent than would be expected under baseline conditions, the impact will be significant. This approach allows for the incorporation of parameters specific to each population and thus accounts for the variable effects of incidental take according to the status and trajectory of each stock.

To calculate the delay in recovery imposed by additive mortality and injury incidental to fishing operations, definitions of the following are needed: the point at which the population is considered to be recovered, the current population size, and the intrinsic rate at which the population is increasing. For species with increasing population trajectories, it is possible to estimate the time until the population will be recovered. For species with negative population trajectories (declining stocks), the time period over which the population would be expected to go extinct can be estimated. If the additional mortality and serious injury resulting from incidental takes in commercial fisheries does not accelerate the estimated time to extinction by more than ten percent, the impact will be determined to be negligible at the population level, thus rendering it insignificant for purposes of this analysis.

Under the best-case scenario, incidental take and entanglement of marine mammals in fishing gear would be zero animal. Yet even under this scenario, the population effect on the species would be insignificant; therefore, effects ratings of (conditionally) significant beneficial are not applicable to this analysis.

Direct/Indirect Effect – Harvest of Key Prey Species (Question 2)

Direct and indirect interactions between marine mammals and groundfish fisheries occur due to overlap in the size and species of groundfish harvested in fisheries that are also important prey for marine mammals, and due to the spatial/temporal overlap in marine mammal foraging and commercial fishing activities. By design, fishing significantly reduces the spawning biomass of harvested species. The relevant question is whether fishing under these global (e.g., large-scale, such as BSAI- or GOA-wide) exploitation strategies reduces the environmental carrying capacity of marine mammals by affecting the prey on which they depend for survival.

Fishery removals of marine mammal prey may cause food availability to become the limiting factor regulating the size of the marine mammal population. If fisheries remove more of a prey species' standing biomass than is required to maintain a marine mammal population at the current size, the fishery would be deemed to have a significant adverse effect at the population level. Alternately, if a fishery management regime is expected to increase the available standing biomass of a prey species to a level such that the size and/or health of the marine mammal population is expected to increase, the fishery would be deemed to have a significant beneficial effect at the population level.

To make a determination of the point at which the alternate fishery regimes affect the availability of key prey species relative to the baseline to the extent that marine mammals experience population-level effects, it is necessary to know the following: the marine mammal's energy requirements; the relative contribution of each prey species to those energy requirements; the adequacy of the existing standing biomass of prey; the standing biomass of the prey species before and after the fishery; and how the change in the standing biomass equates to changes in the marine mammal population's vital rates or carrying capacity. With the best available scientific and commercial data, our current understanding of marine mammal bioenergetic requirements does not allow such a determination.

Due to the limited state of knowledge regarding the effects of the harvest of marine mammal prey species, we relaxed the requirement that varying levels of fishery removals be directly linked to effects which would be detectable at the population level. The significance criteria for this category of effects was selected to allow for informative comparisons of each fishery management alternative relative to the baseline. A 20 percent change in the fishing mortality rate relative to the baseline was selected as the significance threshold, as it was judged to result in large enough changes to the prey field such that significant impacts on marine mammal populations would reasonably be expected due to changes in the standing biomass of their key prey. Predicted fisheries harvest rates were modeled for each FMP scenario and FMP bookend using the Multi-species Analytical Model. Scenarios in which the fishing mortality rate (*F*) of key prey species is projected to increase by at least 20 percent were determined to have significant adverse effects on marine mammals, whereas a decrease in F of at least 20 percent was determined to have a significant beneficial effect. The effect of harvest of prey species was determined to be unknown when there was insufficient diet information for a given marine mammal species to determine if there would be overlap with the fisheries. After assessing the predicted change in fishing mortality rate of individual key prey species, a judgement was reached on the aggregate change in available standing biomass of marine mammal prey based on the factor discussed above, and whether this aggregate change from the baseline would have population-level effects on a species. This method of assessing the availability of prey is similar to the analysis used int the Steller Sea Lion Protective Measures EIS and the Steller Sea Lion BiOp. (NMFS 2001b and 2001c). In some cases the baseline availability of prey is considered adverse for an individual marine mammal species; therefore lack of a change from the baseline would continue to be adverse.

Indirect Effect – Spatial/Temporal Concentration of the Fishery (Question 3)

Overall effects of fisheries on marine mammal populations vary according to the spatial/temporal concentration of the fishery. Although global fishery removals are designed to be precautionary, such that the productivity of target stocks and their ability to support natural predators are not compromised. In the times and locations where fisheries and marine mammals overlap, fisheries compete with marine mammals such that the resource can become limited. The intensity of the effects on marine mammals will vary according to the extent of competition (amount of overlap and degree of resource limitation) and the importance of the resource to marine mammals in a particular season or area. Because it is not possible to quantify the amount of competition between fisheries and marine mammals, nor to state the level of competition that results in changes at the population level, the effects of spatial/temporal fishing concentrations under the various alternatives were assessed qualitatively according to the spatial and seasonal foraging requirements of marine mammals. Alternatives were categorized as having significant adverse effects on marine mammal populations if there was much more spatial/temporal concentration in important foraging habitat and/or critical periods over baseline conditions (fishery conditions under 2002 rules and regulations). Significant beneficial effects were assigned if there was a much lower concentration of the fishery in key areas and seasons compared to baseline conditions. Unknown effects were assigned when there was insufficient information to determine what constitutes the key areas and seasons for a given marine mammal species.

Direct Effect – Disturbance (Question 4)

Activities related to groundfish fisheries in the BSAI and GOA have the potential to affect marine mammal behavior. Disturbance to marine mammals may result from vessel traffic, fishing operations, or underwater noise, such that otherwise normal behavior or movement patterns are altered. As defined here, these disturbances have significant adverse effects on marine mammal populations when marine mammal or forage behavior is modified to the extent that population level impacts could occur. Because it is not possible to quantify disturbance resulting from fisheries, nor to state the level of disturbance that results in changes at the population level, the level of disturbance expected to occur under the various alternatives was compared qualitatively to the baseline level of disturbance to evaluate the significance of the alternatives. The effects analysis for this category incorporated projections from the multi-species management model to determine changes in fishery patterns and information on marine mammal distributions and behavior to infer potential disturbance levels. The significance criterion was similar to that for evaluating fishery concentrations in time and space with substantially more disturbance from baseline conditions leading to a significant adverse finding. Insignificant effects were assigned for those species that do not appear to be disturbed by fishing vessels, and in cases where the level of disturbance was not expected to fluctuate to a large degree relative to the baseline. Under the best-case scenario, disturbance of marine mammals resulting from groundfish fishing activities would be zero. Even under this scenario, the population effect on the species would be insignificant; therefore, effects ratings of conditionally significant beneficial are not applicable to this analysis. Unknown effects were assigned when there was insufficient information to determine what constitutes disturbance for the species.

Marine Mammal Species and Species Groups

The effects of the alternative FMPs were analyzed on either individual species/stocks of marine mammals or on aggregate groupings of marine mammals according to the level and intensity of the expected effects or according to the status of the marine mammal stock. Species or stocks analyzed individually includes the western stock of Steller sea lions, the eastern stock of Steller sea lions, northern fur seals, harbor seals, transient killer whales, and sea otters. Marine mammals analyzed in aggregate include other pinnipeds, toothed whales (including resident killer whales), and baleen whales occurring in the BSAI and GOA groundfish fisheries. Western and eastern Steller sea lion stocks were split in the analysis due to the differences in their population trajectories, ESA listing status, and degree of overlap with groundfish fisheries. Northern fur seals and harbor seals were broken out from the other pinnipeds because they are expected to be more affected, directly or indirectly, by groundfish fisheries than the other pinniped species in the affected area. Transient killer whales were split out from the other toothed whales because their diets differ substantially from the other species in this category.

4.1.3.5 Socioeconomic Effects

Assessment of socioeconomic impacts considers the following important factors:

- Impacts on harvesting and processing sectors, including: catcher vessels, catcher processors, and inshore processors and motherships. Catches of all groundfish species, groundfish ex-vessel value and product value, groundfish employment and payments to labor, excess capacity, product quality, product utilization rates, average costs, and fishing vessel safety were used as variables.

- Regional impacts, on six regions (Alaska Peninsula and Aleutian Islands, Kodiak Island, Alaska southcentral, southeast Alaska, Oregon coast, and Washington inland waters), using processing, harvesting, payments to labor, and employment variables.

- Community Development Quota (CDQ)-related impacts, including changes to the CDQ program and changes to the CDQ species TACs.

- Impacts related to subsistence use of groundfish, Steller sea lions, and salmon, as well as opportunities for practicing subsistence.

- Environmental justice impacts resulting from changes in fishing activity, or impacts to the CDQ program or subsistence.

- Impacts on consumer benefits (U.S. consumers of groundfish products).

- Impacts on benefits from marine ecosystems (other than those benefits related to commercial groundfish fisheries), including non-market (existence value and option value, etc.), and other uses of the ecosystem, such as recreational fishing or tourism.

The socioeconomic impacts of the alternatives have been assessed using the Sector Model to estimate catch and processing amounts and revenues for the fishing and processing sectors and regions described in Section 3.9.2. The Sector Model uses output from the multi-species management model, combined with the historical harvest and processing proportions, to estimate the distribution of catch and processing among the various sectors and regions that rely on the groundfish fishery.

The Sector Model is a three-step process that:

- Estimates total catch and deliveries to processors.

- Proportions out deliveries to specific catcher vessel sectors.

- Distributes catches and processing amounts among the various regions where processors are located or vessels are owned.

In each step of the Sector Model, the catch of each species by gear and subarea is distributed to successive sectors based on the historical distribution from 2001 (the baseline condition for socioeconomic effects). The model and analytical framework used in the analysis for the harvesting and processing sectors are described in Section 4.1.7.

4.1.3.6 Ecosystem

Ecosystems consist of populations and communities of interacting organisms and their physical environment that form a functional unit with a characteristic trophic structure and material cycle (i.e., how energy or mass moves within the unit). Fishing has the potential to influence ecosystems in several ways. Fishing may alter the amount and flow of energy in an ecosystem by removing energy and altering energetic pathways through the return of discards and fish processing offal back into the sea and through mortality of organisms not retained in the gear. The recipients, locations, and forms of this returned biomass may differ from those in an unfished system. Selective removal of species and/or sizes of organisms that are important in marine food web dynamics such as nodal prey species or top predators has the potential to change predator/prey relationships and community structure. Removals concentrated in space and time may impair the foraging success of animals tied to land such as pinnipeds or nesting seabirds; these animals may have restricted foraging areas or critical foraging times that are key to survival or reproductive success. Introduction of non-native species may occur through emptying of ballast water or introduction of hull-fouling organisms from ships from other regions (Carlton 1996). Introductions of such species have the potential to cause large changes in community dynamics. Fishing can alter different measures of diversity. Species-level diversity, or the number of species, can be altered if fishing essentially removes a target or nontarget species from the system. Fishing can alter functional diversity if it selectively removes a trophic or other ecosystem member and changes the biomass distribution among a trophic groups. Fishing gear may alter bottom habitat and damage benthic organisms and communities that serve important functional roles as structural habitat or within the food web. Fishing can alter genetic-level diversity by selectively removing faster growing fish or removing spawning aggregations that might have different genetic characteristics than other spawning aggregations.

A great deal of literature addresses possible indicators of ecosystem status in response to perturbations (e.g., Odum 1985, Pauly *et al.* 1998, Rice and Gislason 1996, Murawski 2000). These indices can show changes in energy cycling and community structure that might occur due to some external stress such as climate or fishing. For example, fisheries might selectively remove older, more predatory individuals. Therefore, we would expect to see changes in the size spectrum (the proportion of animals of various size groups in the system), mean age, or proportion of r-strategists (faster growing, more fecund species, such as pollock) in the system. These changes can increase nutrient turnover rates because of the shift towards younger, smaller organisms with higher turnover rates. Total fishing removals and discards also provide a measure of the loss and re-direction of energy in the system due to human influences. Total fishing removals relative to total ecosystem energy could indicate the importance of fishing removals as a source of energy removal in an ecosystem. Changes in scavenger populations that show the same direction of change as discards could be an indicator of the degree of influence discards have on the system. Discards as a proportion of total natural detritus would also be a measure that could indicate how large discards are relative to other natural fluxes of dead organic material. Levels of total fishing removal or fishing effort could indicate the potential for introduction of non-native species through ballast water in fishing vessels. Fishing practices can selectively remove predators or prey; tracking the change in trophic level of the catch may provide information about the extent to which this is occurring (e.g., Pauly *et al.* 1998). Thus, in this analysis, we use measures of total catch, total discard, and information about the changing mean size of organisms to indicate the potential of each of the alternatives to impact ecosystem energy flow and turnover.

Total catch and trophic level of the catch will provide information about the potential to disrupt predator/prey relationships through introduction of non-native species or altering the food web through selective removal of predators, respectively. Pelagic forage availability will be measured quantitatively by looking at population trends of pollock and Atka mackerel, target species that are key forage for many other fish and marine mammal species in the BSAI and GOA. Bycatch trends of nontarget species, such as the managed forage species group and herring, will be used as indicators of possible fishery impacts on those pelagic forage groups. Angermeier and Karr (1994) recognized that an important factor affecting the trophic base is spatial distribution of the food. The potential for fishing to disrupt this spatial distribution of food, which may be particularly important to predators tied to land, will be evaluated qualitatively to determine the degree of spatial/temporal concentration of fishery removals of forage. We will evaluate these factors to determine the potential of each of the alternatives to disrupt predator/prey relationships.

The scientific literature on diversity is somewhat mixed about what changes might be expected due to a stressor. Odum (1985) thought that species diversity (number of species) would decrease and dominance (the degree to which a particular species dominates the system in terms of numbers or biomass) would increase, if original diversity was high. The reverse might occur, if original diversity was low. Significance thresholds for species-level diversity due to fishing are catch removals high enough to cause the population of one or more target or non-target species to fall below minimum biologically acceptable limits. The MSST for target species, would either trigger ESA listing or would prevent recovery of an ESA-listed species. Genetic diversity can be altered by humans through selective fishing (removal of faster growing individuals or certain spawning aggregations). Accidental releases of cultured fish and ocean ranching tends to reduce genetic diversity (Boehlert 1996). Significance thresholds for genetic diversity impacts due to fishing would be catch removals high enough to cause a change in one or more genetic components of a target or non-target stock that would cause it to fall below minimum biologically acceptable limits (e.g., MSST for target species, ESA listing or non-recovery of ESA-listed species). More recently, there is growing agreement that functional (trophic or structural habitat) diversity might be the key attribute for ecosystem stability (Hanski 1997). This type of diversity ensures there are a sufficient number of species that perform the same function. If one species declines for any reason (human or climate-induced), then alternate species can maintain that particular ecosystem function, and there we would be less variability in ecosystem processes. However, measures of diversity are subject to bias, and we do not know how much change in diversity is acceptable (Murawski 2000). Furthermore, diversity may not be a sensitive indicator of fishing effects (Livingston *et* *al.* 1999, Jennings and Reynolds 2000). Nonetheless, we will evaluate the possible impacts that the alternatives may have on various diversity measures.

Quantitative measures of some of the indicators mentioned above have been identified for each of the alternatives. These include total catch, trophic level of the catch, total discards, total groundfish biomass, trophic level of groundfish biomass, bycatch amount of forage, top predator species, and habitat area of particular concern (HAPC) biota for the BSAI and GOA. We will address for each of the alternatives the possible impacts on predator/prey relationships, including introduction of non-native species; energy flow and redirection (through fishing removals and return of discards to the sea); and diversity.

4.1.4 Cumulative Effects Methodology

4.1.4.1 Introduction

Analysis of the potential cumulative effects of a proposed action and its alternatives is a requirement of NEPA. An EIS must consider cumulative effects when determining whether an action significantly affects environmental quality. The CEQ guidelines for evaluating cumulative effects state that "…the most devastating environmental effects may result not from the direct effects of a particular action but from the combination of individually minor effects of multiple actions over time" (CEQ 1997).

The CEQ regulations for implementing NEPA define cumulative effects as

> *the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (federal or nonfederal) or person undertakes such other actions. Cumulative effects can result from individually minor but collectively significant actions taking place over a period of time" (40 CFR 1508.7).*

Cumulative effects are linked to incremental actions or policy changes that individually may have small outcomes, but that in the aggregate and in combination with other factors can result in greater effects in the BSAI and GOA. At the same time, the CEQ guidelines recognize that it is not practical to analyze the cumulative effects of an action on the universe, but to focus on those effects that are truly meaningful.

The cumulative effects analysis assesses the potential direct and indirect effects of groundfish FMP policy alternatives in combination with other factors that affect physical, biological, and socioeconomic resource components of the BSAI and GOA environment. Peer reviewed literature and quantitative research on the cumulative effects of fishing activities in the Bering Sea and GOA are limited. The cumulative effects analysis presented for each of the FMP policy alternatives addresses the potential magnitude of effects and is somewhat qualitative in nature.

The intent of the cumulative effects analysis is to capture the total effects of many actions over time that would be missed by evaluating each action individually. A cumulative effects assessment describes the additive and synergistic result of the actions proposed in this Programmatic SEIS as they interact with factors external to those proposed actions. To avoid the piecemeal assessment of environmental impacts, analysis of cumulative effects were included in the 1978 CEQ regulations, which led to the development of the CEQs cumulative effects handbook (CEQ 1997) and federal agency guidelines based on that handbook (e.g., USEPA 1999). Although predictions of direct effects of individual proposed actions tend to be more certain, cumulative effects may have more important consequences over the long-term. The possibility of these hidden consequences presents a risk to decision-makers, because the ultimate ramifications of an individual decision might not be obvious. The goal of identifying potential cumulative effects is to provide for informed decisions that consider the total effects (direct, indirect, and cumulative) of alternative management actions. This section characterizes the incremental cumulative effects that potentially arise from external factors in combination with the direct and indirect effects.

4.1.4.2 Methodology

The methodology for cumulative effects analysis in this Programmatic SEIS consists of the following steps:

- *Identify characteristics and trends within the affected environment that are relevant to assessing cumulative effects of the FMP policy alternatives, including lingering effects and how they have contributed to the comparative baseline.* This information is presented in Chapter 3 of this Programmatic SEIS and summarized in the cumulative effects sections for each of the alternatives.

- *Describe the potential direct and indirect effects of each of the four FMP policy alternatives.* This information is presented in detail in Sections 4.5 through 4.9 of this Programmatic SEIS, and is summarized in the cumulative effects ranking tables. The cumulative effects analysis uses the specific direct and indirect effects that have been evaluated for comparison with external factors.

- *Identify past, present, and reasonably foreseeable external factors such as other fisheries, other types of human activities, and natural phenomena that could have additive or synergistic effects.* Past actions must be evaluated to determine whether there are lingering effects that may still result in synergistic or incremental impacts when combined with the proposed action alternatives. The CEQ guidelines require that cumulative effects analysis assess reasonably foreseeable future actions. Because analysis of relevant past, present, and future effects depends on the resource or characteristic being evaluated, the time period for looking at past and reasonably future effects will vary. Both past BSAI and GOA FMP amendments and pertinent external factors used to evaluate potential effects are described further in this introduction.

- *Use cumulative effects tables to screen all of the direct/indirect effects with external factors to capture those synergistic and incremental effects that are potentially cumulative in nature.* Both adverse and beneficial effects of external factors on the criteria used for direct and indirect effects are assessed, and then evaluated in combination with the direct and indirect effects to determine if there are cumulative effects.

- *Evaluate the significance of the potential cumulative effects using criteria established for direct and indirect effects and the relative contribution of the action alternatives to cumulative effects.* Of particular concern are situations where insignificant direct and indirect effects lead to significant cumulative effects or where significant external effects accentuate significant direct and indirect effects.

- *Discuss the reasoning that led to the evaluation of significance, citing evidence from the peer-reviewed literature and quantitative information where available.* As with direct and indirect effects, the term conditional significance has been used where conclusions of significance have been based on reasoned assumptions, and the term unknown is used where there is not enough information to reach a conclusion of significance.

The advantages of this approach are that it closely follows CEQ guidance, employs an orderly and explicit procedure, and provides the reader with the information necessary to make an informed and independent judgment concerning the validity of the conclusions.

The CEQ (1997) has established step-by-step guidelines for conducting a cumulative effects analysis. The guidelines set forth 11 steps that can be classified into four basic stages: scoping, organizing, screening, and evaluating. Table 4.1-10 shows how the cumulative effects assessment for groundfish fisheries management was adapted to closely follow the CEQ guidelines.

4.1.4.3 Scoping

A historical review of the BSAI and GOA FMP amendments was conducted, looking at the intent and consequences of FMP amendments since 1980. This information was used to prepare the comparative baseline that is presented in Chapter 3 and summarized in Section 4.4. In addition to issues that were derived from the historical FMP amendment review, both the scoping process and public review of the first draft of the Programmatic SEIS identified issues to be addressed in the cumulative effects analysis. The scoping comments identified two major issues associated with analysis of potential cumulative effects: the consideration of the additive effects of management actions over time and the cumulative effects of the management regime as a whole, and the consideration of impacts of natural events versus fisheries management on the ecosystem, including the human component (socioeconomic and subsistence) of fishing communities.

Public comments on the first draft of the Programmatic SEIS identified 15 themes associated with the scope and conclusions of the analysis of potential cumulative effects. Among the suggestions was that the cumulative effects analysis use a different baseline to compare the alternatives than the status quo management system. A summary of these issues can be found in the Scoping Summary Report (NMFS 2000a) and Comment Analysis Report (Appendix G).

4.1.4.4 Additive and Cumulative Effects of Past FMP Amendments

The potential effects of the original BSAI and GOA FMPs and their amendments are difficult to substantiate quantitatively. Given the inherently large fluctuations that occur naturally in fish populations and the complexity of the North Pacific fishery, it is not feasible to identify biological responses to managerial decisions designed to fine tune fishery harvests under the mandate of both preserving stocks and maximizing commercial exploitation. Intended and unintended socioeconomic effects on the fishing industries and regions and communities that participate in the groundfish fishery are easier to assess. The analysis of FMP amendments was used to develop the comparative baseline presented in Chapter 3 and summarized in Section 4.4, and to identify lingering effects to carry forward into the cumulative effects analyses in Sections 4.5 through 4.9.

4.1.4.5 Identification of External Factors and Effects

A cumulative effects analysis takes into account the incremental impact of the proposed action when added to other past, present, and reasonably foreseeable future actions (40 CFR 1508.7). External factors play an important role in developing the comparative baseline used to evaluate the effects of the proposed action and its alternatives, and to identify present and reasonably foreseeable future actions that are relevant to the cumulative effects analysis. For the purposes of this Programmatic SEIS, the definition of external actions includes both human controlled events such as other fisheries, pollution, and industrial development, and natural events such as disease, winter mortality, and short-and long-term climate change.

In order to ascertain the importance of the external impacts in the cumulative effects analysis, a comprehensive checklist was produced for each resource category (marine mammals, seabirds, target species, non-target species, prohibited catch species, habitat, socioeconomic characteristics, and ecosystem). Information presented in the checklists was obtained from reviewing EISs, reports and resource studies, and peer-reviewed literature. The identified external factors were discussed in meetings with staff of the NOAA Fisheries Alaska Fisheries Science Center (AFSC) to confirm accuracy, identify any effects that might have been missed, and explore pathways through which the external influences might act in an additive or interactive fashion with the alternatives to produce cumulative effects.

Within each resource checklist the effects were divided into the two main categories: human controlled events, and natural events. Due to inherent differences between socioeconomic resources and biological resources and systems, external effects impacting the socioeconomic category were developed to consider different events and topics, or different aspects of the same event. For example, potential biological factors of other fisheries include disturbance and habitat damage, whereas potential socioeconomic factors include the contribution of participation in other fisheries to the overall viability of fishing industry harvesters and processors. Table 4.1-11 summarizes the external effects that have been incorporated into the cumulative effects analysis.

4.1.4.6 Organizing the Cumulative Effects Analysis

Potential cumulative effects of each of the policy alternative FMPs are presented in Sections 4.5 through 4.9. For each of the alternatives, the analysis of cumulative effects follows the analysis of direct and indirect effects within the discussion of each of the major resource topics (e.g., Target Fish, Marine Mammals, Socioeconomic Characteristics). The structure of the cumulative effects analysis also parallels the direct and indirect effect analysis in the organization of the impact screening tables. The categories of effects evaluated for each of the direct/indirect analyses are used to organize the cumulative effects screening tables.

The categories of effects to be evaluated were developed jointly by analysts preparing the direct/indirect and cumulative effects analyses. These effects appear in the far left hand column of both the direct/indirect and cumulative effects matrices. This approach facilitates evaluating the additive and synergistic effects of the FMP policy alternatives with past FMP amendments and external effects. It also provides transparent logic for those reviewing the Programmatic SEIS.

4.1.4.7 Screening Potential Cumulative Effects

The screening process for the cumulative effects analyses consists of the following steps:

- Identify the cause and effect relationships and incorporate them into the categories of effects to be evaluated for the direct/indirect and cumulative effects analyses.

- Identify whether potential effects on a given resource from past external actions remain, and whether they have a lingering effect on the resource that contributes to the significance of potential cumulative effects.

- Identify potential effects on a given resource from both direct and indirect effects of the policy alternative FMPs and from present and reasonably foreseeable external actions.

- Develop and utilize matrices as the organizational structure to incorporate past effects, direct/indirect effects, and the potential effects of present and reasonably foreseeable events in evaluating the potential for and significance of cumulative effects.

As indicated above, parallel impact assessment tables or matrices have been constructed to screen and evaluate direct, indirect, and cumulative effects, and to ensure that the evaluation is orderly and systematic. Each direct and indirect matrix scores the alternatives with respect to the impacts they could produce on the subject resource component. The range of scores includes insignificant, significant, conditionally significant, and unknown. A plus (+) or minus (-) is added to the significant or conditionally significant score to indicate a beneficial or adverse effect, respectively.

A second series of matrices was prepared for each resource component under each alternative. The cumulative effects matrices tabulate the external factors identified in the scoping process (columns) against the direct and indirect effects that have been identified. Under a single resource category (e.g., marine mammals), a separate cumulative effects matrix was prepared for each resource component (e.g., Steller sea lion, northern fur seal, harbor seal, etc.). The matrices include both beneficial and adverse environmental effects associated with past, present, and potential future management decisions related to the four policy alternatives. External effects that could function additively or interactively with the direct and indirect effects of the alternatives are organized into two major categories of human controlled and natural events.

4.1.4.8 Evaluating the Significance of Potential Cumulative Effects

The potential for cumulative effects and their significance was evaluated for the resources and characteristics of the human environment described in Chapters and 3 and 4. For biological, habitat, and ecosystem resources and characteristics, significance criteria and thresholds take into account the geographic scope, population level implications, and regulatory aspects of potential effects. Significance criteria and thresholds for socioeconomic characteristics take into account the relative magnitude of change, the geographic distribution of effects, and the regulatory aspects of potential effects.

Table 4.1-12 is an example matrix illustrating the approach taken to evaluate cumulative effects. Starting in the far left-hand column, the category of effect used in both the direct, indirect, and cumulative effects analysis is presented, along with a significance rating for the direct and indirect effect. Any persistent past effects to be carried forward in the cumulative effects analysis are identified. Next, reasonably foreseeable future human controlled and natural effects are identified and briefly described, along with the nature of contribution to cumulative effects. Categories include potential adverse or beneficial contribution, not a contributing factor, and unknown. The direct and indirect, persistent past, and external effects are then integrated to determine whether there is a cumulative effect and its significance. The far right hand column summarizes the cumulative effect and whether it is significant, conditional significant, insignificant, or unknown. Several rules of logic are applied to the process. If the direct/indirect effect is unknown, it is not possible to determine the cumulative effect, which is also unknown. If there are no persistent past effects and there are no reasonably foreseeable future effects (not a contributing factor), then there are no cumulative effects for a specific effects category. The logic for applying ratings of conditional significance and unknown is the same for direct and indirect effects (see Sections 4.1.2 and 4.1.3). The cumulative matrix tables are supported by text that describes in more detail the persistent past effects, relevant external factors, and the logic in determining the significance of cumulative effects.

4.1.5 Description of the Multi-Species Analytical Model and its Assumptions

4.1.5.1 Background

In the Draft 2001 Programmatic SEIS, simulation models were developed that evaluated individual stocks independently, as if each species could be caught separately from other species. The simulation model thus failed to reflect the multi-species character of nearly all Alaska groundfish fisheries, which catch a wide variety of species even when targeting a single species. This meant that in many cases, single-species simulations did a poor job of representing the likely consequences of alternative management scenarios. For this revised Programmatic SEIS, simulation models have been developed that reflect the multi-species nature of the fisheries and their management.

Current groundfish management in federal waters of Alaska consists of strict quota management for FMP-managed species. These quotas are closely monitored, and as quotas are approached in a given year, with reserves set aside for bycatch in other fisheries, directed fisheries become closed. Prohibited species catch (PSCs) limits are also closely monitored and affect fishing season length and area openings. These quotas and PSCs effectively become constraints for all groundfish fisheries operating in the GOA and BSAI regions. These constraints are established based on area-specific TACs. The TACs are derived from the NPFMC's annual recommendations for ABC levels. As a matter of policy, the NPFMC's TAC for a given species or species group has always been less than or equal to the ABC for that species. The resulting management system is one that strives to meet the objective of providing fishing opportunities subject to a large number of constraints. Analysis of this type of fisheries regime has been modeled using Linear Programming (e.g., Brown *et a*l. 1979, Siegel *et al.* 1979, and Murawski and Finn 1986). In this Programmatic SEIS, we attempt to mimic management of complex interacting fisheries and their impact on GOA and BSAI living marine resources using a similar approach.

Simulating current groundfish management in the U.S. North Pacific economic zone involves considering interactions between a large number of species, areas, and gear types. These fisheries are managed subject to a large number of constraints (e.g., ABCs and PSCs). Management decisions are based on expectations about the array of species likely to be captured by different gear types and the cumulative effect that each individual fishery has on the allowable catch of each individual species or species group. The expectations of capture by different fisheries are based on historical catch data of each species within area and gear strata. The ABC constraints come from probabilistic projections of future stock dynamics for each individual species. Given these constraints, the predicted catch for each example FMP is then computed from an inseason management model. This management model accounts for the technical multi-species interactions of the groundfish fisheries (see Ackley 1995 for an example application of within-year patterns for the EBS fishery). Finally, the predicted catches are fed back into the age-structured information for each species to compute the correct fishing mortality level and are then projected through each year. This provides a reasonable representation of the current fisheries management practice for dealing with the multi-species nature of bycatch in target fisheries. Fisheries are defined by distinct target species, gear type, and area. The optimal decision-making process related to actual removals is simulated using historical information on catch composition of these fisheries. A schematic of the modeling approach is presented in Figure 4.1-1.

This section begins with a description on how individual stocks are treated and projected into the future, including details on how the constrained optimization is used to mimic management. A critique of the approach and assumptions follow. The subsequent section describes how catch estimates were derived, followed by how specific alternatives were modeled (including the data that were used). This section then concludes with a brief description on how model results were applied in different resource categories (e.g., to assess the impact on marine mammals).

4.1.5.2 Methods

Treatment of Stocks

For the stocks with age-structure information, the model is very similar to those used for the stock assessments upon which ABC recommendations are currently based, and it contains features and assumptions common to many fishery population dynamics models. Parameters and other inputs were obtained for each stock. They were taken directly or inferred from the most recent Stock Assessment and Fishery Evaluation (SAFE) report or obtained from AFSC scientists. The simulations began with numbers of a given age in 2002, which were projected forward using a random recruitment simulator (Inverse Gaussian) and a fishing mortality rate defined by the FMP under consideration. Recruitments were drawn from a statistical distribution that is described below. The parameters consisted of maximum likelihood estimates obtained from the recruitments listed in the 2002 SAFE report. Recruitment estimates after 1978 were used to estimate distribution parameters. No serial correlation was assumed. The age of recruitment varied between stocks, corresponding to the minimum age used in the respective assessment models. For stocks where age-structure information is not available, but ABCs are set, the model used the most recent estimates of ABC as the upper limit on total catch. The list of species considered for the BSAI and GOA is presented in Table 4.1-13. The actual age-structure data used for the analyses are available online at www.fakr.noaa.gov/sustainablefisheries/seis/data.

Projection Model

The following presents details on the steps of the projection simulations. A glossary of notation is provided at the end of this section for reference.

Step 1: Select the Catch Composition Array Appropriate for the Alternative

As presented below, separate hypothetical catch-composition arrays were developed for each alternative. A catch-composition array can be simply thought of as a table where the rows represent a specific fishery defined by target species, area, and gear type, and the columns represent the catch by species group or stock (See www.fakr.noaa.gov/sustainablefisheries/seis/data).

Step 2: Project Recruitments for all Years and Simulations

Recruitment estimates for the years 1978 through 2001, or the largest available subset thereof, were obtained from each of the respective 2002 stock assessments. For each stock, these recruitments were used to find maximum likelihood estimates for the inverse Gaussian distribution parameters. The distribution was parameterized such that one of the parameters represented the distribution mean. A recruitment time series was obtained for each simulation by drawing randomly from this parametric distribution.

Step 3: Estimate Actual Fishing Mortality Rates for the Initial Year

The steps in this part of the model are described below. Because the example FMPs were assumed not to take effect until after 2002, these steps were conducted only once, rather than separately for all eight FMPs. Compute the fishing mortality rate that would set catch equal to C_t by solving the following implicit equation:

$$C_{2002} = F_{2002} \sum_{a=1}^{n_{age}} \left[N_{a,2002} \left(\frac{1 - \exp\left(-M_a - F_t \sum_{k=1}^{n_{gear}} s_{a,k} d_k \right)}{M_a + F_t \sum_{k=1}^{n_{gear}} s_{a,k} d_k} \right) \sum_{k=1}^{n_{gear}} w_{a,k} s_{a,k} d_k \right]$$

Step 4: Project Numbers at Age for all Ages, Years, and Simulations

For each example FMP, 200 projection simulations were conducted. The projected numbers at age in each year were based on an annual feedback of actual catch obtained from the linear programming constrained optimization algorithm, hereafter referred to as the LP. The steps for these projections for a given species were as follows:

1. Initialize the simulation index:

   $u = 0$

2. Increment the simulation index:

   $u = u + 1$

3. Initialize the time index:

   $t = 1$

4. Compute numbers at age for initial year of simulation u:

   $$N_{a,t,u} = R_{t,u} \quad \text{for } a = 1, t = 1$$
   $$N_{a,t,u} = n_a \quad \text{for } a > 1$$

5. Set fishing mortality rate for initial year of simulation u:

   $F_{t,u} = F_{2002}$

6. Increment time index:

$$t = t + 1$$

7. Compute numbers at age in year t of simulation *u*:

$$N_{a,t,u} = R_{t,u}, \quad R_{t,u} \sim \text{InvGaussian}(\beta, \gamma) \qquad \text{for } a=1$$

$$N_{a,t,u} = N_{a,t-1,u} \exp\left(-M_a - F_{t-1,u} \sum_{k=1}^{n_{gear}} s_{a,k} d_k \right) \qquad \text{for } 1 < a < n_{age}$$

$$N_{a,t,u} = N_{a,t-1,u} \exp\left(-M_a - F_{t-1,u} \sum_{k=1}^{n_{gear}} s_{a,k} d_k \right) + N_{a-1,t-1,u} \exp\left(-M_{a-1} - F_{t-1,u} \sum_{k=1}^{n_{gear}} s_{a-1,k} d_k \right) \qquad \text{for } a = n_{age},$$

8. Compute the ABC fishing mortality rate that establishes the TAC for year *t* of simulation *u*.

The appropriate fishing mortality rate was determined by the projection year and the relative spawning biomass of the stock as shown in the table below (B_{ref} corresponds to $B_{40\ percent}$ in all cases unless otherwise specified). F_{ref} corresponds to the fishing mortality specified as the F_{ABC} value.

Relative spawning biomass	**Fishing mortality rate**
$B_{t,u} < \alpha B_{ref}$	$F_{t,u}^{ABC} = 0$
$\alpha B_{ref} \le B_{t,u} < B_{ref}$	$F_{t,u}^{ABC} = F_{ref} \left(\frac{B_{t,u}}{B_{ref}} - \alpha \right) / (1 - \alpha)$
$B_{ref} \le B_{t,u}$	$F_{t,u}^{ABC} = F_{ref}$

where $B_{t,u} = \sum_{a=1}^{n_{ages}} N_{a,t,u} m_a w_a \phi_{a,t,u}$ and $\phi_{a,t,u}$ is the total mortality rate between the beginning of the year and the time of spawning. The value of $B_{t,u}$ was computed iteratively (since it can be a function of fishing mortality). Note also that for some FMPs described below these rules change for some species. For a given FMP *I,* the fishing mortality is treated as a function of the F_{ABC} value.

$F_t^{Alt} = f\left(F_{t,u}^{ABC}\right)$ as specified by the FMP.

9. Compute the TAC value as annually varying limit on catch. For a given species and value of (for $F_t^{Alt_l}$ alternative *l*) the projection model computes the TAC used in the constraint as

$$TAC_t^{Alt_l} = \sum_{k=1}^{n_{gear}} \sum_{a=1}^{n_{age}} N_{a,t} w_{a,k} \frac{F_t^{Alt_l} s_{a,k} d_k}{F_t^{Alt_l} s_{a,k} d_k + M_a^p} \left[1 - e^{-F_t^{Alt_l} s_{a,k} d_k - M_a^p} \right]$$

10. Compute the actual catch, $C_{t,u}$, given the suite of constraints from the LP optimization described below.

11. Solve for the fishing mortality rate $X_{t,u}$ that would set catch equal to $C_{t,u}$ in year *t* of simulation *u* as estimated from the multi-species management constrained optimization problem described below and varies by FMP by solving the following implicit equation:

$$C_{t,u} = X_{t,u} \sum_{a=1}^{n_{age}} \left[N_{a,t} \left(\frac{1 - \exp\left(-M_a - X_{t,u} \sum_{k=1}^{n_{gear}} s_{a,k} d_k \right)}{M_a + X_{t,u} \sum_{k=1}^{n_{gear}} s_{a,k} d_k} \right) \sum_{k=1}^{n_{gear}} w_{a,k} s_{a,k} d_k \right]$$

12. Check to see if all years of simulation *u* have been completed, then continue as necessary:

If $t<n_{pro}+1$, return to (6)
If $t=n_{pro}+1$, end simulation *u*.

13. Return to (2) until all simulations are complete.

Step 5: Store Stock Performance Statistics from the Above Projections

A series of individual stock performance indicators for species with specified age-structure results were computed separately for each FMP as follows:

Total biomass in each year and simulation:

$$T_{t,u} = \sum_{a=1}^{n_{age}} N_{a,t,u} w_a$$

Spawning biomass and catch, as specified above, were stored for each species, year, and simulation. Approximate confidence bounds were computed from the simulation output by simply ranking results from the simulations and computing the percentile values corresponding to the desired intervals (here taken as the 10^{th} and 90^{th} percentile). Also computed was the implied spawning biomass per recruit (SPR) rate, given the level of catch in a single year and simulation. (For example, the theoretical percentage of unfished spawning output expected from a single recruit if fishing mortality were equal to the estimated fishing mortality over the life of the species.)

Average age for each stock in the final projection year across all simulations was computed as:

$$A = n_{sims}^{-1} \sum_{u=1}^{n_{sims}} \frac{\sum_{a=1}^{n_{age}} a\, N_{a,2002+n_{pro},u}}{\sum_{a=1}^{n_{age}} N_{a,2002+n_{pro},u}} + a_{\min} - 1$$

The Linear Programming Algorithm

LP is an active research branch of operation research that has proved to be useful in resource management. In this context, an optimization problem is considered linear if all objective function and constraint coefficients can be arranged in a linear way. The linear optimization problem, in this case, consists of finding the optimal catch allocation in order to maximize the overall catch or total revenue across all fisheries and subject to a certain number of linear constraints. We used a revised Simplex algorithm (Press *et al.* 1992) to find the optimal vertex in this multidimensional space.

The objective function and constraint coefficients were computed primarily from the NOAA Fisheries, Alaska Region blend dataset. The data were averaged over the period 1997 to 2001, so all the coefficients represent averages from this time period. FMP-specific constraints were developed for both the BSAI and GOA. Namely TAC constraints for each FMP area complex, special gear sconstraint for some species, lower and upper bound constraints on the variation of catch relative to average levels for each fishery, and constraints of the maximum allowable biological removals of each system.

Objective Function Coefficients

The target function consisted of coefficients derived from the blend data set for FMP-managed species across different fisheries. The ex-vessel value ($V_{j,g}$) for each species and proportion retained by each fishery were used to compute the coefficients of the linear objective function:

$$A_g = \sum_{j=1}^{n_{species}} \sum_{k=1}^{n_{area}} V_{j,g} C_{j,k,g}^{N} R_{j,g}$$

with the overall objective function to be maximized in year *t* is given as:

$$\Theta_t = \sum_{g=1}^{n_{fish}} A_g Y_{t,g}$$

where

A_g	Objective function coefficients applied to each fishery
$C_{j,k,g}^{N}$	Catch data from the blend dataset by species, sub-area and fishery
$R_{j,g}$	Retained fraction of catch
$Y_{t,g}$	Relative total catch between fisheries within each year (main result returned from the constrained optimization)

$V_{j,g}$ Estimated ex-vessel value of each species within different fisheries

t Year

j Species

k Sub-area

g Fishery

h Gear-type

Linear Constraints

In our optimization problem there are two types of constraints: values that are maxima or upper bounds, and values that are minima or lower bounds. There were five types of upper-bound constraints and one type of lower-bound constraint, these are presented below in consecutive order. The coefficients were computed only once for a specific FMP since the catch-composition data is constant for this model version over time and assumed known without error.

The bounding information or constraints were based on a number of sources detailed below. Note that some constraints change over time (e.g., the ABC/TAC constraints).

Acceptable Biological Catch (ABC/TAC) Constraints

These constraints determined an upper bound equivalent to the TAC for each species in each sub-area. Each constraint has one coefficient and represents the average annual catch by FMP species and area as:

$$\sum_{g=1}^{n_{FA}} Y_g a_{j,k,g}^{ABC} \leq b_{j,k}^{ABC_t}$$

$$a_{j,k,g}^{ABC} = C_{j,k,g}^{N}$$

$$b_{j,k}^{ABC_t} = TAC_{t,j,k}\ f_k$$

where $TAC_{i,j,k}$ = Total allowable catch for species *j*, in sub-area *k* in year *I* and f_k is the split by area for a particular species, and the bounds of the constraints are calculated as a function of a fixed allocation fraction of the TAC across sub-areas and the estimates for TAC by year.

Gear Type (G) Constraints

Gear allocations for a specific annual TAC were included to reflect the current practice. In the model, these constraints were specified as

$$\sum_{g=1}^{n_G} Y_{t,g} a_g^G \leq b^G$$

$$a_g^G = \sum_{g=1}^{n_{area}} C_{k,g}^N$$

$$b^G = TAC_e f_k^G$$

where e = Index for species with gear restrictions

f_k^G = Proportion of TAC allocated to each gear type, G, of each species in sub-area k.

For example, sablefish TAC's are allocated between longline fixed gear and trawl gear. The model accounts for these allocations as added constraints.

Fishery Expansion Constraints

Upper-bound constraints on relative catch are placed by FMP species upper limit (UL) so that relative catch does not grow unreasonably beyond the baseline data or 1997 to 2001 average.

$$Y_{t,g} a_g^{UL} \leq b_g^{UL}$$

b_g^{UL} values typically ranged from 1.3 to 3. However, some alternatives specified different values as detailed in Section 4.1.5.5 Description of the Alternatives.

Fishery Contraction Constraints

Based on extensive initial runs of this model, the optimal solution often eliminated a number of fisheries. To prevent this, and to ensure that the catch remains positive, the following set of lower-limit (LL) constraints were applied.

$$Y_g a_g^{LL} \geq b_g^{LL}$$

where $a_g^{LL,}$ is a scalar for fishery g.

Overall Optimum Yield (OY) Constraint

The specification that the OY cap could not be exceeded was given as:

$$\sum_{g=1}^{N_{fish}} Y_{t,g} a_g^{OY} \leq b^{OY}$$

$$a_g^{OY} = \sum_{e=1}^{N_{sp}} \sum_{k=1}^{N_{Area}} C_{e,k,g}^N$$

$$b^{OY} = OY$$

where OY = optimum yield summed for the geographical area (e.g., BSAI) for all target FMP species

e = index of target species used for optimum yield.

Note that this was generally two million metric tons (mt) for the BSAI and 800,000 mt for the GOA. However, some alternatives specified different values as detailed below in the FMP descriptions section.

Optimizing the Objective Function Subject to the Constraints

To find the optimum solution in standard tableau notation (Press *et al.* 1992), we can reduce the system of equations to the following array with columns 2 to *g+1* corresponding to each fishery:

where

m_{ABC} Number of ABC type of constraints (number of species that have TAC)

m_G Number of gear type of constraints

m_{UL} Number of upper limit constraints on relative catch of FMP species

m_{LL} Number of lower limit constraints on relative catch of FMP species

m_{OY} Number of optimum yield constraints (only one)

Some of the coefficients (A_i , a_i^j) are zero but they are presented here in a general notation.

$$
\begin{array}{cccccc}
0 & A_1 & \cdots & A_i & \cdots & A_g \\
b_{i,j,k}^{ABC_1} & -a_{j,k,1}^{ABC_1} & \cdots & -a_{j,k,i}^{ABC_1} & \cdots & -a_{j,k,g}^{ABC_1} \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
b_{i,j,k}^{ABC_{m_{ABC}}} & -a_{j,k,1}^{ABC_{m_{ABC}}} & \cdots & -a_{j,k,i}^{ABC_{m_{ABC}}} & \cdots & -a_{j,k,g}^{ABC_{m_{ABC}}} \\

$$

4.1.5.3 Data

Estimation of the 1997 to 2001 Catch by Species and Fisheries

We used the NOAA Fisheries, Alaska Region blend estimates of catch by area, species, gear, and target species combined with observer fish ticket data. The fish tickets are landing receipts recorded by Alaska Department of Fish and Game (ADF&G) statistical areas.

The North Pacific Groundfish Observer Program currently provides all of the information we have on fishery interactions with non-target species. Observers estimate total catch and species composition of the catch in a random sample of hauls. All animals are counted, weighed, and identified to the lowest practical taxonomic level, regardless of their status as a target species, or whether they will later be discarded by the vessel. The Observer Program is extensive, covering the majority of fishing effort in the BSAI and up to 30 percent of fishing effort in the GOA.

Despite the large size and extent of the Observer Program, not all fishing is observed at all times. Only fishing vessels over 124 feet (ft) in length must carry an observer for all days fishing. Smaller vessels (60-124 ft) are only required to carry an observer for 30 percent of days fishing, and vessels under 60 ft are never required to carry an observer. Therefore, we had to extrapolate the data collected by observers to the reported catch from all observed and unobserved fishing in order to estimate the total catches of non-target species groups from all fishing for this analysis. This assumes that observed fishing and unobserved fishing have the same catch composition. Although this assumption is unverified, observer data is the best and only source of information on non-target species catch.

Catches were estimated by species group for the recent domestic fishery, 1997 to 2001, using the following method: within each year, each vessel's observed catch of a given species group was summed within statistical area, gear type, and week. A target fishery was then assigned to each vessel's weekly catch, generally by assuming that the species with the highest retained catch for that week was the target species. The Programmatic SEIS describes target fishery designations and the specific algorithm for assigning targets. This is consistent with target assignments done as part of the inseason management system at the regional office. Catch by target species and non-target species, where available, was then summed for each year over all observed vessels within each area, gear, and target fishery. The ratio of observed non-target species catch to observed target species catch within each area, gear, and target fishery was multiplied by the total reported (regional office blend-estimated) target species catch within that area, gear, and target fishery. Data from years prior to 1997 could not be assigned to target fisheries in a way that is consistent with total catch targets assigned by the NOAA Fisheries Alaska regional office due to changes in the structure of the observer database. We do not consider this a problem because the most recent years of catch information are most valuable for the purposes of this analysis. Catches of other species, forage fish, and grenadiers were estimated for 1990 through 2001 as part of the annual stock assessment process and are reported in annual SAFE documents for the BSAI and the GOA.

The catch-composition data were processed to reflect area and time closures specific to each alternative. Since the catch-composition estimates were assigned to spatial/temporal strata, then the effect of changes in management measures could be reflected by modifying the catch-composition arrays accordingly. For example, if an alternative had specific closed areas, then the catch-composition data that fell within those categories were deleted. The notion here was simply to try to reflect how catch-composition might change under alternative area-time constraints.

Methods Used to Apportion the Estimates of Total Catch, Retained Catch, and Ex-Vessel Value by Processor Group and Vessel Class and to Estimate Product Value by Processor Group

We used blend estimates of total catch and retained catch and fish ticket estimates of retained catch for 1999 to 2001 to apportion the catch and ex-vessel value projections discussed above by processor group and vessel class. The resulting estimates of retained catch by processor group were used with 2001 estimates of product value per mt of retained catch to generate the estimates of product value. The methods used are discussed below.

Step 1: Define Processor Groups and Identify the Processors in Each Group

We defined the following six groups of inshore processors and six groups of at-sea processors to assist in analyzing the economic and social effects of the GOA and BSAI groundfish fisheries both historically and for the alternatives being considered in this Programmatic SEIS.

1. Large BSAI pollock processors (the American Fisheries Act [AFA] inshore sector processors that operate in or near Unalaska and Akutan.

2. Other Alaska Peninsula and Aleutian Island processors.

3. Floating processors (non-AFA floating processors).

4. Kodiak processors.

5. Southcentral processors.

6. Southeast processors.

7. Surimi factory trawlers.

8. Fillet factory trawlers.

9. Head and gut factory trawlers.

10. Longline catcher processors.

11. Pot catcher processors.

12. Motherships.

We then identified the processors in each of these mutually exclusive groups.

Step 2: Distribute Catch and Ex-vessel Value Projections by Processor Group

We used blend estimates of total catch and retained catch by fishery, species (for the TAC species), and processor group from 1999 to 2001 to estimate the shares of total catch and retained catch by fishery and species associated with each processor group. The fisheries were defined by target species, gear, and area. We then applied the total catch shares to the alternative-specific total catch projections to estimate alternative-specific total catch by fishery, species, and processor group. The retained catch shares were used in a similar way with the alternative-specific retained catch and ex-vessel projections to generate comparable estimates of retained catch and ex-vessel value. Data for 1999 to 2001 were used because the AFA was implemented in 1999, significantly changing the shares of catch among processor groups.

Step 3: Estimate Product Value by Processor Group

For each inshore processor group, we used 2001 Alaska Commercial Operator's Annual Report (COAR) estimates of groundfish purchases and product value by species to estimate product value per mt of retained catch. For each at-sea processor group, we used 2001 COAR product price data for at-sea processors, supplemented by 2001 product price data provided by representatives of the Head and Gut Factory Trawlers, together with Weekly Production Report production and retained catch data to estimate product value per mt of retained catch.

Step 4: Define Catcher Vessel Classes and Identify the Catcher Vessels in Each Group

We defined the following nine classes of groundfish catcher vessels to assist in analyzing the economic and social effects of the GOA and BSAI groundfish fisheries both historically and for the alternatives being considered in this Programmatic SEIS.

Bering Sea pollock trawl catcher vessels greater than or equal to 125 ft in length

- Bering Sea pollock trawl catcher vessels 60 to 124 ft in length.
- Diversified AFA-eligible trawl catcher vessels greater than or equal to 60 ft in length.
- Non-AFA trawl catcher vessels greater than or equal to 60 ft in length.
- Trawl catcher vessels less than 60 ft in length.
- Pot catcher vessels less than or equal to 60 ft in length.
- Longline catcher vessels less than or equal to 60 ft in length.
- Fixed gear catcher vessels 33 to 59 ft in length.
- Fixed gear catcher vessels less than or equal to 32 ft in length.

We then identified the catcher vessels in each of these mutually exclusive vessel classes.

Step 5: Estimate Retained Catch and Ex-vessel Value by Catcher Vessel Class

We used State of Alaska fish ticket estimates of retained catch by species, area, processor group, and vessel class from 1999 to 2001 to estimate the share of retained catch by species and area associated with each catcher vessel class. We then applied the retained catch shares to the alternative-specific retained catch and ex-vessel value projections by processor group to generate alternative-specific estimates of retained catch and ex-vessel value by species, area, and catcher vessel class.

Assumptions

The resulting estimates of total catch, retained catch, ex-vessel value, and product value are based on the assumptions that the following will not vary, either by alternative or from what has been observed recently for the BSAI and GOA groundfish fisheries:

- Species composition (i.e., bycatch rates) of TAC species in any individual fishery, where a fishery is defined by area, gear, and target species.
- Distribution of catch among processor groups in any individual fishery.
- Retention rates for a fishery, species, and processor group.
- Product mix for a species and processor group.
- Distribution of retained catch among catcher vessel classes for each processor group.
- Ex-vessel prices.
- Product prices.

We do not believe these assumptions are either equally valid for all the alternatives or valid for most of the alternatives. Unfortunately, the information necessary to estimate alternative-specific differences in bycatch rates, the distribution of catch among processor groups and vessel classes, retention rates, product mix, ex-vessel prices, or product prices is not available. This problem is addressed qualitatively in the sections that present the projections of ex-vessel value and product value for the various alternatives.

Estimates of Ex-Vessel Value Per Metric Ton of Retained Catch

We used 2001 Alaska COAR groundfish purchase data to estimate ex-vessel value per mt of catch by species, gear, and area for the species that are not almost exclusively processed at sea. For the other species, such as BSAI Atka mackerel, flatfish, and rockfish, we estimated that the ex-vessel value per mt of retained catch was 40 percent of the product value per mt of retained catch.

Description of the Fishery Definitions Used in the Model

In the GOA, 32 different fisheries were defined as having gear-area-target significance. These are listed in Table 4.1-14. Table 4.1-15 lists the 35 fisheries defined for the eastern BSAI regions (Figures 4.1-2 and 4.1-3).

To summarize characteristics of each ,fishery we devised a method to show the diversity of species mix observed in the catch. We used Simpson's (1949) index of diversity (κ) commonly used in population biology. For each fishery the index is computed as

$$\kappa = \frac{1}{\sum_{i=1}^{nspp} p_i^2}$$

where p_i is the proportion of catch in biomass over all species or species groups (55 different categories in the GOA and 56 in the BSAI). This index can be interpreted as roughly the effective number of species. For example, Figure 4.1-4 illustrates a hypothetical catch composition of five species caught in four different fisheries at different proportions. The effective number of species for Fishery A is very close to 1.0 (1.02) due to the fact that 99 percent of the catch is attributed to Spp_1. At the other extreme, Fishery D caught all five species in equal proportions leading to an index value exactly equal to 5. In Fishery B, only two species are caught in equal proportion, hence the effective number of species is exactly 2. In Fishery C, all five species occur, but in diminishing proportions; therefore, the effective number of species is slightly lower than 3.

Presenting the species mix for fisheries in this way provides a simple way of examining the differences between fisheries. More importantly, it can be used to show the effect of how sampling variability and time trends may affect the estimated catch composition of each fishery. For example, computing the effective number of species using five-years of NOAA Fisheries blend data in aggregate average catch by species and fisheries showed that for both the GOA and BSAI regions, flatfish and rockfish fisheries tend to have higher catch diversity, since these are fundamentally mixed-species fisheries. Pollock fisheries and fisheries using pot gear tended to have the lowest diversity (Figures 4.1-5 and 4.1-6). However, these figures show that the catch diversity in some fisheries can be quite different between years. This is presumably largely due to sampling error and partly due to real changes in catch composition. Another contribution to this variability could be how target fisheries are defined. (i.e., a target fishery is defined based on the dominant species catch reported by week). If a vessel actually targets multiple species within a week, then the diversity of the reported catch may be unrealistically high. These factors highlight important caveats regarding the ability to accurately predict how catch diversity levels may change from one year to the next. These problems would be exacerbated by using subsets of catch composition data within years that have closed areas. For this reason, we chose to assume that the best available estimates of fisheries catch composition were based on data aggregated from 1997 to 2001. Since many of these fisheries defined may reflect relatively small levels of catch, we evaluated this index for the major fisheries and examined the trend over time. For the GOA, 11 of the 32 fisheries represented 80 percent of the catch. These fisheries still had considerable inter-annual variability in catch diversity (Figure 4.1-7), but no apparent trend. In the BSAI, 8 fisheries represented 91 percent of the catch and had less inter-annual variability (Figure 4.1-8). The flatfish fisheries appeared to have a slightly increasing trend in diversity from 1997 to 2001. This suggests that the assumption of constant species compositions may be inappropriate. Further research on what has caused this apparent trend in catch diversity is warranted.

4.1.5.4 Critique of Assumptions and Approach

Forecasting fisheries behavior is an endeavor fraught with uncertainty. Even under a relatively constant management system, changes in socioeconomic and environmental conditions can result in substantial future uncertainty. Add in a complex set of alternative management measures, such as those presented in this document, and the uncertainty is magnified. The following describes an attempt to model key aspects of the current fisheries management system and, to the extent possible, modifications according to the specific management measures for the four alternatives and their range. The model's predictive power given the system complexity is poor. However, this multi-species technical interaction model does provide a more objective approach to evaluate alternative management actions compared to single species examinations.

The NPFMC Scientific and Statistical Committee (SSC) provided feedback on the modeling approach. In particular, they raised a number of concerns about using this type of approach (i.e., using LP to mimic fisheries management). For example, using ex-vessel value estimates as part of the objective function fails to reflect the costs. Unfortunately, extensive cost data are unavailable. The SSC noted that ex-vessel prices are likely to change over time. While modeling how these may change over time would be valuable, the degree of difficulty and added complexity prohibited development along these lines. This aspect seems unlikely to have a large-scale effect over the five-year simulation projection.

Within alternatives, the catch-composition array is assumed to be constant. That is, there is no random variability, nor are there trends in the underlying catch composition within a fishery. In reality, catch-composition values are likely to vary from year to year. Observation error and other sources of variability and potential biases mask this variability. The model was developed so that catch-composition variability can be implemented in the simulation. However, since available data are limited to five years, the magnitude of this uncertainty could not be assessed in time for this analysis. Explicitly modeling the catch composition of each fishery is an area of research that needs to be pursued, particularly as dynamic species interactions are introduced.

The fact that the catch-composition array is constant over time may not be unreasonable given the short time frame of the main projections (2003 to 2007). However, the long-term projections assess conditions to 2023; these results should be viewed much more cautiously. These long-term projections were done to provide some indication of general trends between stocks. For the five-year time frame used for estimating the catch composition by fisheries and species matrix (1997-2001), there appeared to be little or no trend in the diversity of the catch for the main fisheries (e.g., Figure 4.1-8). The annual variability in the diversity of the catch highlights the importance of including details on the effect of area closures on catch by species and fisheries matrices. Clearly, sampling error plays a large role, and, as finer geographic resolution is included, the effect of sampling error will increase. This will likely compromise real changes in bycatch patterns due to area closures.

The uncertainty in current abundance levels is not modeled. The point estimates for parameter values (e.g., the numbers-at-age) in the assessments published in the 2002 SAFE are used. This clearly underestimates the variability in the current abundance levels for all species of groundfish. Under FMP 3.2, estimation uncertainty is accounted for and is applied as a risk-averse adjustment. It is possible to add this type of estimation uncertainty explicitly within the projection model. However, time limitations and the additional complexity in the presentation of the results would detract from the analysis.

Another factor that tends to underestimate variability to some extent is the omission of stock-recruitment relationships from the projection model. The reason for this omission is that, with the exception of EBS walleye pollock, reliable estimates of the stock-recruitment relationship do not exist for any BSAI or GOA groundfish stock. When making projections over the long-term, omission of the stock-recruitment relationship will tend to understate the impacts on biomass and recruitment resulting from a sustained change in the harvest rate. However, when projections are restricted to the near future, as they are for the most part in this document, it is less likely that omission of the stock-recruitment relationship will bias results significantly unless one or more of the following conditions holds: 1) the stock-recruitment relationship for a stock is extremely strong, 2) the average lifespan of individuals in a stock is extremely short, or 3) the average harvest rate for a stock is extremely different from that which generated the initial conditions. Examination of existing stock-recruitment data for BSAI and GOA target groundfish stocks indicates that none of them appear to exhibit extremely strong stock-recruitment relationships, which is one of the reasons why it has proven so difficult to estimate such relationships in the past. Furthermore, none of the BSAI or GOA target groundfish species is extremely short-lived. Finally, while the average harvest rates for Alternatives 2 through 4 typically differ to some extent from the average harvest rates in Alternative 1, the only cases in which the differences are truly extreme occur under Alternative 4. Therefore, it is unlikely that omission of the stock-recruitment relationship will lead to significant biases in the results, with the possible exception of results pertaining to stocks whose average harvest rates under Alternative 4 diverge sharply from the corresponding average harvest rates under Alternative 1.

The SSC also recommended that alternative objective functions be considered. They noted that the purpose of the model is to project likely management actions under the alternatives. Hence, it might be useful to express the objective as a minimization of the weighted sum-of-squared deviations between actual and target levels of catch, where the weights reflect management preferences for meeting TACs. This would provide a non-linear, quadratic objective function with linear constraints, and would add a seemingly desirable feature to the model, at least for the status quo (FMP 1) specification. Time limitations precluded implementation of a Quadratic Programming approach. Furthermore, this approach would require subjective specification of the weights for the different alternatives. For the Linear Programming approach used here, the imperfect objective function requires fewer assumptions about how weights may change by alternative.

For this implementation, the results were largely insensitive to the objective function specification. Some of the assumptions that constrained the solution space most severely were limits placed on the ability of individual fisheries to expand and contract relative to the patterns observed during 1997 through 2001. Sensitivity analysis showed that as these bounds were relaxed, the overall catch and revenue based on ex-vessel value increased at the expense of greater departures from the status quo, and increased sensitivity to the objective function. For these sets of model specifications, bounds were selected based on discussions with economists in the iterative process of examining model results. There is clearly room for improvement in specifying these sets of constraints. One approach would be to poll a wider group of experts to arrive at more refined sets of limits. Such a setting would also provide needed feedback for model improvements and may provide insights to management on the relative benefits of different fisheries.

In summary, the complex interactions among changes in biomass levels, fisheries economic performance, and management effectiveness are just some of the reasons why any such forecast must be viewed cautiously.

4.1.5.5 Description of the Alternatives

The projection model was designed to approximate the general patterns of catch that might be expected given the multi-species nature of groundfish fisheries. The analyses rely on two main sources of information: observer and fish ticket data, the blend data and stock assessment estimates of population parameters, abundance-at-age in 2002, and recruitment variability. The first step in developing model configurations for each of the example FMPs was to process the observer catch-composition data to reflect, to the extent possible, the impact of each FMP. The baseline catch-composition data was derived from observer and fish ticket reports for the period 1997 through 2001. For certain fisheries where characteristics changed dramatically, such as the implementation of the AFA in 2000, the number of years included differed from this baseline. The details of estimating the catch-by-fisheries data used in the model is presented in a separate section below.

The second part of setting up alternative specifications involved limiting TACs either through different harvest control rules or specific ABC reductions. The following sections provide some descriptions about how the model is affected by the different alternatives.

For the main reported species, the PSC species and the other non-target species have been compiled for gear-area-target fisheries using 1997 to 2001 as the baseline average. For all FMPs, except FMP 2.2, the EBS pollock fishery and the Aleutian Islands Atka mackerel fisheries, the average of 2000 and 2001 data were used to better reflect the AFA and other recent management measures. Unless otherwise noted, the values for retention rates are shown in Tables 4.1-16 and 4.1-17, while the estimated average ex-vessel price by species and gear type is given in Tables 4.1-18 and 4.1-19. The catch by species and fisheries for the GOA and BSAI is available from the web (www.fakr.noaa.gov/sustainablefisheries/seis/data). An overview of the key differences between the alternatives as modeled is given in Table 4.1-20. It is important to note that yield and biomass results for any alternative cannot typically be attributed to any single aspect of alternative specification since all aspects are being implemented simultaneously.

FMP 1

This alternative is considered the baseline status quo relative to the 2001 fishing year. The ABC follows Amendment 56 for setting quotas. Furthermore, the ABC setting for FMP 1 is adjusted downward as appropriate and is typically based on recommendations from assessment authors and NPFMC.

For example, in the 2002 SAFE, the ABC fishing mortality for a number of species was set at $F_{t,u}^{Alt1} = \omega F_{t,u}^{ABC}$ where ω is 0.87 for Pacific cod in both the BSAI and GOA. For pollock ω is an added buffer added as a function of spawning biomass, as presented in the GOA pollock SAFE by Dorn *et al.* (2002). For non-Steller sea lion forage species α = 0.05, while for pollock, Pacific cod, and Atka mackerel, α =0.5. In the BSAI, an overall OY cap of 2 million mt of groundfish catch was an added constraint, while for the GOA the cap was set at 800,000 mt (FMP species only).

FMP 2.1

For this alternative, the catch-composition data are the same as FMP 1, with one exception: the pre-Individual Fishing Quota (IFQ), catch-composition rates for sablefish fisheries and earlier estimates of halibut mortality were used. The use of earlier data represents only a small difference when compared to the current estimates; and is available on the website (www.fakr.noaa.gov/ sustainablefisheries/seis/data). The F_{ABC} for this FMP is set equal to F_{OFL}, or the overfishing level (OFL), which, by NPFMC definitions, equals the point estimate of F_{msy}. This fishing mortality rate is held constant over all stock sizes, including as the stock drops below $B_{40\%}$ (i.e., $F^{ABC}_{t,u} = F_{msy}$ for $B_{t,u} > 0$). For all age-structured stocks, the F_{msy} was set equal to the SPR fishing mortality rate of $F_{35\%}$. For survey biomass stocks Tier 4 through 6 from Amendment 56, the ABC was set equal to the overfishing level (OFL). Additional measures for Steller sea lion prey species were omitted.

In FMP 2.1, the OY is set to the sum of ABC's in both the GOA and BSAI. Also, there are no constraints due to PSC limits. For example, bycatch of Pacific halibut will not constrain fishery development. The fishery-expansion constraint is set to 100 (i.e., fisheries can expand effort beyond the average level observed over 1997 through 2001).

FMP 2.2

Example FMP 2.2 is similar to FMP 1, except that the OY is set to the sum of ABCs in both the GOA and BSAI, instead of at a fixed cap. Also, the maximum permissible ABC value was used instead of the author's adjustment (see for FMP 1).

FMP 3.1

This FMP is similar to FMP 1, except that the constraint on Pacific halibut mortality is reduced by 10 percent and, therefore, more constraining. Also, the author's recommendation for ABCs (see for FMP 1) is omitted (e.g., the GOA pollock OFL buffer).

FMP 3.2

For example FMP 3.2, catch species by fishery data are modified to reflect improved rationalization. That is, the bycatch of discarded species is reduced by using existing total catch estimates and changing the fraction that is discarded. Specifically, for given species and fishery, the catch that has been estimated as being discarded in the data will be reduced by 20 percent. This means that under fisheries rationalization, the fishing behavior will change such that the actual incidental catch will be reduced. This change is implemented by modifying the input data on catch species by fishery and is sometimes referred to as the bycatch matrix. These data are available on the NOAA Fisheries website: http://www.fakr.noaa.gov/sustainablefisheries/seis/data.

Another aspect of improve rationalization specifies that the retention rates of what is caught in the future will increase; in other words, at which species are discarded the rate will be reduced 20 percent. This change is implemented by modifying the retention rate matrices for GOA and BSAI shown in Tables 4.1-21 and 4.1-22.

For example FMP 3.2, the OY is set to the sum of ABCs instead of the current 2 million mt capacity. Also, the halibut mortality limit is reduced by 30 percent relative to FMP 1.

One objective under FMP 3.2 was to incorporate formal estimates of uncertainty already estimated in many of the stock assessments. A large-scale research effort on developing methods to use fully Bayesian risk-averse methods is in progress, and a version of this development is used here.

Under the current system a common assumption is that the $F_{35\,\%}$ rate is a good proxy for F_{msy}, and thereby determines the F_{OFL}. Similarly, $B_{35\,\%}$ is commonly taken as a good proxy for B_{msy}. Given the parameter values from stock assessment results to determine these quantities, the NPFMC has implicitly accepted that the $F_{40\,\%}$ fishing mortality rate is suitably risk-averse regardless of uncertainty in future recruitment and current stock size. The risk-averse adjustment to the F_{msy}, here assumed to be $F_{35\,\%}$, formally accounts for the uncertainty in current stock size and future recruitment. In addition to the standard selectivity, average mass-at-age, natural mortality, current numbers-at-age, and maturity-at-age schedules, the method developed requires estimates of the covariance matrix of the current numbers-at-age and the time series of recruitment estimates. The advantages of the method developed include: 1) that the upper bound of the F_{ABC} is set to a constant level of risk-aversion; 2) simulations to determine the appropriate adjustment level can be avoided; 3) analytical solutions are available for all steps except one final maximization; and 4) the ability to assess the value of improving estimates and reducing variance of current stock size. A key feature of this analysis is the development of a method for calculating the stock-recruitment relationship given estimates of B_{msy} and F_{msy} and the other age-specific schedules listed above. The actual values for the adjustment are shown in Table 4.1-23 and a presentation of two scenarios where the risk-averse adjustment appears to be due to different sources is shown in Figure 4.1-9.

The application of the risk-averse adjustment was applied for all stocks:

$$F_{Har} = F_{msy} * \text{Adjustment}$$
$$F_{ABC} = \min(F_{Har}, F_{40\,\%}, F_{OFL\_Alt1})$$

While for rockfish species an added measure of precaution was applied where

$$F_{ABC\_RF} = \min(F_{60\,\%}, F_{Har})$$

FMP 4.1

In this example FMP, the OY constraint is set to the sum of ABCs. Note that this is effectively the same as omitting an OY constraint since the individual species" ABCs are constraints themselves. The species catch by fishery was modified so that fisheries with more than 33 percent bycatch of a species not listed as the target specie was eliminated. Pacific cod, pollock, and arrowtooth flounder were not included as a bycatch species to these fisheries.

Uncertainty corrections to the ABCs were based on survey catcher vessels Also, the F_{ABC} was set to $F_{75\%}$ for all Steller sea lion prey species and for all species of rockfish. Note that uncertainty corrections applied to the $F_{75\,\%}$ values, too.

Agency analysts discussed how to incorporate the formal estimates of uncertainty already estimated in some of the stock assessments (e.g., AD Model Builder applications or Bayesian analyses). This is an ongoing area of research; however, the example regime was deliberately designed to be applicable to all stock assessments regardless of the software used. Incorporating formal estimates of uncertainty available for some stocks would continue to impose the largest adjustments only on the best known stocks. For example, the current process for TAC setting does not reduce harvest levels when the reference biomass level ($B_{40\%}$) cannot be estimated for stocks in Tiers 4 to 6 of Amendment 56/56 ABC and OFL definitions. Stocks qualify for management under Tiers 4 to 6 only if reference stock levels cannot be estimated reliably.

The formal incorporation of uncertainty was accomplished by setting the fishing mortality rate associated with ABC (F_{ABC}) at specified fractions of the maximum allowable fishing mortality rate maximum F_{ABC}. This fraction varies directly with the uncertainty or variance of the survey biomass estimates. Specifically, this is accomplished by computing the average coefficient of variation for the survey biomass estimates in the time series and then computing the lower bound of the 90 percent confidence interval for a lognormal distribution with this coefficient of variation and a median of unity. This lower bound is the specified fraction by which to reduce maximum F_{ABC}. The specified fraction by which to reduce maximum F_{ABC} is provided as input to the model for FMP 4.1. All target species with biomass estimates were analyzed. Exceptions are made in the model projections for some species whose stock assessment F_{ABC} is below maximum F_{ABC}. These adjustment values, corresponding to the lower bound of the 90 percent confidence interval, are given in Table 4.1-24.

For FMP 4.1, the prohibited species cap for Pacific halibut mortality was reduced to 50 percent of the current level, causing a higher level of constraint.

FMP 4.2

No fishing was allowed for the 5 year-projection. We presume that under this example FMP, fisheries authorized following review would take the form of that regime being illustrated by FMP 4.1.

4.1.5.6 How Model Results Were Applied in Assessing Impacts of the Alternatives on Different Resources

Target, Forage, Prohibited, Other, and Non-Specified Species

For the target species, the multi-species, multi-fisheries simulation projection model provided fundamental dynamics to the model behavior. That is, as the biomass of an FMP species changed in the future, the constraint via ABC/TAC control also changed. The outputs from the model were primarily intended to reflect these dynamics and the interactions with the species composition of the different fisheries.

The significance of the impacts on target species were evaluated with respect to fishing mortality, change in biomass level, spatial/temporal concentration of the catch, prey availability, and habitat suitability.

The significance of the effects of the alternative fishing mortality levels are evaluated with respect to the overfishing mortality rates as set forth in Amendment 56/56. Fishing mortality rates that exceed the overfishing mortality rate are considered to jeopardize the capacity of the stock to produce MSY on a continuing basis and adversely impact the sustainability of the stock. A related measure of this potential is indicated by change in biomass levels. The significance of effects of the current spatial/temporal concentration of the catch and the level of prey availability and habitat suitability for target species are evaluated with respect to each stock's current size relative to its MSST. An action that jeopardizes the stock's ability to sustain itself at or above its MSST is considered to adversely affect the sustainability of the stock.

Species or species complexes that fall within Tiers 1 though 5 have estimates of the current fishing mortality rates, and are evaluated with respect to exceeding the overfishing mortality rate or fishing mortality effect. Species or species complexes that fall within Tiers 1, 2, or 3 have reliable estimates of MSST, and are evaluated for the effects of spatial/temporal concentration of the catch, prey availability, and habitat suitability. Species or species complexes that fall within Tiers 4, 5, or 6 do not have reliable estimates of MSST; therefore, we cannot evaluate the significance of these effects. This inability to evaluate the significance of the effects occurs for the forage, prohibited, and non-specified species. Since several species or species complexes do not have estimates of abundances-at-age, in this version of the model, their abundance levels simply reflect the most recent estimate. For these groups, analysis of the effects of the example FMPs were limited to catch projections and likely consequences given patterns in related fauna.

Habitat

A quantitative estimate of habitat impact under each example FMP requires an estimate of the fishing effort applied in areas remaining open under each scenario. The amount of effort should take into account the catch levels expected under the alternatives in each TAC management area and the amount of catch taken under the baseline that would have been taken inside and outside the area to be closed by the FMP. Because of the limitations in the multi-species bycatch model, not all species and their area-specific catches are easily explained by the stock dynamics. The impact of alternative-specific management practices on model outputs are also difficult to interpret on detailed area fishery and species scales. While stockwide projections of most major species are more easily understood, catch by TAC management area is required for the effort estimation. The time required to complete a rigorous analysis to validate, and in some cases correct, area-specific catch levels exceeds the time available to prepare this Programmatic SEIS. This necessitated a more qualitative evaluation in this Programmatic SEIS of the expected impacts on habitat based on known fishery characteristics.

Seabirds

The analysis of direct and indirect effects on seabirds relies on the projection model's estimates of fishing effort in mt by different gear types in the BSAI and GOA under the different FMP bookends. Hook-and-line or longline and trawl effort are particularly important for analysis of incidental take. For analysis of FMP 2.1, the projection model’s output essentially eliminates the BSAI longline cod fishery and triples the GOA longline cod fishery, and is based on small price differentials between gear types. This situation is considered an unrealistic artifact of the model's rules for allocating catch between gear types in lieu of specified allocations. For FMP 2.1, the BSAI longliners are assumed to take about the same volume of cod as they have under the baseline conditions, with the balance going to trawl and pot gear. For the GOA, longliners are assumed to take the same percentage of the cod TAC as they had under the baseline, which translated into a moderately higher catch because of the higher TAC. The implications of different spatial/temporal restrictions are also analyzed, especially as they relates to effects on prey availability for nearby seabird colonies and potential for trawling in critical habitat areas of eiders. Other factors that were not modeled, including implementation of seabird protection measures and the potential for a directed forage fish fishery, were also included in the analysis.

Marine Mammals

Results from the multi-species management model are used to analyze the effects of the example FMPs on marine mammal populations. Catch projections from the model are used to estimate incidental take of marine mammals and to evaluate harvest levels of marine mammal prey species. Total projected groundfish catch was averaged from 2003 to 2007 for each example FMP. This average projected catch is multiplied by the incidental take rate, calculated as marine mammal takes/mt of groundfish of each marine mammal species as derived from Angliss *et al.* (2001), to estimate changes in incidental take under each example FMP. The average annual fishing mortality rate (*F*) projected from 2003 to 2007 is compared to the baseline (2002) to determine the change in *F* expected under each alternative bookend for all key marine mammal prey species. Percent changes in *F* relative to the baseline were used to indicate changes in the prey field for affected marine mammal species. These analyses employ unmodified model results as they were reported and, therefore, incorporate all the assumptions that went into the model.

Socioeconomic

The output from the multi-species management model is used as the starting point for development of the socioeconomic impact model, referred to in the remainder of the document as the Sector Model. The Sector Model uses the multi-species management model output of catch of each species by gear in each area. The Sector Model distributes those catches and associated values, as well as income and employment, to the various fishing and processing sectors that depend on the groundfish resources, and to the geographic regions where the activities occur and where factor owners reside. A detailed description of the Sector Model is included in Section 4.1.7.

Ecosystem

The multi-species bycatch model is used to derive indicators for assessing the impacts of the alternatives on the ecosystem. The indicators chosen are ones that would characterize changes in predator/prey relationships, energy flow, and diversity. In predator/prey relationships, model outputs are used to obtain estimates of pelagic forage biomass of target species, such as the walleye pollock and Atka mackerel in the BSAI, and walleye pollock in the GOA. Total biomass of these species is used to derive this index. Bycatch estimates of squid, herring, and the managed forage species group from the model are used as another indicator of the magnitude of fishing impacts on these other forage species. Trophic level of the catch is an indicator of fishing down the food web, which is the sequential fishing down of species high in the food chain, such that over time the fisheries are left only with mid-trophic level species as targets. Model estimates of catch biomass for each target and nontarget species group are combined with estimates of trophic level of each species group, derived from food habits information to obtain estimates of the overall trophic level of the catch for each example FMP. Fishing effects on top predator species are evaluated through model estimates of bycatch of sharks and birds. Model estimates of total retained catch, and discards for target and nontarget species, are used as an indicator of the effects of the alternatives on energy cycling characteristics of the ecosystem through energy removal or total retained catch, and/or energy redirection discards. Finally, model estimates of bycatch of HAPC biota were used as an indicator of effects of fishing on functional structural habitat diversity.

Glossary of symbols used in description of the model

Dimensions

a_{max}	Maximum age used in the model (plus group)
a_{min}	Minimum age used in the model
n_{age}	Number of ages in the model
n_{gear}	Number of gear types for which separate selectivity schedules are used (as in the assessments)
n_{pro}	Number of years to project beyond the initial year in each simulation
n_{sims}	Number of simulations
n_G	Number of gears with allocation constraints
n_{Fsh}	Number of fisheries
n_{sp}	Number of species
n_{area}	Number of management areas defined for each species

Indices

a	Relative age index, $1 \leq a \leq n_{age}$
g	Fishery index, $1 \leq g \leq n_{Fsh}$
k	Sub-area
h	Fishing gear type
t	Projection year index, $1 \leq t \leq n_{pro}$
u	Simulation index, $1 \leq u \leq n_{sims}$
I	Alternative index
j	Species index

Life History and Fishery Parameters

d_h	Proportion of total instantaneous fishing mortality rate distributed to gear *h*
M_a	Natural mortality rate at age *a*
m_a	Proportion of age *a* fish that are mature
w_a	Weight-at-age *a* in the population
p	Proportion of females in the population
$s_{a,h}$	Selectivity of gear type *h* for fish of age *a* (scaled so that max(s)=1)
$w_{a,h}$	Weight of age *a* fish as sampled by gear *h*

Other Parameters and Expressions Used in Projections

SPR	Spawning biomass per recruit
ABC	Acceptable biological catch
TAC	Total allowable catch
OY	Optimum yield summed for the geographical area (e.g., BSAI) for all target (FMP) species
B_{ref}	A parameter of the control rules used to set the overfishing rate and to constrain F_{ABC}
$B_{t,u}$	Spawning biomass in projection year *t* of simulation *u*
C_{2002}	Actual catch observed in 2002 (or projected to be caught)

$C_{t,u}$	Catch in projection year *t* of simulation *u* for each population after the LP
$F_{t,u}$	Fishing mortality rate in projection year *t* of simulation *u* for each population
F_{lim}	A parameter of the control rule used to set the overfishing rate
F_{ref}	A parameter of the control rule used to constrain F_{ABC}
$X_{t,u}$	Fishing mortality rate in projection year *t* of simulation *u* for each population after the LP
$\phi_{a,t,u}$	Total mortality rate between the beginning of the year and the spawning period
$N_{a,t}$	Numbers at age *a* in projection year *t*
$N_{a,t,u}$	Numbers at age *a* in projection year *t* of simulation *u*
n_a	Numbers at age *a* in 2002
$O_{t,u}$	Rate of fishing mortality that constitutes overfishing in projection year *t* of simulation *u*
P	Probability of overfishing in at least one year of the projection period
R_{2003}	Recruitment for 2003 predicted in the 2002 stock assessment
$R_{t,u}$	Recruitment in projection year *t* of simulation *u*
$T_{t,u}$	Total biomass (between ages a_{min} and a_{max}) in projection year *t* of simulation *u*
TAC_{2002}	TAC actually specified for 2002
$X_{t,u}$	Fishing mortality rate that sets catch in projection year *t* of simulation *u* equal to C_{max}
A	Average age for each stock in the final projection year across all simulations
f_k	Proportion of the catch allocated to sub-area *k* for a particular species

Parameters and Expressions

Θ_t	Total objective function value
m_{ABC}	Number of ABC type of constraints (number of species that have TAC)
m_G	Number of gear type of constraints
m_{UL}	Number of upper limit constraints on relative catch of FMP species
m_{LL}	Number of lower limit constraints on relative catch of FMP species
m_{OY}	Number of optimum yield constraints (only one)
A_g	Objective function coefficients applied to each fishery
$C^{N}_{j,k,g}$	Catch data from the blend dataset by species, sub-area and fishery
$R_{j,g}$	Retained fraction of catch
$Y_{t,g}$	Relative total catch between fisheries within each year (main result returned from the constrained optimization)
$V_{j,g}$	Estimated ex-vessel value of each species within different fisheries

Computation of SPR values

SPR values are computed using species-specific demographic values (see www.fakr.noaa.gov/sustainablefisheries/seis/data), fishing mortality rates (e.g., $F^{y}_{40\%}$) that would reduce the female spawning stock (per recruit) to some fraction of the unfished level. The age-specific factors are selectivity, natural mortality, maturity, and weight or fecundity. For example, to compute $F^p_{40\%}$, an algorithm to solve the following set of implicit equations was used:

$$0.4B^p_{100\%} = \sum_{a=1}^{n^o_{ages}-1}\left[w^p_a m^p_a \prod_{j=2}^{a} e^{-\left(M^o_{j-1}+F^p_{40\%}s^o_{j-1}\right)}\right] +$$
$$w^p_{n^o_{ages}} m^p_{n^o_{ages}} \prod_{j=2}^{n^o_{ages}} e^{-\left(M^o_{j-1}+F^p_{40\%}s^o_{j-1}\right)}\left(1-e^{-M^o_{n^o_{ages}}-F^p_{40\%}s^o_{n^o_{ages}}}\right)^{-1}$$

where $B^p_{100\%}$ corresponds to the spawning stock per recruit of population *p* in an unfished equilibrium state. This information was used within the management rule that determines the quota. For some species and alternatives different F-spr rates were used.

4.1.6 Habitat Impacts Model

To evaluate the impacts of fishing on living habitat, the model developed by Fujioka (2002) is used. This model incorporates basic factors determining impacts of fishing on habitat. Given either estimated or assumed values of fishing intensity, where *f* equals the absolute effort in area swept per year divided by the area size, q_H equals sensitivity of habitat to fishing effort, ρ equals habitat recovery rate, the model predicts a value of equilibrium (i.e., long-term) habitat level, H_{eq}, as a proportion of the unfished level, H_0.

$H_{eq} = H_0 \cdot \rho\, S/(I + \rho\, S)$ where H_0 = unfished habitat level, $I = f\, q_H$, and $S = e^{-1}$.

Habitat impact or effect level, *E*, for the given effort, sensitivity, and recovery rates, would be 1- H_{eq}. Letting H_0 = 1.0, then

$E = I/(I + \rho\, S)$

Various habitat features could be impacted by fishing gear. Initially, this analysis focused on the impact to the biostructure habitat feature of living habitat composed of organisms such as soft corals, tunicates, and sponges with assumed recovery rates of 2 to 15 years. Where applicable, we attempted to address impacts to living habitat with slower recovery rates (i.e., 200 years), such as gorgonian corals (e.g., red tree coral, Primnoa). A widely accepted management policy has been to avoid impacting such long-lived organisms.

Habitat Sensitivity Rate (q_H)

The habitat sensitivity rate, q_h, is the proportion of habitat impacted by one pass of the fishing net. Organisms considered as indicators of habitat sensitivity range from relatively small and flexible (soft corals) to larger, more erect organisms (sea whips). Vulnerability of the organisms varies greatly depending on their physical characteristics and the characteristics of the trawl gear. The vulnerability may be difficult to determine. Certain features of the gear may make the gear more damaging to one type of organism than to another type. For biostructure sensitivity to bottom trawl gear, two values of q_H, 0.10 for less sensitive, and 0.25 for more sensitive, are proposed as plausible.

Habitat Recovery Rate (ρ)

Recovery rate, ρ , reflects the rate at which impacted habitat changes back into unimpacted habitat, H. In the absence of further impacts, impacted habitat would decrease exponentially with all habitat was in H the unimpacted condition. The recovery time, R, can be thought of as the average amount of time the impacted habitat stays in the impacted state, which would equal 1/ ρ in the absence of further impacts.

Little is known about the recovery rate of various benthic organisms that provide biostructure in waters off Alaska. The recovery rate as modeled includes any recruitment required to initiate recovery and the growth necessary to reach a size that can to provide habitat function. Recovery times as much as 15 (=1/ρ) years are within a plausible range. For this analysis, two biostructure recovery rates are used to cover a plausible range of impact. Scenario 1 is where ρ = 0.5 the 2-year or rapid recovery, and Scenario 2 is where ρ =.0667, the 15-year or long recovery. Table 4.1-25 shows the corresponding impact given levels of fishing intensities. For example, for f = 0.25, where the bottom area is swept once every four years, for ρ = 0.50, when habitat recovers in 2 years, and for a sensitivity rate q_H = 0.10, where one-tenth of the organisms are removed per sweep of the net, the long-term impact level, E, would be 0.049. That is, the habitat would be reduced slightly to 95.1 percent (H_{eq}) of its unfished level. If recovery rate ρ = 0.067, where habitat recovers in 15 years, and sensitivity q_H =0.25, where one-fourth of the organisms are removed per sweep of the net, the impact level would be 0.499, or 50.1 percent of its unfished level. This demonstrates that as f increases, impact level also increases, and the equilibrium level of habitat decreases.

Fishing Effort or Intensity (*f*)

Bottom trawl fishing effort has been estimated for each 5 kilometer (km) square block in the BSAI and GOA regions by Rose and Jorgenson (2002). Fishing intensity of a block is the fishing effort per year measured in area swept.High quality fishing effort data are available from the groundfish observer program. Individual sets were tallied for 5 x 5 km blocks for the years 1998 to 2002. This 5-year period was selected to represent the current level of fishing effects. Reported effort or duration for trawls was converted into swept areas. Trawl durations were multiplied by speed, trawl width, and proportion of effort on the bottom. Width and speed were estimated using a survey of trawlers on gear usage and from information collected by observers. The estimate for the proportion of pelagic trawl effort contacting the seafloor considered both the amount of time in which any part of the trawl contacted the seafloor and the width of trawl contact with the seafloor during different periods of the fishery (e.g., day/night, A and B seasons). Information for this estimate was provided by fishing organizations. As the vulnerability of pelagic trawls to damage precludes their operation on rough and hard substrates, bottom contact was set at zero for the hard bottom habitats of the GOA and Aleutians Islands.

Habitat Impact (*E*)

Impact is a function of sensitivity, recovery rate, and fishing intensity. For the given values of sensitivity q_h, recovery rate ρ, and bottom trawl fishing intensity *f* estimated for each 5 x 5 km block, habitat impact, $E_i = I_i/(I_i+\rho S_i)$, can be calculated for the 5 x 5 km block represented by the *I* parameter. Larger values of *E* equate with more impacts. Results for a region can be presented in a single value as a mean impact, as frequency distribution of impacts for each block, and as the geographic distribution of the impacts.

A draft report by Rose (2002) describes a proposed approach to quantifying impacts using the function = $(\sum E_i \cdot \text{Area}_i) / (\sum \text{Area}_i)$ summed over all area in waters less than 1,000 meters (m) deep (i.e, fishable EEZ waters). This is a single-valued metric which provides for simplified comparisons and evaluations. Ideally, any area summations would be weighted by habitat quantity and value as well, but such information is currently unknown and is set at 1.

In the analysis for this Programmatic SEIS, rather than summing the estimated impact block by block, the fishing intensity for each block is tabulated by intensity intervals, as shown in Table 4.1-26. For example, in the Bering Sea, 1,003 blocks were fished at an intensity level between 0.25 and 0.50, 822 blocks watershed at an intensity level between 0.50 and 1.00, and so forth. This information can be used to estimate the mean relative impact level for all the fished blocks, or for all fishable blocks (<1,000 m). This is approximated here by summing the frequency weighted midpoint impact levels and dividing by the number of fished blocks or number of fishable blocks. For example, for ρ=0.50 and q_H=0.10, the impact level for f=0.25 is 0.049, and for f = 0.50 is 0.095, with a midpoint of 0.072. The frequency weight of the interval 0.25 to 0.50 is 1,003. The interval midpoint impact levels are weighted and summed and divided for the Bering Sea by either 7,121 (number of fished blocks) or 31,995 (number of blocks <1,000 m in depth). For the more slow growing and more sensitive parameter scenario, the mean impact of fished areas is 0.419 and 0.093 for all fishable blocks.

This approximation should produce mean impact levels similar to the more exact computation method demonstrated in a report by Rose (2002). Ideally, any area summations would be weighted by habitat quantity and value as well, but such information is currently unknown and neither computation takes into account differences in the unfished level of biostructure habitat or habitat suitability that probably exist. This is a single-valued metric, which provides for simplified comparisons and evaluations. If all habitat over the fishable EEZ is of equal value to the productivity of the fisheries, then the simple mean impact estimates are indicative of the baseline fishing impacts. However, when summed over such broad categories of habitat, the mean impact value may not reflect effects if impacts are concentrated on specific habitat types, because not all habitat may be of equal value to stock productivity. Comparing impact expressed as a single value presumes that the value of different levels of impacts is additive. That is, two units of habitat each impacted to H_{eq} = 0.75 (E = 0.25) are equivalent to two units of habitat, one heavily impacted to H_{eq}=0.50 (E = 0.50) and one unimpacted at H_{eq} = 1.0 (E = 0.0). Thus, the average impacts are equal in both cases, but the actual effect on the ecosystem may not be equivalent. One could argue that all else being equal, the latter case provides a wider range of habitat type and greater diversity over the same amount of habitat and is preferred over a uniform distribution of impact. In contrast, if H_{eq} only needs to be greater than 0.5 to be effective EFH, the former case would be preferred. Whatever the case may be, comparison of the frequency distribution provides increased discernment of potential impact. Thus, the distribution of the impacts needs to be considered.

Mean impact levels were assessed in conjunction with the distribution information to further evaluate the baseline. While the mean impact values could be considered to indicate minor impacts, the distribution information shows that for the Bering Sea, for example, 552 + 277 = 829 blocks, or more than 8,000 sqare miles, are fished at an intensity of f = 1.00 or greater (Table 4.1-26). A map of the fishing distribution (Figure 4.1-10) shows that the heavily fished blocks are concentrated in a few large geographically extensive areas that are uninterrupted by any current fishing closures that might provide protection to or diversity in impact levels. The impact model estimates that those areas could have an impact level to bioshelter organisms of 18.1 percent or greater for the fast recovery rate parameter scenario, or as much as 82.8 percent for the slow recovery rate/more sensitive scenario. Concern for areas where such potential impact could be occurring is a major consideration in the evaluation of the baseline and comparison of the alternatives.

General results using the habitat model are used qualitatively to evaluate the closure strategies of the alternatives. The rates of relative change of catch and impact can be examined by combining the habitat impact model with standard fishery catch models. In general, closing large amounts of heavily fished areas may not result in significant reduction in net habitat impact, as large amounts of fishing effort are displaced. This results in increased impact levels in previously less heavily fished area. Such a large change in the system has high potential for unforeseen consequences. A strategy of closing only lightly fished habitat reduces further impact in those areas while displacing only moderate amounts of effort to heavier fished areas. An increase of effort in already heavily fished habitat increases habitat impact relatively less than an increase in lightly fished habitat. Such a strategy, however, does not address potential ongoing impacts in heavily fished areas. A strategy of closing only small proportions of heavily fished habitat and larger proportions of lightly fished areas can achieve similar or greater reductions in impact with only moderate increases in effort in the remaining open areas. With closures positioned appropriately, this strategy can protect a cross-section of habitat types and address the potential impacts of heavily fished habitat while minimizing economic effects and the chances of unforeseen consequences.

4.1.7 The Sector Model–An Adaptation of the Multi-Species Model To Estimate Socioeconomic Effects

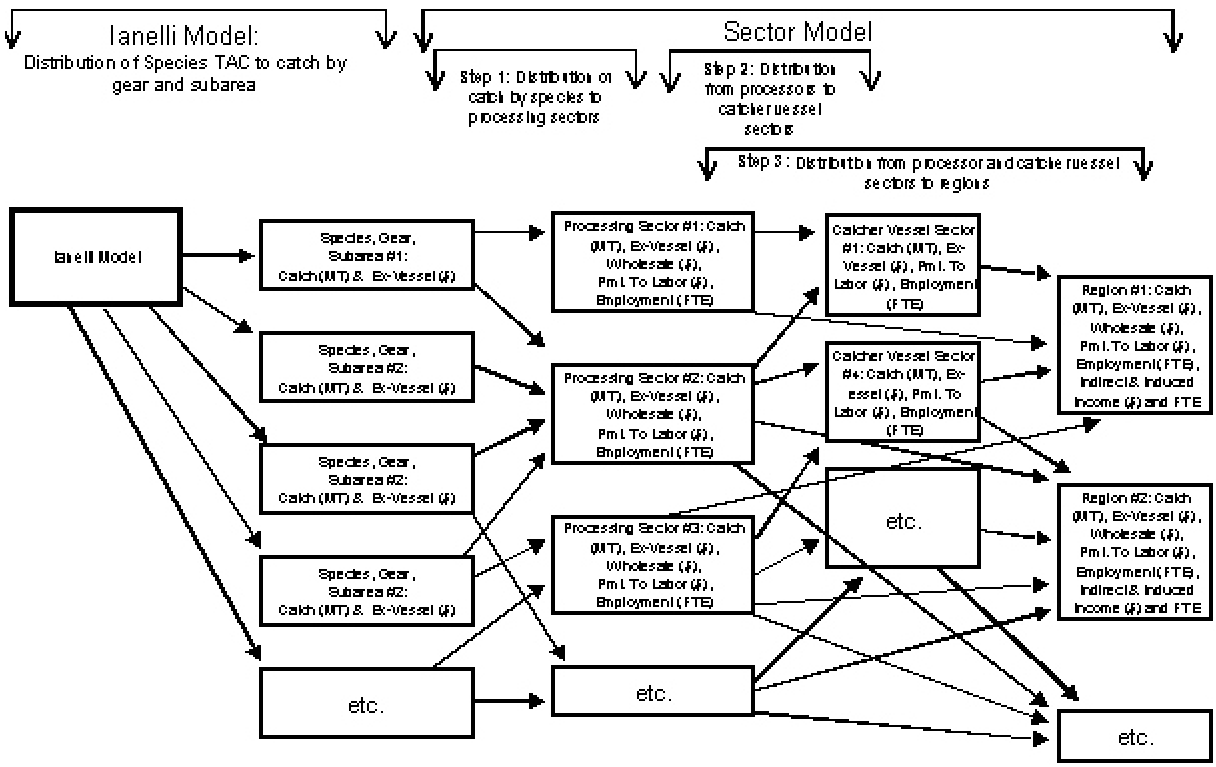
The socioeconomic impacts of the alternatives have been estimated using an extension of the multi-species model based on the harvesting and processing sectors and regions described in Sections 3.9 and 3.9.3. For the remainder of this discussion, the socioeconomic model extension is referred to as the sector model. The sector model applies 2001 harvest and processing proportions to the multi-species management (Ianelli) model output related to species catch by gear and subarea in order to estimate the distribution of catch and processing amounts among sectors and regions that rely on the groundfish fishery. A schematic representation of the linkages between the two models is shown below.

The sector model entails the following three-step process:

1. Estimate total catch and deliveries to processors.
2. Proportion out deliveries to specific catcher vessel sectors.
3. Distribute catches and processing amounts among the various regions where processors are located or vessel owners reside.

In each step of the sector model, the catch of each species by gear and subarea gets distributed to successive sectors based on the comparative baseline distribution in 2001.

The steps of the sector model can best be illustrated by providing a specific example. The multi-species management (Ianelli) model estimates that 1,472,600 mt of pollock will be harvested from the Bering Sea with trawl gear in 2003 under FMP 1. In step 1 of the sector model, this pollock is distributed to each processor sector according to the proportion of the total 2001 Bering Sea trawl pollock catch that the individual sector processed, including discards. In addition to total catch, the model uses 2001 information on each sector's retention percentage, wholesale value per round ton, payments to labor per dollar of wholesale product value, and full time equivalent (FTE) employment. These numbers are taken from the comparative baseline data presented in Section 3.9.9. Table 4.1-27 shows the 2001 conditions and how they are applied to generate the 2003 sector estimates for FMP 1. The results from Step 1of the sector model are used to estimate the direct economic impacts of the alternative FMP bookends on the various processing sectors.



As shown in the upper portion of the table, surimi trawl catcher processors caught 35.3 percent of the 2001 pollock trawl harvest from the Bering Sea and retained 99.8 percent of their catch. In the lower portion of the table, 35.3 percent of the 1,472,600 mt Bering Sea pollock trawl total under FMP 1 in 2003 is assigned to the surimi trawl catcher processor sector. The table also shows that 99.8 percent of the 519.3 mt of groundfish caught was retained. Assuming a wholesale product price of $604.4 per ton, the 2003 estimated wholesale product value for surimi trawl catcher processors is $313.8 million, with an estimated 35 percent ($109 million) of that be paid to labor. Employment generated by this sector is estimated to be 1342.8 FTEs, or 4.3 FTEs per million dollars of wholesale product value. A similar process is used to estimate the economic effects on other processing sectors.

Step 2 of the sector model distributes each processing sector's total retained catch amount back to the catcher vessels that delivered it, based on the proportion of each processing sector's deliveries from catcher vessel sectors in 2001. The analysis developed for each species, gear, and subarea, a processor sector/catcher vessel sector distribution matrix based on 2001 deliveries. The matrix for the Bering Sea trawl pollock sector is shown in Table 4.1-28. The table includes deliveries of catcher vessels to surimi and fillet catcher processors, inshore processors, and motherships. Although catcher vessels delivered only a relatively small amount of fish to surimi and fillet trawl catcher processors, they provided all the fish processed by other processing sectors. For example, the row for Bering Sea pollock shore plants indicates that 61.5 percent of their Bering Sea trawl pollock was delivered by Bering Sea pollock trawl catcher vessels greater than or equal to 125 ft, while Bering Sea pollock trawl catcher vessels 60 ft to 125 ft in length delivered 34.8 percent of the pollock catch. The remaining 3.6 percent was delivered by diversified AFA-eligible trawl catcher vessels greater than or equal to 60 ft and non-AFA trawl catcher vessels greater than or equal to 60 ft. The various catcher vessel sectors are defined and discussed in detail in Section 3.9.2.

The percentages, like those in Table 4.1-28, are multiplied by the total catch for the species gear and subarea for each processor to generate the total retained catch assigned to each catcher vessel sector for the FMP bookend and year. Ex-vessel prices and payments to labor and employment factors are applied to retained catches to generate the remaining catcher vessel sector indicators. Table 4.1-29 illustrates this process with numbers for the Bering Sea trawl pollock sector for FMP 1 in year 2003.

The third step of the sector model translates sector level activities to regional activities. This step is complex because the various sectors interact with regions in different ways, as described below:

- **Shore-Based Processors:** The sector model assumes that shore-based processors are closely related to the regions in which they are located. In fact, the shore-based processors are designated according to their associated region. Two exceptions are the Bering Sea Pollock Shore Plants, which are assigned to the Alaska Peninsula/Aleutian Islands region, and the Other States Shore Plants, which are assigned to the Washington inland waters region (most are located in Bellingham, Washington). The sector model assumes that ex-vessel values attributed to shore-based processors are directly linked to the region in which they are located through fish taxes. Further, the sector model assumes that all labor payments and employment generated by shore-based processors accrue within the region in which they are located.[1] This method of assigning employment to regions is similar to that used by state and federal agencies. Insufficient information exists to provide a more accurate account of regional employment patterns in the groundfish fisheries. Finally, the sector model assumes that the expenditures of shore-based processors for deliveries of raw fish and other supplies, as well as the expenditures of their employees, have indirect and induced impacts within the region in which they are located.[2]

[1] The method of assigning employment to regions used in this analysis does not attempt to account for the formal or legal residency of workers in shore-based processors. For example, the labor force of many of the shore plants in Alaska, especially those in the Alaska Peninsula and Aleutian Islands region (defined in Section 3.9.2.4), have been traditionally dominated by persons considered non-residents or relatively short-term residents of Alaska communities or the state. In part, residency is a matter of definition, as community population count varies by information source. U.S. Census methodology, for instance, counts every person present at the time of enumeration as part of the official population of the community, with very few exceptions. Additional information on workforce demographics and the role that transient processing workers play in the groundfish fishing industry and communities can be found in Section 3.9.6.

[2] Another shortcoming of the sector model is that it is unable to track expenditures of processors and catcher vessels in other regions. For example, many of the shore-based processing plants have headquarter offices in Seattle, and clearly some of their expenditures are made in the location of their headquarters. Further, because many of the employees of shore-based plants are seasonal, they are likely to spend most of their earnings in their hometowns.

- **At-Sea Processors (Catcher Processors, Motherships, and Floating Processors):** The sector model assumes that an at-sea processor generates most of its regional impacts in the region represented by the vessel owner's address as listed in Commercial Fisheries Entry Commission vessel registration files or NOAA Fisheries Federal permit data. Typically, the location of the corporation that coordinates the operations of the vessel is listed. Consequently, the model assumes that crewmembers on a catcher processor or other at-sea processor are hired from the same region in which the vessel's operations are coordinated.[3] Although this method of assigning employment to regions is similar to that used by state and federal agencies, it is recognized that this is a simplification, as vessels (and corporations) may have complex ownership structures that influence various operational parameters, including point-of-hire employment decisions.[4] As noted above, insufficient information exists to provide a more accurate account of regional employment patterns in the groundfish fisheries. Other economic impacts, such as those resulting from purchases of equipment and supplies, are also assumed to accrue to the vessel owner's region.

- **Catcher Vessels:** In order to be consistent with the way in which at-sea processing employment is assigned, catcher vessel employment is assigned to the region represented by the vessel owner's address as listed in Commercial Fisheries Entry Commission vessel registration files or NOAA Fisheries Federal permit data.[5] catcher vessels affect regions by making deliveries to processors and providing earnings for their returning owners and crew to spend in the region. When these vessels make deliveries to processors located outside of the region, they bring their outside earnings into their home region when they return. However, when catcher vessels make deliveries to local processors, their earnings are already counted as expenditures by the local processors. Therefore, it is important to track not only the catcher vessels' home regions, but also the locations where they delivered fish. The sector model assumes that all vessel owner and crew income contributes to the regional economy, but, to avoid double counting, only the income from landings made outside the region is used to calculate indirect and induced income and employment.

A matrix showing the home regions of vessels participating in the pollock trawl fishery in 2001 in shown in Table 4.1-30. Similar matrices were developed for each species, gear, and area combination.

Multiplying the numbers in the regional matrix in Table 4.1-30 by the catches by sector (Table 4.1-27 for at-sea processors and Table 4.1-29 for catcher vessels) yields the regional apportionment of Bering Sea trawl

---

[3] The method of assigning employment to regions used in this analysis does not attempt to account for the formal or legal residency of workers in the at-sea processing sector.

[4] As one example of this complexity, the western Alaska CDQ program has created many seasonal job opportunities for residents of eligible Alaska communities aboard catcher processors as a result of CDQ investment in this sector, among other factors. Beyond employment considerations, additional information regarding the importance of CDQ program-related investments and industry partnerships in increasing the participation of Alaska residents in the groundfish fisheries, especially those in Alaska Native communities, is provided in Section 3.9.4.

[5] The method of assigning employment to regions used in this analysis does not attempt to account for the formal or legal residency of workers aboard catcher vessels. For example, some of the catcher vessels owned by residents of the Washington Inland Waters Region (WAIW) region (defined in Section 3.9.2.4) that frequently berth in Alaska ports may hire residents of those ports. Moreover, as in the case of the at-sea processing sector, complex corporate ownership structures may influence vessel operational patterns, including crew employment decisions.

pollock catches for 2003 from FMP 1 (as shown in Table 4.1-31). A similar process is used to assign catches of other species, gears, and areas to regions for other years and for other FMP bookends.

The next step in estimating regional effects of catcher vessels involves distinguishing in-region deliveries and extra-regional deliveries. In-region deliveries are defined as deliveries to processing facilities assigned to the same region to which the catcher vessel is affiliated. For example, when a vessel owned by a resident of Kodiak makes a delivery to a Kodiak shore plant, it is considered an in-region delivery. When that same boat makes a delivery to an Alaska Peninsula/Aleutian Islands shore plant, it is considered an extra-regional delivery. It should be noted that at-sea deliveries are considered in-region ,if the both the owner of the catcher vessel and owner of the at-sea processor are from the same region. As indicated earlier, the regional effect of catcher vessels making an in-region delivery are counted as part of the regional shore-based processor effects, while the regional effects of extra-regional deliveries are assigned to the catcher vessels. Table 4.1-32 shows the 2003 value of in-regional and extra-regional deliveries of Bering Sea trawl pollock by the catcher vessel sectors for FMP 1.

The sector model's final step calculates and assigns income and employment multipliers for each region. The multipliers relate total output in dollars from the fishing sector in a region to the additional indirect and induced income and employment that are generated. Part of this additional income and employment occurs in the businesses whose goods and services are used as inputs in the groundfish fisheries, such as fuel suppliers, chandlers, gear manufacturers, boatyards, and insurance brokers. These firms are commonly referred to collectively as the support service sector of the fisheries. Moreover, people earning incomes directly or indirectly from the fisheries make expenditures within the economy as well, generating additional jobs and income. These indirect and induced economic benefits can be substantial, especially for regions such as the WAIN region. The multipliers used in this analysis are estimated with IMPLAN Version 2.[6] The IMPLAN software was used to create an input-output model for each region considered in the analysis. The input-output model is a mathematical representation of the inter-industry/institution transactions that occur within a defined economic region. The model traces how many times a dollar is re-spent within the regional economy before leaving the region, and the economic impact of each round of spending. The economic base concept was used to determine the level of aggregation of the more than 200 economic sectors that have backward linkages to the fishing sector in the regions considered. The multipliers for these economic base sectors or aggregated sectors were generated from IMPLAN, and were used to determine the additional income and employment effects, or secondary effects, that the fishing sector contributes to each region. Table 4.1-33 shows the regional multipliers used in the analysis.

It is important to note that the sector model does not directly estimate inter-regional linkages. For example, the model does not specifically include income and employment resulting from expenditures of at-sea processors in regions outside of a vessel owner's region. While it is recognized that there are inter-regional effects, the data necessary to reasonably estimate those effects are not available. It is also important to note that the lack of inter-regional effects is offset to some extent by the assumption that all of the employment and income effects of a shore-based processor occur within the region in which the processor is located.

An example of the tables used in the regional effects assessment is provided in Table 4.1-34. The example shows the effects of the Bering Sea pollock trawl fishery on the Alaska Peninsula/Aleutian Islands region for FMP 1 and 2003.

---

[6] 1999 IMPLAN baseline data, which are the most current available, were used to estimate the multipliers.

4.2 Introduction of Analytical Framework – Example Fishery Management Plans

Four policy alternatives and a preferred alternative are analyzed in this document. In order to provide sufficient detail to the analysis of the policies, each alternative is accompanied by, and associated with, a set of example FMPs. A description of the framework concept, followed by a summary of each alternative policy and their associated FMPs, is provided below.

4.2.1 Concept of the Analytical Framework

Each alternative is composed of three elements: a management approach statement that describes the goals, rationale, and assumptions behind the alternative; a set of management objectives that complement and further refine the goals set forth in the management approach; and, except for Alternative 1 (status quo), a pair of example FMP bookends that illustrate and frame the range of implementing management measures for that alternative. The management approach statement and objectives serve to define the direction the NPFMC and NOAA Fisheries wish to take in the managing the fisheries. The example FMP bookends serve two purposes: first, they provide an additional level of analytical detail that will facilitate the comparison of the physical, biological, and socioeconomic effects of the alternatives and the status quo; second, they provide the public with an illustration of the types of management measures the NPFMC and NOAA Fisheries envision using to achieve the goals of the alternative. The preferred alternative identified in this document includes a policy statement accompanied by a set of management objectives and a set of example FMP bookends that illustrates a range of management actions for that policy. This FMP framework structure communicates to the public how NPFMC and NOAA Fisheries intend to pursue their policy objectives in the future. By providing a range of potential management measures (as illustrated by the example FMP bookends as part of the preferred alternative), management flexibility is maintained under the MSA to adaptively manage the fishery through FMP amendments.

4.2.2 Description of the Example Fishery Management Plan Frameworks

Alternative 1 – Continue Under the Current Risk-Averse Management Policy

Under Alternative 1, the groundfish fisheries would continue to be managed based upon the present risk-averse policy. Alternative 1(a) represents the policy language currently stated in the FMPs, dating from 1979 and 1985 for the BSAI and GOA FMPs, respectively (see Section 2.6.1 for the full text of the alternative). These policies, based on the best scientific information available, avoid irreversible or long-term adverse effects on fishery resources and the marine environment, while at the same time providing for optimum yield.

Alternative 1(b) is a substitute for the written policy language in the current FMPs that would include objectives that specifically address the variety of concerns that are balanced in current management considerations (see Section 2.6.2 for the full text of the alternative). Alternative 1(b) encapsulates a risk-averse conservation and management program that is based on a conservative harvest strategy. This policy assumes that fishing does result in some adverse impacts to the environment, and as these impacts become known, mitigation measures will be developed and appropriate FMP amendments will be implemented.

FMP 1 (Current BSAI and GOA Groundfish FMPs)

Alternative 1(a) and 1(b) policies are both represented by FMP 1, which is the current fisheries management program for the BSAI and the GOA and incorporates management measures approved by the NPFMC through the June 2002 meeting. FMP 1 is described in full in Table 4.2-1.

In the current FMPs, the TAC is determined annually based on a conservative harvest strategy that calculates the OFL and the ABC for each managed stock or stock complex. The current FMPs specify the OFL and maximum ABC (max_{ABC}) by means of a six-tier system, wherein the amount and quality of information available for a given stock or stock complex determine the formula that is used to define F_{OFL} and max F_{ABC} (Tiers 1-5) or OFL and max_{ABC} directly (Tier 6). Most stocks are currently managed under Tier 3, where max F_{ABC} equals $F_{40\%}$ if biomass is above $F_{40\%}$. Precautionary adjustments are made, including decreasing F_{OFL} and F_{ABC} linearly with biomass whenever biomass falls below a tier-specific reference level, but only Tier 1 stocks include an uncertainty variation in max_{ABC}. The status of each stock in Tiers 1 through 3 is also examined annually with respect to the MSST, as defined in the National Standard Guidelines.

OY is specified in the current FMPs as a range that is aggregated across all stocks and does not vary with biomass. The current FMPs require the sum of the individual groundfish TACs to fall within the OY range. In the BSAI, the high end of the range, 2 million mt, acts as a cap on the TACs, as the aggregated ABCs regularly exceed this limit. In practice, although it is not required in the current FMPs, TACs are never set higher than the corresponding ABCs. Taking into account the ecosystem considerations of the food web, the current FMPs also prohibit directed fishing for forage species.

Through amendments over the last twenty years, the current FMPs have built up a network of spatial/temporal closed areas intended to protect resources of concern, as well as to minimize gear conflicts. In the BSAI, various areas around the Pribilof Islands and in Bristol Bay are closed year-round to trawling in order to protect red and blue king crab habitat, and there are chinook and chum salmon areas that are closed seasonally. Also in the BSAI, waters within 12 nautical miles (nm) of the Walrus Islands are closed to groundfish fishing to minimize disturbance near walrus haulouts. In the BSAI and the GOA, areas within 3 nm of Steller sea lion rookeries are permanently closed to fishing. Additionally, Steller sea lion protection measures impose trawl prohibitions within 10 to 20 nm of all rookeries and haulouts and prohibit fishing in Seguam Pass. In the GOA, trawling is prohibited in southeast Alaska west of 140°W longitude. Also, a 2.5 square nm (nm^2) area designated as the Sitka Pinnacles Marine Reserve in the GOA is closed to groundfish fishing to protect habitat for rockfish and lingcod (Figure 4.2-1).

The current BSAI FMP prohibits directed fishing for pollock with non-pelagic trawl gear. There is no similar restriction on pollock trawling in the current GOA FMP. Directed fishing for sailfish with longline pot gear is prohibited in the GOA. Non-pelagic trawling is prohibited in the Bristol Bay Red King Crab Savings Area in the BSAI and in the Cook Inlet in the GOA. Additionally, various areas around Kodiak Island are closed to non-pelagic trawling either year-round or seasonally to protect crab stocks (Figure 4.2-1; specific details on the FMP 1 map illustration are provided in Section 4.2.3).

Groundfish fisheries in the BSAI and GOA are required to discard any incidental catch of halibut, salmon, crab, herring, or Steelhead trout, known collectively as prohibited species. The FMPs currently set PSC limits on many of these species, with penalties ranging from closure of a particular zone or of the whole management area to closures of a directed fishery or fisheries for a specified season or for the remainder of the year. In the BSAI FMP, stairstep-based limits (i.e. the catch limit varies based on stock abundance) for trawl bycatch within specified zones are set for red king crab and C. bairdi crab. The BSAI FMP also specifies an absolute trawl catch limit for chinook salmon and "other salmon" within specified zones. Once the apportioned PSC limit for a trawl fishery is reached within a zone, the fishery is prohibited from fishing within that zone. The BSAI FMP specifies a trawl catch limit for herring in the BSAI at one percent of annual biomass. Catch limits on C. opilio crab and halibut bycatch in the BSAI are established in regulation. The C. opilio catch limit applies to a specified zone and is based on an adjusted percentage of biomass that must fall within a certain range. The halibut catch limit is a BSAI-wide limit measured in mt and is based on halibut mortality. In the GOA FMP, catch limits on halibut bycatch are authorized and set by the NPFMC as part of the annual procedure for setting groundfish harvest levels. There are no other PSC limits set in the GOA.

Other bycatch reduction measures are required under FMP 1. The Improved Retention/Improved Utilization (IR/IU) program requires that vessels fishing for groundfish fully retain all pollock and Pacific cod fit for human consumption, as well as fully utilizing the two species by inshore processors. A minimum utilization standard of 15 percent is set for all at-sea processors. The NPFMC is also adopting a policy to require full retention of demersal shelf rockfish by hook-and-line and jig vessels in the Southeast Outside District of the GOA. A Vessel Incentive Program (VIP) encourages bycatch reduction by setting bycatch reduction standards biannually. Vessels that fail to meet these standards can be penalized. Inseason bycatch management measures establish fishing seasons for bycatch management and give the NOAA Fisheries, Alaska Regional Administrator the authority to close areas with high bycatch.

The Reasonable and Prudent Alternative (RPA) measures adopted from the most recent USFWS biological opinion on the short-tailed albatross stipulate the use of certain seabird avoidance measures and require that the take of more than four short-tailed albatross within 2 years trigger consultation with the USFWS and the potential closure of fisheries. To further reduce the possibility of the fisheries' take of albatross, the NPFMC in 2001 required all longline vessels to adopt more stringent seabird avoidance methods.

A Licence Limitation Program (LLP) for groundfish vessels over 32 ft in length (with certain jig gear exceptions) and a moratorium on entry into the groundfish fisheries is in place for the BSAI and the GOA. An IFQ program is in place for sablefish in the BSAI and GOA, which includes provisions for community purchase of quota share. In the BSAI, the directed fishery for pollock is organized into cooperatives as authorized under the AFA. A multi-species CDQ program apportions 7.5 to 10 percent of all BSAI groundfish quota to 65 eligible western Alaska communities.

FMP 1 monitors the groundfish fishing effort through federal and state reporting requirements and through the use of the North Pacific Groundfish Observer Program. All vessels between 60 ft and 125 ft in length are required by regulation to have an observer on board 30 percent of the time; for vessels over 125 ft in length this increases to 100 percent. For AFA and CDQ catcher boats greater than 60 ft in length, one observer must be on board at all times, and for catcher processors and motherships, two observers must be on board at all times. The program also requires observers at inshore processing plants. An additional monitoring tool is the reporting requirements for BSAI and GOA vessels to submit daily or weekly logbooks that include information on the composition of catch and the locations of the hauls. The ADF&G also collects data from fish tickets at the point that catch is sold. Mandatory Vessel Monitoring Systems (VMS) verify vessel locations for all directed Atka mackerel, pollock, and Pacific cod fishing.

Alternative 2 – Adopt a More Aggressive Harvest Management Policy

Alternative 2 would maximize biological and economic yield from the resource while still preventing overfishing of the groundfish stocks. Such a management approach would be based on the best scientific information available, would take into account individual stock and ecosystem variability, and would continue to work with other agencies in protecting threatened and endangered species. A more aggressive harvest strategy would be implemented based upon the concept that the present policy is overly conservative and that larger harvests can be taken without overfishing the target groundfish stocks. This policy assumes that fishing at the recommended levels would have no adverse impact on the environment, except in specific cases that are known and mitigated. For the full text of the alternative, see Section 2.6.3.

Example FMP 2.1

Example FMP 2.1 illustrates a more aggressive harvest strategy than Alternative 1 by removing many of the existing constraints from the fisheries. Example FMP 2.1 is described in full in Table 4.2-1. As the policy is based on an assumption that the impacts of fishing on the environment are generally known and mitigated, the precautions currently built into the existing TAC-setting process would be alleviated. The buffer between the ABC level and the OFL would be removed, and the maximum OY for the groundfish stocks in the BSAI would be released from its 2 million mt cap and allowed to float as the sum of the OFLs for the BSAI groundfish stocks. Additionally, example FMP 2.1 removes the precautionary element included in the current FMPs that decreases F_{ABC} linearly with biomass when the biomass falls below a specific reference level.

Example FMP 2.1 would also remove physical constraints from the fisheries by repealing the various closure areas currently in place. The fishery would be returned to an open-access scenario, where time and area closures, gear restrictions, and prohibited species catch restrictions are repealed. The potential impact of the groundfish fisheries on Steller sea lions, however, means that the current mitigating suite of protection measures that constrain fishing around rookeries and haulouts and protect Steller sea lion prey species (pollock, Pacific cod and Atka mackerel) when at low biomass levels would remain in place (Figures 4.2-2 and 4.6-1; specific details on the example FMP 2.1 map are provided in Section 4.2.3). This is required by the ESA to avoid determinations of jeopardy and adverse modification to Steller sea lions. The same applies to the impact of groundfish fishing on short-tailed albatross, where the current take limits would remain in effect.

The federally-mandated effort limitation program for the directed BSAI pollock fishery, enacted under the AFA, would remain in place, with its accompanying CDQ allocation, but all other effort limitation programs (such as the sailfish IFQ program and the multi-species CDQ program) would be repealed. Reporting requirements would remain in place, but the observer program, except as federally mandated by the AFA, would be repealed, as would VMS requirements.

Example FMP 2.2

A more moderate illustration of Alternative 2, example FMP 2.2, also represents a more aggressive harvest strategy than Alternative 1. Example FMP 2.2 is described in full in Table 4.2-1. In this case, the mechanisms for setting ABC and TAC remain the same as in the current FMPs (see FMP 1 for further detail), but the existing regulatory capped maximum OY of 2 million mt in the BSAI would be removed in favor of a maximum OY equaling the sum of individual groundfish ABCs in the BSAI. Additionally, bycatch reduction incentives and bycatch restrictions would be repealed, other than those related to PSC limits or IR/IU. Under the assumption that fishing does not have an impact on the environment other than what is generally known and mitigated, the more stringent seabird avoidance measures enacted in 2001 would be repealed, leaving only the mitigation measures recommended by USFWS to avoid jeopardy or adverse modification for short-tailed albatross. Closure areas in example FMP 2.2 are the same as those in FMP 1 (Figure 4.2-3; specific details on the example FMP 2.2 map are provided in Section 4.2.3).

Alternative 3– Adopt a More Precautionary Management Policy

Alternative 3 would seek to increase the existing precautionary management measures through community or rights-based management, ecosystem-based management principles, and, where appropriate and practicable, increased habitat protection and additional bycatch constraints. Under this approach, additional conservation and management measures would be implemented as necessary to respond to social, economic or conservation needs, or if scientific evidence indicates that the fishery was negatively impacting the environment. This policy recognizes the need to balance many competing uses of marine resources and different social and economic goals for fishery management. For the full text of the alternative, see Section 2.6.4.

Example FMP 3.1

Example FMP 3.1 illustrates a management approach that accelerates precautionary management measures by increasing conservation-oriented constraints on the fisheries where necessary, formalizing precautionary practices in the FMPs, and initiating scientific review of existing practices as a precursor to the decision of how to best incorporate adequate precautions. Example FMP 3.1 is described in full in Table 4.2 1.

Example FMP 3.1 implements changes to the TAC-setting process following a comprehensive review. Precautionary measures such as setting TAC less than or equal to the ABC and specifying MSSTs for Tiers 1 through 3 in accordance with National Standard Guidelines, would be formalized in the FMP. Sharks and skates would be removed from the Other Species management category and given their own TACs, and criteria to do the same for other target stocks would be developed. Efforts would be accelerated to develop ecosystem indicators for setting TAC limits, as per ecosystem management principles,.

In order to balance the needs of social and economic stability with habitat protection and resource conservation, a review would be conducted of the existing closure areas in the BSAI and the GOA (for closure areas under FMP 3.1, see Figure 4.2-4 and Section 4.2.3). The closure areas would be evaluated against a Marine Protected Area (MPA) methodology, which would be developed as part of this alternative. The NPFMC and NOAA Fisheries would also seek to initiate joint consultation and research with USFWS to develop fishing methods that reduce incidental take of threatened and endangered species. To mitigate any adverse impacts of fisheries management decisions on fishing communities, and to comply with other national directives, formal procedures would be implemented to encourage increased participation of Alaska Natives in fishery management.

Example FMP 3.1 recognizes that the anticipated community or rights-based management programs may ultimately address bycatch reduction objectives (a review of bycatch rates under current programs has been initiated) but, a moderate reduction of PSC limits will be initiated as an intermediary step. Additionally, PSC limits for crab, herring, and salmon would be authorized in the GOA, in addition to the halibut PSC limits authorized under the current GOA FMP. Effective monitoring and timely reaction to change in the environment and the fisheries would be enhanced through improvements in the observer program and third party verification of economic data.

Example FMP 3.2

Example FMP 3.2 implements the increase of existing precautionary measures on a more rapid timeline than example FMP bookend 3.1. Example FMP 3.2 is described in full in Table 4.2-1. Rather than reviewing existing practices prior to incorporating increased precautions, this bookend implements changes to many aspects of the FMPs concurrently with the initiation of scientific research efforts necessary to bring management measures in line with a precautionary policy.

Example FMP 3.2 significantly accelerates precautionary management by incorporating an uncertainty correction into the estimation of ABC for all species. Additionally, OY would be specified separately for each stock or stock complex rather than for the groundfish complex as a whole (i.e., OY would be set as a formula rather than as a range, eliminating the BSAI 2 million mt OY cap), and would be set equal to the respective stock or stock complex's TAC. The current precautionary practice of setting TAC less than or equal to ABC would be formalized in the FMP. Example FMP 3.2 would also incorporate stock-specific biological reference points in the tier system where scientifically justifiable. This could result in Tier 3 rockfish stocks, for example, being capped at $F_{60\%}$ rather than $F_{40\%}$. In implementing this bookend, criteria would be developed for specifying MSSTs for Tiers 4 through 6, along with a list of priority candidate stocks; and the development of criteria for moving stocks from the Other Species and Nonspecified Species management categories would minimally result in sharks and skates being given their own TACs.

Example FMP 3.2 also reexamines the existing closure system in the BSAI and the GOA. The bookend sets a guideline of 0 to 20 percent of the EEZ (3 to 200 nm) to be closed as an MPA, of which no more than 5 percent should be completely closed to commercial fishing as a designated No-Take Marine Reserve. The remainder of the closed area would be designated as a no-bottom-contact MPA. The objective of these measures would be to provide greater protection to a full range of marine habitats within the 1,000 m bathymetric line (Figure 4.2 5; specific details on the example FMP 3.2 map are provided in Section 4.2.3). The guideline aims to provide greater protection for a wide range of species, from Steller sea lions to slope rockfish to prohibited species, while at the same time respecting traditional fishing grounds and maintaining open area access for coastal communities. Additionally, the bookend would extend the existing bottom-trawl ban on pollock to the GOA.

Additional conservation benefits would be realized in example FMP 3.2 through the comprehensive rationalization of all fisheries (except those already part of a cooperative or IFQ program.) In adopting rationalization programs such as cooperative-style programs with built-in community protections, habitat and bycatch concerns would also be addressed by reducing concentrated effort in the fisheries. To increase precautions regarding bycatch, PSC limits would be significantly reduced (and set for all prohibited species in the GOA), but would not be expected to act as a proportionate restraint on the fisheries due to the incentives for bycatch reduction under cooperatives, or other bycatch incentive programs implemented as necessary under this bookend.

In accordance with ecosystem principles, the NPFMC and NOAA Fisheries would seek to initiate joint consultation and research with USFWS to develop fishing methods that reduce incidental take of all seabird species. Formal procedures would also be implemented to increase consultation with and representation of Alaska Natives in fishery management.

Effective monitoring and timely reaction to change in the environment and the fisheries would be enhanced through increase of observer coverage and improvements to the observer program, as well as an increase in the use of VMS and the range of economic data collected from industry.

Alternative 4 – Adopt a Highly Precautionary Management Policy

Alternative 4 represents an extremely precautionary approach to managing fisheries under scientific uncertainty. This type of management policy shifts the burden of proof to the users of the resource and the NPFMC/NOAA Fisheries to demonstrate that the intended use would not have a detrimental effect on the environment. It would involve a strict interpretation of the precautionary principle. Management discussions would involve and be responsive to the public, but would decrease emphasis on industry and community concerns in favor of ecosystem processes and principles. This policy assumes that fishing does produce adverse impacts on the environment, but we have little information regarding these impacts. The initial restrictive and precautionary conservation and management measures would be modified or relaxed when additional, reliable scientific information becomes available. For the full text of the alternative, see Section 2.6.5.

<u>Example FMP 4.1</u>

Example FMP 4.1 illustrates an FMP where current levels of fishing are reduced and other precautionary restrictions are implemented until scientific research shows that the fisheries have no adverse effect on the sustainability of the resource and the environment. Example FMP 4.1 is described in full in Table 4.2-1.

Example FMP 4.1 would substantially reduce the potential of the fisheries to have adverse environmental impacts on the environment. A modified TAC-setting process would create a more substantial buffer between ABC and the OFL by setting the fishing mortality rate at $F_{75\%}$ for all Steller sea lion prey species (pollock, Pacific cod, and Atka mackerel) and for rockfish (a long-lived, slow-growing species). Also, the max F_{ABC} for each stock or stock complex in Tiers 1 through 5 would be adjusted downward based on the lower bound of a confidence interval surrounding the survey biomass estimate. OY would be specified separately for each stock or stock complex rather than for the groundfish complex as a whole (i.e., OY would be set as a formula rather than as a range, eliminating the BSAI 2 million mt OY cap), and would be set equal to the respective stock or stock complex TAC. The current precautionary practice of setting TAC less than or equal to ABC would be formalized in the FMP. For species managed as members of a stock complex, rather than setting TAC as the aggregate of the individual members' ABCs, the max_{ABC} value for each stock would be determined and the TAC set equal to the lowest value. Where sufficient biological information is available, such as with EBS pollock, TAC would be distributed on a smaller spatial scale. MSSTs would be determined for all tiers.

To further mitigate the possibility of the fisheries having a detrimental biological and ecosystem impact, 20 to 50 percent of the EEZ would be designated as a No-Take Marine Reserve (i.e., no commercial fishing), covering the full range of marine habitats within the 1,000-m bathymetric line (Figure 4.2-6; specific details on the example FMP 4.1 maps are provided in Section 4.2.3). As part of this area in the Aleutian Islands, a Special Management Area would be established to protect coral and other live bottom habitats. The closed area would include spawning reserve areas for intensively fished species. Under the FMP 4.1 example, comprehensive trawl exclusion zones would be set to protect all Steller sea lion critical habitat, and trawling would be restricted to only those fisheries that cannot be prosecuted with other gear types (i.e, the flatfish fisheries).

In an effort to reduce waste and the risk of adverse impact to the environment, existing PSC limits would be halved under this bookend, as would bycatch (discard) and incidental catch rates. IR/IU would be extended to all target species. Stringent PSC limits would be set for salmon, crab, and herring in the GOA, and as information becomes available, bycatch limits would be set for non-target species also. Protection measures would be set for all seabird species.

Because this policy alternative necessitates greater research and data-gathering efforts, example FMP 4.1 would expand observer coverage to 100 percent for all vessels over 60 ft in length and require 30 percent observer coverage on vessels presently exempted from observer coverage (i.e., vessels under 60 ft in length). VMS would be made mandatory for all groundfish vessels, as would motion-compensated scales for weighing all catches at sea or at shore-based processors. Cooperative research and data-gathering programs would be initiated as well to expand the use of traditional knowledge in fisheries management.

Example FMP 4.2

Example FMP 4.2 expands the precautionary principles of Alternative 4 by suspending all fishing until the fisheries can be shown to have no adverse effect on the resource and its environment. The TAC for all species would be set at zero. All areas of the EEZ would be closed to all types of fishing (e.g., commercial, recreational, and subsistence) (Figure 4.2-7; specific details on the example FMP 4.2 map are provided in Section 4.2.3); bycatch and incidental catch, as well as the take of seabirds and marine mammals, would then be reduced to zero. Example FMP 4.2 is described in full in Table 4.2-1.

Scientific research and data-gathering efforts would continue. When a fishery can be shown to pose no significant threat of adverse biological and environmental impacts, or if adverse effects can be successfully mitigated through use of fishery-specific regulations, fishing would be allowed to resume.

Under this FMP illustration, it is assumed that each groundfish fishery currently conducted in federal waters in the BSAI and GOA would be individually reviewed by the NPFMC and NOAA Fisheries. Upon completion of this review (which may take up to 2 years), the agency would certify those fisheries that have no significant adverse impacts on the environment and authorize fishing under a specific set of regulations. If a fishery is found by this review to produce significantly adverse environmental effects, and mitigation measures can not be designed to mitigate those effects, that fishery would not be certified and would remain closed until more scientific information is known.

The Preferred Alternative

The preliminary Preferred Alternative represents a management approach that incorporates forward looking conservation measures that address differing levels of uncertainty. This management approach has, in recent years, been labeled the precautionary approach. As part of its policy, appropriate measures would be considered and adopted that accelerate the precautionary, adaptive management approach through community or rights-based management, ecosystem-based management principles that protect managed species from overfishing, and, where appropriate and practicable, increased habitat protection and bycatch constraints. This management approach recognizes the need to balance many competing uses of marine resources and different social and economic goals for fishery management, and will utilize and improve upon the NPFMC and NOAA Fisheries' existing open process to involve the public in decision-making. For the full text of the alternative, see Section 2.6.9.

Example FMP PA.1

Example FMP PA.1 illustrates a conservative management approach that continues current risk-averse management practices, increases conservation-oriented constraints on the fisheries as appropriate, formalizes precautionary practices in the FMPs, and initiates scientific review of existing practices in order to assess and improve fishery management. Example FMP PA.1 is described in full in Table 4.2-2.

Example FMP PA.1 builds on the existing conservative procedure for determining ABC and annual quotas. The example FMP would implement changes to the TAC-setting process following a comprehensive review. Precautionary practices, such as setting TAC less than or equal to the ABC, and specifying MSSTs for Tiers 1 through 3 in accordance with National Standard Guidelines, would be formalized in the FMP. The NPFMC and NOAA Fisheries would continue to use and improve harvest control rules to maintain a spawning stock biomass with the potential to produce sustained yields on a continuing basis, and to distribute allocations by area, season, and gear as appropriate. Efforts to develop ecosystem indicators to be used in TAC-setting, as per ecosystem management principles, would be continued.

In order to balance the needs of social and economic stability with habitat protection and resource conservation, the NPFMC would develop an MPA efficacy methodology, including the development of definitions, program goals, objectives, and criteria for establishing MPAs. Additionally, existing habitat and bycatch area restrictions would be maintained. Measures to protect ESA-listed species would also be retained. To minimize bycatch, a moderate reduction of PSC limits in the BSAI would be initiated, and PSC limits or other appropriate measures for the protection of crab, herring, and salmon would be authorized in the GOA. Effective monitoring and timely reaction to change in the environment and the fisheries would be enhanced through improvements in the observer program and existing reporting requirements.

Existing programs to address excess capacity and overcapitalization would be maintained under this example FMP, with continued development of rights-based management to be undertaken as needed. In order to mitigate any adverse impacts of fisheries management decisions on fishing communities, and to comply with other national directives, procedures to encourage increased participation of Alaska Natives in fishery management would be pursued.

Example FMP PA.2

Example FMP PA.2 accelerates adaptive, precautionary management by increasing conservation measures that provide a buffer against uncertainty, instituting research and review of existing measures, and expanding data collection and monitoring programs. Example FMP PA.2 is described in full in Table 4.2-2.

Example FMP PA.2 significantly increases precautionary management by incorporating an uncertainty correction into the estimation of ABC for all species. The current precautionary practice of setting TAC less than or equal to ABC would be formalized in the FMP. The calculation of te OY caps would be periodically reviewed to determine their relevancy to current environmental conditions and stock levels. Example FMP PA.2 would also develop and implement criteria for using key ecosystem indicators in TAC-setting, and other precautionary practices such as developing appropriate harvest strategies for rockfish stocks. In implementing this bookend, analysis and data collection would allow for specification of MSSTs for priority stocks in Tiers 4 and 5. The development of criteria to manage target and non-target species consistently, and for moving stocks from the Other Species and Non-specified Species management categories, would initially consider moving sharks (in the BSAI and GOA) and skates (in the BSAI) out of the Other Species group for setting TAC limits.

Example FMP PA.2 also re-examines area restrictions in the BSAI and the GOA by reviewing existing closure areas (for closure areas under example FMP PA.1, see Figure 4.2-8 and Section 4.2.3), and evaluating them in conjunction with the development of MPAs. The example FMP would adopt MPAs, based on a designation guideline of 0 to 20 percent of the EEZ (3 to 200 nm). The objective of these measures is to provide greater protection to a full range of marine habitats within the 1,000 m bathymetric line (Figure 4.2-9; specific details on the example FMP PA.2 map are provided in Section 4.2.3). This MPA would incorporate an Aleutian Islands management area to protect coral and live bottom habitat, and would also include any modification to the 2002 Steller sea lion closures. The guideline aims to provide greater protection for a wide range of species, from Steller sea lions to slope rockfish to prohibited species, while at the same time respecting traditional fishing grounds and maintaining open area access for coastal communities. Additionally, the bookend would extend the existing BSAI bottom-trawl ban on pollock to the GOA.

To increase precautions regarding bycatch, existing PSC limits would be reduced, and limits would be set for all prohibited species in the GOA with appropriate in-season closure areas. The achievement of these bycatch reductions would be realized through the comprehensive rationalization of all fisheries (except those already part of a cooperative or IFQ program), which reduces concentrated effort in the fisheries, or through bycatch incentive programs implemented in this example FMP.

In accordance with ecosystem principles, the NPFMC and NOAA Fisheries would seek to cooperate with USFWS to develop fishing methods that reduce incidental take of all seabird species in the longline and trawl fleets. Procedures would also be pursued to increase consultation with and representation of Alaska Natives in fishery management.

Increases in observer coverage and improvements to the observer data that are collected would enhance effective monitoring and improve the ability to react to change in the environment and the fisheries. Additionally, the bookend explores programs that would expand mandatory economic data collected from industry.

4.2.3 Description of the Example Fishery Management Plan Maps

FMP 1 Map

FMP 1 (Figure 4.2-1) illustrates different types of spatial management areas across the BSAI and GOA. All of these areas currently comprise the spatial management regime for 2003. These areas are color-coded on the map; bathymetry contours to 1,000 m are also color-coded, ranging from dark green (0 m) to a pale beige (1,000 m). In the legend, titles for measures developed specifically for protection of Steller sea lions are printed in blue. Bycatch closures that are triggered once a PSC limit is reached are not included on the map or in the spatial analysis, since in recent years some of these limits are no longer reached.

FMP 1 illustrates the current Steller sea lion-related closures west of 144°W longitude necessary for the Alaska groundfish fisheries to avoid a determination of jeopardy and adverse modification for Steller sea lions under the ESA. The Steller sea lion population west of 144°W longitude has been listed as endangered under the ESA since 1990. The portion of the Steller sea lion population found east of 144°W longitude is currently listed as threatened. Closures related to protection of Steller sea lions are color-coded as follows:

Yellow:	3 nm No-Transit Zones (No-Take Reserves)
Blue:	No Hook-and-Line and Pot or Trawl for the Steller Sea Lion Prey Species
Red:	No Trawling for Steller Sea Lion Prey Species
Red Hatching:	Seasonal and Harvest Limit Closures for Atka Mackerel and Pacific Cod
Tan Hatching:	Additional Atka Mackerel Closures
Blue Hatching:	Additional Pollock Closures

The No-Transit Zones shown on the map have been in effect since 1992, and serve to restrict all water-born vessel traffic year-round, unless under a federal scientific permit.

Areas designated as "No Hook-and-Line and Pot or Trawl for Steller Sea Lion Prey Species" are those areas that currently restrict the harvest of Steller Sea lion prey species by hook-and-line and pot and bottom and pelagic trawl gear. These restrictions are in effect year-round.

Areas labeled "No Trawling for Steller Sea Lion Prey Species" restrict both bottom and pelagic trawl fishing for Steller sea lion prey species and are in effect year-round.

In the BSAI, areas designated as "Seasonal and Harvest Limit Closures for Atka Mackerel and Pacific Cod" are those areas where Atka mackerel fishing is closed all year within 20 nm of Steller sea lion rookeries and haulout sites in waters east of 178°W longitude. In waters west of 178°W longitude, constraints on Atka mackerel harvest are triggered once 40 percent of the Aleutian Islands Atka Mackerel TAC is reached. After the 40 percent threshold is reached in the Aleutian Islands, all other Atka mackerel fishing must occur at least 20 nm from Steller sea lion rookeries and haulout sites. To prevent localized depletion of prey species, Pacific cod (which are managed under a single TAC for the BSAI) may not be targeted west of 178°W longitude after 40 percent of that BSAI TAC is reached.

Additional closures include those areas closed to directed fishing of Atka mackerel and pollock, The GOA west of 144°W longitude is closed year-round to directed fishing for Atka mackerel. The entire Aleutian Islands subarea is closed year-round to directed fishing of pollock, and both the GOA and the Bering Sea have additional seasonal pollock restrictions.

Non-Steller sea lion related spatial closures, including areas closed to all trawl, non-pelagic trawl, and all fishing, are presented in the example FMP 1, FMP 2.2, and FMP 3.1 maps (Figures 4.2-1, 4.2-3, and 4.2-4, respectively). These closures include the following areas:

Closed to All Trawl

- Nearshore Bristol Bay Closure Area: Bering Sea area closed year-round since 1996.
- Pribilof Islands Area Habitat Conservation Zone: Bering Sea area closed year-round since 1994.
- Southeast Outside Closed Area: closed year-round since 1997.
- Chiniak Gully Research Area: closed from August 1 through September 20.

Closed to Non-Pelagic Trawl

- Red King Crab Savings Area: Bering Sea area closed year-round since 1996.
- Kodiak Type I Crab Closure Areas: GOA area closed year-round.
- Kodiak Type II Crab Closure Areas: GOA area closed between February 15 to June 15.

Closed to All Fishing

- Cape Edgecumbe (Sitka) Pinnacles: closed to groundfish fishing year-round since 1997.

All of these spatial measures (closures) combined protect 10.7 percent of the EEZ (Table 4.2-3). Because groundfish resources and EFH are usually found to be associated with the continental shelf and continental slope, for purposes of this analysis we have defined "fishable area" as those waters over the continental shelf and continental slope, or all waters to a depth of 1,000 m. When examined in this way, the spatial measures described for example FMP 1 protect 28.8 percent of the fishable area of the BSAI and GOA. (Table 4.2-3).

Example FMP 2.1 Map

The map for example FMP 2.1 (Figure 4.2-2) illustrates six different types of spatial management areas across the BSAI and GOA. Example FMP 2.1 includes only the current Steller sea lion-related closures west of 144°W longitude, necessary for the Alaska groundfish fisheries to avoid a jeopardy determination for Steller sea lions under the ESA. These closure areas are color-coded on the map; bathymetry contours to 1,000 m are also color-coded, ranging from dark green (0 m) to a pale beige (1,000 m). Closures related to protection of Steller sea lions are color-coded as follows:

Yellow:	3 nm No-Transit Zones (No-Take Reserves)
Blue:	No Hook-and-Line and Pot or Trawl for the Steller Sea Lion Prey Species
Red:	No Trawling for Steller Sea Lion Prey Species
Red Hatching:	Seasonal and Harvest Limit Closures for Atka Mackerel and Pacific Cod
Tan Hatching:	Additional Atka Mackerel Closures
Blue Hatching:	Additional Pollock Closures

Descriptions of these six spatial management areas do not deviate from those presented under the FMP 1 map at the beginning of this section. All of these spatial measures (closures) combined protect 4.2 percent of the EEZ, and 14.6 percent of the fishable area of the BSAI and GOA (Table 4.2-4).

Example FMP 2.2 and Example 3.1 Maps

The maps for examples FMP 2.2 and FMP 3.1 are identical to the map for example FMP 1 (Figures 4.2-3 and 4.2-4). See Tables 4.2-5 and 4.2-6 for descriptive statistics on FMPs 2.2 and 3.1, respectively.

Example FMP 3.2 Map

The map for example FMP 3.2 (Figure 4.2-5) illustrates six color-coded spatial management areas. Bathymetry contours to 1,000 m are also color-coded, running from dark green (0 m) to pale beige (1,000 m). In the legend, titles for measures developed specifically for protection of Steller sea lions are printed in blue. Closures are color-coded as follows:

Yellow:	3 nm No-Transit Zones (No-Take Reserves)
Blue:	No-Take Marine Reserves
Dark Green:	No Steller Sea Lion Prey Species Hook-and-Line, Pot, or Trawl Fishing MPA
Purple:	No Steller Sea Lion Prey Species Trawling MPA
Light Green:	Eastern GOA No Steller Sea Lion Prey Species Hook-and-Line, Pot, or Trawl MPA
Pink:	No-Bottom-Contact Trawling MPA

The map has been developed from the following information and data sources: bathymetry; EFH from the 1997 EFH EA (NMFS 1997); Steller sea lion critical habitat; 2002 Steller sea lion closures; survey and bycatch data for coral and sponge distribution; historical commercial fisheries catch data; location of ports; locations of test and study areas; and review of various alternatives and potential mitigation measures being developed by the NPFMC EFH Committee. Using the latest data to determine Steller sea lion foraging behavior, a 15 nm buffer from the coastline in the GOA and Bering Sea was applied, as were 15 nm buffers from Steller sea lion rookeries and haulouts in the Aleutian Islands.

The ADF&G groundfish statistical areas were applied as management units to designate five different types of management areas including No-Take Marine Reserves; No Steller Sea Lion Trawling MPA; No Bottom Trawling MPA; No Steller Sea Lion Hook-and-Line, Pot or Trawl MPA; and, in the eastern GOA, No Steller Sea Lion Hook-and-Line, Pot or Trawl and No-Trawl MPA.

The ADF&G statistical areas are approximately 35 nm wide and 30 nm tall. ADF&G subdivides their statistical areas at 3 nm from the shoreline. These management units, when grouped into larger spatial regions, are presumably large enough to 1) prevent habitat fragmentation; 2) protect large portions of HAPC; 3) form clearly defined, manageable, navigable, and enforceable alternatives; 4) provide contiguous fishing restrictions for protecting spawning populations, key critical habitat, demersal and pelagic fish species, and marine mammals; and 5) where possible, provide open areas near fishing ports.

From a biological and fishery point of view, the ADF&G groundfish statistical area boundaries are arbitrary and do not always line up with the spatial distribution of significant biological and habitat resources. Therefore, a 40 percent rule was applied: when 40 percent of a statistical area had a significant concern as determined by a weighted qualitative factor, the area was tagged as a "No-Take Marine Reserve", or one of the other MPAs. This effect was normalized to a certain extent during the analysis because a statistical area that did not quite meet the benchmark would not be designated as an MPA (e.g., an area where less than 40 percent was of concern would be left entirely open). In some cases, areas would be totally closed to create a contiguous closure necessary to capture a broad range of inshore to offshore habitats.

The benthic fishing habitat used in this analysis generally follows the continental shelf and goes out to a depth of 1,000 m (500 fathoms), which we consider here to constitute the fishable bottom habitat. Blocks of closures extend from the shore to a 1,000-m depth, protecting a full range of habitat types. Area protected by FMP 3.2 spatial measures, when combined, constitutes 17.8 percent of the EEZ, and 47.8 percent of the fishable area of the BSAI and GOA (Table 4.2-7).

<u>Aleutian Islands</u>

The Aleutian Islands subarea merits special attention since the fishing grounds are all relatively nearshore. Example FMP 3.2 defines a 5 percent No-Take Reserve and 15 percent MPA rule across a full range of habitat types. Where in the Bering Sea and GOA, 15 nm buffers from shore were described in the frameworks, in the Aleutian Islands, a 15 nm buffer was applied to each of the Steller sea lion rookeries and haulouts. This buffer does not specifically implement a No-Take Reserve or other MPA, but is likely to be a weighting factor in any future development of restrictions.

Due to the narrow continental shelf along the Aleutian Island chain, and the fact that state statistical areas are utilized in this Programmatic SEIS, a much higher percentage of fishable area (79.9 percent) is afforded protection in the example FMP 3.2 in the Aleutian Islands area compared to the Bering Sea (32.6 percent) and western/central GOA (65.6 percent).

Thirty-nine Steller sea lion rookeries fall within Steller sea lion critical habitat, 19 of which are located in the Aleutian Islands. All rookeries carry a 3 nm No Transit area with an additional 10 nm (or more) designated as a No Trawling for Steller Sea Lion Prey Species area. The No Transit areas are the only No-Take reserves in the Aleutian Islands. These closures have been in effect since 1992, all of which are logical candidates for no-take marine reserves or MPAs. Many of these Steller sea lion No Transit/No-Trawl areas are clustered and transfer easily to corresponding ADF&G statistical areas. Although other non-Steller sea lion prey species fisheries such as rockfish fisheries, occur inside No Steller Sea Lion Prey Species Trawl areas, these no-trawl areas were weighted heavily in the analysis as representing conceptual No-Take reserves and less so for gear-specific MPAs. Coral data from bycatch and trawl survey data, as well as from NOAA dive test areas, were used in the development of the No-Take marine reserve examples.

The MPAs considered for analysis of example FMP 3.2 include No Steller Sea Lion Prey Species Hook-and-Line, Pot, and Trawling MPAs; No Steller Sea Lion Prey Species Trawling MPAs; and No Bottom Contact Trawling MPAs. To encompass existing closures areas, the Pacific cod Hook-and-Line and Pot and Trawling restrictions were extended to constitute No Steller Sea Lion Prey Species Hook-and-Line and Pot MPAs, if not already closed as No-Take Reserves. Other current Steller sea lion prey species restrictions include closing trawl fisheries for Atka mackerel, pollock (the entire Aleutian Islands subarea), and Pacific cod. To better protect habitat, a suite of MPAs for No Bottom Contact Trawling (currently defined simply as non-pelagic trawling) were created around areas of low and medium fishing intensity areas where bycatch or trawl survey data contained coral and sponge. Some of these low intensity areas can be seen on Bowers Ridge, west of Attu Island, and west of the Bogoslof District.

Through the development of these no-take reserves and MPAs, the 40 percent rule was applied to ADF&G statistical areas in order to illustrate a contiguous and fairly non-fragmented environment available for marine mammals, benthic habitats, seabird avoidance, and spawning fish populations without jeopardizing commercial fisheries.

Bering Sea

Guidelines in the example FMP 3.2 MPAs and EFH component define a 5 percent No-Take Reserve and a 15 percent MPA rule across a full range of habitat types. Bering Sea benthic habitat is much different than the habitat Aleutian Islands, due to its broad, muddy, and sandy shelf. The Bering Sea also contains many legacy areas established for habitat protection, such as the Near Shore Bristol Bay No-Trawl area, the Red King Crab No Non-Pelagic Trawl area, the Pribilof Habitat No-Trawl area, and a full suite of No Steller Sea Lion Prey Species Hook-and-Line and Pot and Trawl Areas. Other existing closures in the Bering Sea have been used for the creation of No-Take Reserves and MPAs (i.e., five No Transit zones and their associated 10 nm No Steller Sea Lion Prey Species Trawling areas with various sized hook-and-line and pot closures). A large section of the Steller sea lion conservation area (the Bogoslof District) is closed to all Steller sea lion prey species fishing (with a small exemption area near Dutch Harbor for catcher vessels less than 60 ft in length.

A buffer from the shore of 15 nm was used to help determine designation of the No-Take Reserves and the MPAs. As in the Aleutian Islands, we have applied a 40 percent rule to ADF&G statistical areas to illustrate contiguous and fairly non-fragmented environments.

The Bogoslof District currently contains significant amount of No-Take Reserves, along with many No Steller Sea Lion Prey Species Hook-and-Line and Pot and Trawling areas. More No Steller Sea Lion Hook-and-Line and Pot Trawling areas develop to the east along the lower Bering Sea shelf. The 3 nm statistical areas around the land bordering the rookeries are listed as No-Take Marine reserves. Other No-Take Reserves include a large area around the Cape Pierce Walrus Protection area and the Walrus Island Steller sea lion rookery in the Pribilof Islands.

The Pribilof Habitat Conservation and Nearshore Bristol Bay areas remain closed to trawling, and the Red King Crab Savings Area remains closed to non-pelagic trawling. The two northernmost haulouts and the haulouts in the Pribilofs are closed to Steller Sea Lion Prey Species Hook-and-Line and Pot and Trawling.

Along the northwestern shelf of the Bering Sea, three large No-Bottom-Contact Trawling MPAs were developed to coincide with the no-bottom-trawling areas the EFH Committee is considering to protect benthic habitat. These general areas are being considered as potential sites for a rotational MPA, where areas are periodically opened and closed to particular types of fishing.

GOA – West of 144°W

Similar to the BSAI area, example FMP 3.2 sets a 5 percent No-Take Reserve and a 15 percent MPA rule across a full range of habitat types in the GOA (west of 144°W) . Unlike the Bering Sea, however, the GOA is somewhat more restrictive as to where effective closures can be designated and leaves areas open near fishing ports.

Fifteen Steller sea lion rookeries are listed in the GOA, 13 of which include 3 nm No Transit areas and 10 nm No Steller Sea Lion Prey Species Trawling areas. These areas, along with other existing Steller sea lion restrictions (such as the 15 nm buffers from the shore, the Type I & II No-Trawl areas (areas that are closed year round to all trawling but pelagic gear, and areas that are closed to pelagic gear from Feb 15-June 15, respectively), and the Chiniak Gully Research Area); known locations of Steller sea lions and other marine mammals (such as harbor seals); pollock spawning areas; bycatch and survey data of coral and sponges; the shelf's gullies, canyons, and breaks; and EFH, were used as weighted measures for the illustration of the No-Take Reserves and MPAs in FMP 3.2.

The 40 percent rule was again applied to the ADF&G statistical areas to illustrate large, non-fragmented environments.

In order to protect a full range of habitat, perpendicular tracks of No-Take Marine Reserves were created from the shoreline to a depth of 1,000 m. Where possible, the No-Take Reserves were created at Steller sea lion rookeries and where existing No Hook-and-Line and Pot and Trawl for Steller Sea Lion Prey Species closures coexist, such as at Marmot Island, south Chignik in RPA District 4, selected Steller sea lion rookeries and haulouts, and RPA Districts 10 and 11 (below the Bogoslof District). Other areas that were designated No-Take Reserves for purposes of our analysis included a section of the shelf and slope below the Shumagin islands and Portlock Banks, and smaller sections of the shelf below Prince William Sound (PWS).

When Steller sea lion restrictions were dominant but did not reach the benchmark for creating No-Take Reserves, there were no Steller Sea Lion Prey Species Hook-and-Line and Pot and Trawl closure areas created using the weighted measure. Instead, No-Trawl for Steller Sea Lion Prey Species and No-Bottom-Contact Trawling closures were created using these same sets of weighted criteria.

GOA – East of 144°W

As in the BSAI, example FMP 3.2 for the GOA (east of 144°W longitude) defined a 5 percent No-Take Reserve and a 15 percent MPA rule across a full range of habitat types.

Currently there are no Steller sea lion closures east of 144°W. The Steller sea lion population east of 144°W is listed as threatened; therefore, we included an example measure to provide some protection to this part of the population. The No-Trawl closure east of 140°W was strengthened in this illustration to include an MPA for No Hook-and-Line and Pot or Trawl for Steller Sea Lion Prey Species. The MPA also includes a smaller area near Icy Bay and Cape Yakataga.

The example No-Take Reserves were developed to protect habitat in areas with low to medium fishing intensity and within 3 nm of three Steller sea lion rookeries. The Sitka Pinnacles are located within one of the example No-Take Reserves.

Example FMP 4.1 Map

There are two versions of the example FMP 4.1 map, both of which illustrate the same suite of spatial closures. Figure 4.2-6 provides a map illustration using the same color scheme used in maps for example FMPs 1 through 3.2, so that the maps may be easily compared. Figure 4.2-11 uses the same color scheme (magenta) as the map for example FMP 4.2 map (Figure 4.2-7). Both example FMPs 4.1 and 4.2 illustrate a major shift in management policy from current policy. Unlike current management practice, where any type of fishing is generally permitted unless specifically prohibited (e.g., the maps are blank unless closures/restrictions are shown), the maps for example FMP 4.1 illustrates a management policy where all areas and types of fishing are closed unless shown otherwise. Bathymetry contours to 1,000 m are also color-coded, ranging from dark green (0 m) to pale beige (1,000 m). In the legend, titles for measures developed specifically for protection of Steller sea lions are printed in blue. Figure 4.2-11 illustrates four types of spatial management areas that are color-coded as follows:

Yellow:	3 nm No Transit Zones (No-Take Reserve)
White:	Open to Fishing
Magenta Hatching:	Open to Commercial Fishing Except Trawling
Magenta (solid):	No-Take Marine Reserves

The map has been developed from the following information and data sources: bathymetry; EFH from the 1997 EFH EA (NMFS 1997); Steller sea lion critical habitat; 2002 Steller sea lion closures; survey and bycatch data for coral and sponge distribution; historical commercial fisheries catch data; location of ports; locations of test and study areas; the Aleutian Islands special management area; public comments; and the legacy closures and restricted areas identified in Table 4.2-1.

ADF&G statistical areas were applied as management units to designate open fishing areas, No-Trawling areas (all species, all types of trawls), and No-Take Marine Reserves (where commercial fishing is prohibited). The ADF&G groundfish statistical areas are approximately 35 nm wide and 30 nm tall. ADF&G subdivides their statistical areas at 3 nm from the shoreline. These management units, when grouped into larger spatial regions, are presumably large enough to 1) prevent habitat fragmentation; 2) protect large portions of HAPC; 3) form clearly defined, manageable, navigable, and enforceable alternatives; 4) provide contiguous fishing restrictions for protecting spawning populations, critical habitat, demersal, and pelagic fish species, and marine mammals; and 5) where possible, provide open areas near fishing ports.

From a biological and fishery point-of-view, the ADF&G statistical areas are arbitrary and do not always represent the spatial distribution of significant biological and habitat resources. Therefore, a 25 percent rule was applied in the following manner: when 25 percent of a state statistical area had a significant concern, the area was designated as either a No-Take Marine Reserve or a No-Trawl MPA. This effect was normalized to a certain extent during the analysis because a statistical area that did not quite meet the benchmark would not be designated as an MPA (e.g., an area where less than 25 percent was of concern would be left entirely open, as was the case when attempting to close Steller sea lion critical habitat). In some cases, areas were totally closed, even if the 25 percent benchmark was not reached, to create a contiguous closure that captured a broad range of inshore to offshore habitats.

Area protected by example FMP 4.1 spatial measures, when combined, is 19.0 percent of the EEZ, and 51.1 percent of the fishable area of the BSAI and GOA (Table 4.2-8). The primary difference between this map and the FMP 3.2 map is that most of the spatial closures used in this illustration are No-Take Marine Reserves where all commercial fishing is prohibited. This form of closure is intended as an extremely precautionary policy that places emphasis on protecting marine mammals, target groundfish stocks, and EFH.

Aleutian Islands

The Aleutian Islands subarea merits special attention since the fishing grounds are near the shore. Example FMP guidelines specify that 20 to 50 percent of each management area, including all representative habitats contained therein, should be managed as a No-Take Marine Reserve. The Aleutian Islands Special Management Area illustrated in example FMP 4.1 covers a contiguous area specifically to protect coral and other living substrates; and Steller sea lion critical habitat. Although the Aleutian Islands Special Management Area was originally intended to encapsulate the entire Aleutian Islands subarea, excluding a swath of fishable area at Unimak Pass, this is not shown on the map since the Bogoslof District and RPA Districts 10 and 11 are already analyzed as No-Take Marine Reserves in their own regions.

Benthic fishing habitat to a depth of 1,000 m (500 fathoms) was used in this analysis, which we considered fishable bottom habitat. In most cases, perpendicular blocks of closures extend from one side of the 1,000 ms contour to the other, protecting a full and broad range of habitat.

Thirty-nine Steller sea lion rookeries are located within designated Steller sea lion critical habitat; 19 of which are contained in the Aleutian Islands. All rookeries have a 3 nm No-Transit Zone and an additional 10 nm No Steller Sea Lion Prey Species Trawling area. These closures have been in effect since 1992, all of them making excellent candidates for No-Take Marine Reserves under Alternative 4 policy. Many of these areas are clustered and would transfer easily to the corresponding ADF&G statistical areas. Areas that currently have high densities of no-trawl, hook-and-line, and pot fishing were designated No-Take Marine Reserves in the example FMP 4.1 illustration. A good example of this can be seen in the area from 170°W to Seguam Pass. Blocks on the Petrel Banks were closed due to high coral bycatch. A string of closed statistical areas are located along the Petrel Banks because these areas have had at least some coral bycatch and are relatively unstudied. One block on the southeastern side of Petrel Banks (north slope) was left open. Historically high catch rates in this area and a need to create at least some open areas for fishing prompted this action. No-take reserves along Steller sea lion critical habitat and the 1,000 ms contour created significant contiguous benthic and biologic protection in the Aleutian Islands.

Bering Sea

Example FMP 4.1 guidelines specify that 20 to 50 percent of each management area, including all representative habitats contained therein, should be managed as No-Take Reserves. Specifically mentioned in example FMP 4.1 are submarine canyons, Unimak Pass, old Crab Pot Sanctuary, areas near the Pribilof Islands, area southwest of St. George, Misty Moons, and the Red King Crab Savings Area. These examples were recommended by public stakeholders as candidate areas for analysis in this Programmatic SEIS.

Steller sea lion critical habitat (including the entire Steller Sea Lion Conservation Area) was closed to trawling as an illustration of a No-Trawl MPA, or designated as No-Take Marine Reserves, as were other legacy closures such as the Nearshore Bristol Bay No-Trawl area. And since the Bering Sea has a much broader benthic plane, more options were available to analysts for illustrating a management scenario meeting the criteria of example FMP 4.1 by protecting a full range of habitat types using a combination of both No-Trawl MPAs and No-Take Marine Reserves.

For purposes of this analysis, we designated the Bogoslof District (RPA District 9) as a No-Take Marine Reserve, with blocks of reserve leading east to include large portions of old Crab Pot Sanctuary Area, thereby illustrating continued protection of this important crab spawning area. A tract of No-take Marine Reserve leaves the old Crab Pot Sanctuary area running north to intercept the coast near Cape Pierce and the Walrus Islands closures. A track of No-Trawl MPA extends from Cape Pierce to the west, intercepting the No-Trawl Marine Reserve formed by the Pribilof Conservation Area. Below the Pribilof Conservation Area is Misty Moon canyon; a No-Take Marine Reserve was designated here because of historically high bycatch of corals and sponges. An open fishing area was created both to the north and south of the Misty Moon area to permit groundfish fishing where catches have been historically good, but with lower bycatch. For purposes of illustrating this policy, other large No-Take Marine Reserves were designated along the inner, middle, and outer Bering Sea shelf breaks. The five northern Steller sea lion haulouts became No-Take Marine Reserves using coincident ADF&G statistical areas. Unlike the Aleutian Islands, the area analysis includes only that part of the ADF&G statistical area that coincides with 1,000 m bathymetry. The exception is that the Bogoslof foraging area is included in the percentage of Bering Sea EEZ calculation.

GOA – West of 144°W

As with the BSAI, GOA (west of 144°W) guidelines suggest that 20 to 50 percent of each management area, including all representative habitats contained therein, should be managed as No-Take Marine Reserves. Specific areas mentioned for analysis are the Davidson Banks, Shumagin Islands, the Type I & II area to the southeast of Kodiak Island, and the Gulf shelf breaks. Unlike the Bering Sea , the GOA is somewhat more restrictive as to where effective closures can be created, while leaving some areas open.

Steller sea lion critical habitat, current Steller sea lion-related closures (trawl, hook-and-line, and pot), pollock spawning areas, fishing ports, and the shelf's gullies, canyons and breaks, were taken into account in the creation of No-Take Marine Reserves and No-Trawl MPAs. In order to protect a full range of habitat, perpendicular tracks of No-Take Marine Reserves were created using ADF&G statistical areas from the shoreline to the 1,000-m break. Where possible, these No-Take Marine Reserves were created at Steller sea lion rookeries and where current Steller sea lion no-trawl and no hook-and-line and pot closures coexist, such as Marmot Island and RPA Districts 4, 10, and 11. Other areas that were designated as No-Take Marine Reserve in this example FMP included the Shumagin Islands (an important pollock spawning area and high catch area), a portion of Davidson Bank, Portlock Banks shelf break, and blocks of areas in and around PWS. Unlike the Aleutian Islands, the area analysis in the GOA (west of 144°W) includes only that part of the ADF&G statistical area that coincides with 1,000 m bathymetry.

GOA – East of 144°W

Because the Southeast Outside District does not include Steller sea lion critical habitat but currently has a trawl ban east of 140°W, this area was analyzed separately from the western and central GOA. Again, a suggested 20 to 50 percent of each management area, including all representative habitats contained therein, should be managed as No-Take Marine Reserves. The Sitka Pinnacles are is the only area currently designated as No-Take among the example FMPs. Coral and sponge bycatch, shelf breaks, and proximity to ports were used in the illustration of No-Take Marine Reserves. The No-Take Marine Reserves protect a full range of habitat from the coast to the 1,000 m (fishable area) shelf break. Unlike the Aleutian Islands, the area analysis for the GOA (east of 144°W) includes only that part of the ADF&G statistical area that coincides with 1,000 m bathymetry.

Example FMP 4.2 Map

The map for example FMP 4.2 (Figure 4.2-7) illustrates a management plan that completely closes the EEZ to groundfish fishing until such time that NPFMC and NOAA Fisheries have reviewed each fishery and determined whether the fishery will result in any significant adverse impacts on the physical or biological environment. The process of review, certification, and development of fishery-specific regulations could take up to two years, at which time those fisheries authorized to harvest groundfish would be permitted. This map would then change for those fisheries, with certain areas opening to them. Some fisheries may never receive authorization. As fisheries are authorized, their fishery-specific maps would begin to look similar to the example FMP 4.1 map illustrations, depending on the fishery (Table 4.2-9).

For purposes of this programmatic analysis, the map for example FMP 4.2 provides an opportunity to estimate the economic and social value of the commercial groundfish fisheries and realize the impact of a temporary suspension of groundfish fishing. Such a management plan serves as a useful bookend for comparing this example FMP scenario with example FMP 4.1, which illustrates a significantly reduced fishery in lieu of total suspension.

Example FMP PA.1

The map for example FMP PA.1 (Figure 4.2-8) is identical to the map for example FMP 3.1.

Example FMP PA.2

The map for example FMP PA.2 (Figure 4.2-9) is identical to the map for example FMP 3.2.

4.3 Overview of Fishery Management Plan Components and Qualitative Analysis Papers

As introduced in Section 4.1, each of the 11 FMP components in the analytical framework is analyzed in relative isolation of other components. The analysis is intended to provide insight into the range of management tools and measures that can be used to address individual or multiple policy objectives, as well as to address the specific management measures that are included in the example FMPs. Each FMP component paper presents an illustration of how the measures could work and what the environmental consequences would be, based on a review of the scientific literature and past management experience in Alaska and elsewhere. These qualitative analysis papers serve to describe the historical use of the component and provide details on the impacts of the measures themselves. Because each FMP component is analyzed in isolation of the others, however, the papers by themselves do not predict impacts at the alternative level, as they do not take into account the accumulated changes (for example, Steller sea lion protection measures are applied in combination with the creation of MPAs or the reduction in catch limits). The alternatives as a whole are analyzed later in this chapter.

This section contains the abstracts of the 11 qualitative analysis papers prepared for each of the FMP components in the analytical framework. The full text of the papers can be found in Appendix F.

4.3.1 The Total Allowable Catch-Setting Process

The different policy alternatives bear numerous implications for the annual process of setting TAC for the groundfish fisheries. The qualitative analysis paper examines how various constraints on harvest compare between the alternatives. Five aspects of the TAC-setting process are reviewed: 1) the structure and composition of groundfish management categories such as target fish; 2) the setting of OFLs and ABC; 3) the setting of OY and TAC; 4) the MSST required by the National Standards Guidelines for implementing National Standard 1 of the MSA, but which is not currently operative for certain groundfish fisheries in the BSAI and GOA; and 5) the ecosystem implications of the TAC-setting process. Under Alternative 1, existing constraints would be retained in their present configuration. The more aggressive harvest strategies proposed under Alternative 2 could lead to the relaxing of certain constraints. Conversely, the increasingly precautionary and risk-averse policies of Alternatives 3 and 4 would lead to a tightening of those constraints. For further detail on this FMP component and its likely environmental consequences, see Appendix F-1.

4.3.2 Spatial/Temporal Management of Total Allowable Catch

The times at which the groundfish fisheries may be open to allow fishing, and the areas that may be fished provide crucial variables for fisheries managers, who allocate the TACs by spatial/temporal determinations appropriate to various biological, environmental, and economic concerns. This qualitative analysis paper provides a broad overview of the current rationale for spatial/temporal management of the target fish TACs and examines how the measures identified in the alternatives and their FMP bookends would impact the spatial/temporal management of the target groundfish TACs. Potential changes would occur under Alternatives 3 and 4, where measures would be taken to manage all species on smaller spatial/temporal scales. For further detail on this FMP component and its likely environmental consequences, see Appendix F-2.

4.3.3 Marine Protected Areas and Essential Fish Habitat

Protection of marine habitats is an integral component of the groundfish FMPs for the BSAI and GOA. This qualitative analysis paper provides a review of proposed closure areas under the four policy alternatives and their direct/indirect effects on EFH and other aspects of the biological, physical, social, and economic environments. Beyond the continuation of the present risk-averse policy under Alternative 1, the more aggressive harvest policy of Alternative 2 assumes that present policy is overly conservative and may allow the opening of certain areas presently closed with the exception of Steller Sea Lion Protection Measures. Alternatives 3 and 4 represent increasingly risk-averse policies that would increase habitat protections and reduce fisheries impacts on habitat. For further detail on this FMP component and its likely environmental consequences, see Appendix F-3.

4.3.4 Steller Sea Lion Measures

Protection of Steller sea lions from potentially adverse impacts by the BSAI and GOA groundfish fisheries has been a component of the FMPs since 1990, when Steller sea lions were listed under the ESA. After a review of background information available on the decline of Steller sea lions and hypotheses for the decline, this qualitative analysis paper describes the current protection measures in place and evaluates the qualitative impacts of the four alternatives, as represented by their respective FMP bookends, on Steller sea lions. The present Steller sea lion protection measures, described in Alternative 1, are also included in the policies of Alternatives 2 and 3. Alternative 2, however, proposes a less precautionary approach that views additional regulatory safeguards as unwarranted. Alternative 3 assumes a greater impact on a number of environmental factors and consequently places more emphasis on research and on improving monitoring and enforcement of fishing restrictions within Steller sea lion critical habitat. Alternative 4 substantially increases protections for Steller sea lions by providing for a more conservative, risk-averse approach than the first three alternatives. Under Alternative 4, uncertainty about impacts and the shifting of the burden of proof would lead to significant reductions in current TACs and the establishment of larger buffer zones to further separate the groundfish fisheries from Steller sea lion critical habitat. The NPFMC could choose to suspend all fishing entirely until each fishery could be reviewed and certified as resulting in no significant adverse impacts. Certified fisheries would be subjected to more scrupulous monitoring and enforcement to ensure compliance with restrictions. A key component of all four alternatives is the requirement to remain in compliance with the ESA, and any changes that substantially alter the underlying requirements would require further Section 7 consultations under ESA. For further detail on this FMP component or its likely environmental consequences, see Appendix F-4.

4.3.5 Bycatch and Incidental Catch Restrictions

Bycatch is defined in the MSA as fish that are harvested in a fishery, but which are not sold or kept for personal use. This includes the portion of catch that is discarded back into the sea, and unobserved mortality due to a direct encounter with fishing gear that does not result in the capture of that species by a fisherman. The latter includes mortality due to lost or discarded fishing gear, as well as dropoff and escapement mortality. Discards include species that must be returned to the sea by law (known as regulatory discards), and fish that are discarded at the discretion of the fisherman because they are not worth keeping (know as economic discards). This qualitative analysis paper provides a broad overview of the different bycatch species and the four proposed policy alternatives as they pertain to the regulation of bycatch in the groundfish fisheries of the BSAI and GOA. Beyond the status quo policy of Alternative 1, the more aggressive harvest strategies of Alternative 2 could remove some of the current protections for some bycatch species. Conversely, added protections under Alternatives 3 and 4 would increase protection for at-risk bycatch species. The more restrictive bycatch limitations proposed under Alternatives 3 and 4 could place greater economic burdens on the groundfish industry. The rationalization and bycatch reduction incentive programs included in FMP 3.2 would tend to decrease the cost and increase the benefit of reducing bycatch for individual fishing operations. This would make further reductions in bycatch practicable, address the source of the problem of excess bycatch, and decrease the need for less efficient command and control solutions to the bycatch problems. For further detail on this FMP component and its likely environmental consequences, see Appendix F-5.

4.3.6 Seabird Measures

More than 70 species of seabirds occur over waters off Alaska and could potentially be affected by direct and indirect interactions with the federal groundfish fisheries off Alaska. This qualitative analysis paper compares the four policy alternatives and their respective FMP bookends specifically in regard to those management measures designed to protect seabirds. The four alternatives cover a wide range of possibilities for the evolution of seabird protection measures. Alternative 2 would require the minimum protection necessary to comply with the ESA concerning listed seabird species. Alternative 3 would place more emphasis on reducing incidental takes of all species of seabirds by improving seabird deterrent devices and avoidance techniques. Alternative 3 would also expand the Observer Program to improve the quality and amount of data collected on seabirds. Alternative 4 would seek to reduce incidental seabird take to levels approaching zero, in large part through the reduction in fishing effort until respective fisheries can be certified as having no adverse environmental impact. For further detail on this FMP component and its likely environmental consequences, see Appendix F-6.

4.3.7 Gear Restrictions and Allocations

Allocation of fishing privileges among users of different gear types is an important tool for managing the groundfish fisheries to achieve a number of biological and socioeconomic objectives. This qualitative analysis paper discusses current and proposed gear restrictions and allocations in the BSAI and GOA groundfish fisheries. The paper begins by identifying various types of management tools used to address allocation issues or implement allocation decisions, focusing particularly on gear restrictions. The paper then describes recent trends in the application of such allocation measures in the Alaska groundfish fisheries and concludes with a qualitative comparison of the impacts of the alternatives on gear restrictions. Alternative 1 would maintain current gear restrictions and allocations in the Alaska groundfish fisheries, as would FMP bookends 2.2 under Alternative 2 and 3.1 under Alternative 3. Example FMP 2.1, however, would eliminate all trawl and fixed gear restrictions, as well as trawl closure areas, with the exception of those closures implemented to protect Steller sea lions. The remaining, increasingly restrictive FMP bookends (example FMPs 3.2, 4.1, and 4.2) place greater prohibitions on the use of non-pelagic bottom trawl gear to harvest pollock in the GOA (example FMP 3.2); prohibit trawling in all fisheries that can be prosecuted with other gear types (example FMP 4.1); and prohibit all fishing for groundfish in the EEZ off Alaska (example FMP 4.2). For further detail on this FMP component and its likely environmental consequences, see Appendix F-7.

4.3.8 Overcapacity

Fishing capacity is the ability of a vessel or fleet of vessels to catch fish. Overcapacity occurs in an open access or regulated open access fishery where the race for fish induces fishermen to put increasingly more time, money, and effort into competing with other fishermen to maintain their share of the TAC. This qualitative analysis paper provides a discussion of various management systems for limiting effort and reducing excess capacity under the four policy alternatives. Alternative 1 would retain present effort limitation programs, such as the sablefish IFQ Program. Under the more aggressive harvest strategies of Alternative 2, such programs would be repealed with the exception of effort limitation measures under the AFA. The increasingly risk-averse policies represented by Alternatives 3 and 4 would either maintain or augment existing effort limitations programs. The paper speculates, however, that the extremely risk-averse policy of example FMP 4.2 would lead to extreme conditions of overcapacity. For further detail on this FMP component and its likely environmental consequences, see Appendix F-8.

4.3.9 Alaska Native Issues

Marine resources have always been an important part of the lives of Alaska Natives, both as subsistence resources and as integral parts of their different cultures. Consequently, changes in fisheries management policy proposed under the alternatives would have socioeconomic impacts on Alaska Natives. This qualitative analysis paper offers an analysis of those potential impacts, as well as the impacts that Alaska Natives themselves may have on management of the fisheries. Alaska Natives contribute to management through representation on the NPFMC and its Advisory Panel, through input into the decision-making process, and through the integration of local and Traditional Knowledge into scientific understanding of the resources and their environment. After reviewing issues of representation and input implicated by the alternatives, this paper proceeds to review impacts the alternatives may have on subsistence issues and concomitant concerns in regard to Environmental Justice for Alaska Natives. Measures contained in the FMP bookends for Alternatives 2 and 4 that would restrict or repeal the CDQ program or proscribe subsistence fishing would result in significant adverse impacts on the Native communities that rely on such fisheries. For further detail on this FMP component and its likely environmental consequences, see Appendix F-9.

4.3.10 The Observer Program

The North Pacific Groundfish Observer Program collects, maintains, and distributes data for the fisheries scientists and managers who must rely on such data to fulfill their responsibilities under the MSA. This qualitative analysis paper provides a description of the administration and operations of the Observer Program in detail and a qualitative discussion of the need for and impact on observer coverage under each of the four policy alternatives. The most drastic impacts would occur under Alternative 2. Example FMP 2.2 would leave the Observer Program essentially the same as at present, and example FMP 2.1 would virtually eliminate the Observer Program and its data collection activities. With the exception of AFA and CDQ pollock and crab fisheries, all other fisheries would cease to be monitored by observers, and the amount of data available for inseason management, as well as for scientific investigation, would be drastically reduced. Under the increasingly risk-averse policies of Alternatives 3 and 4, the Observer Program would either remain basically the same as at present (example FMP 3.1) or be modified to allow for increased observer coverage and data-collection (example FMPs 3.2, 4.1, and 4.2). For further detail on this FMP component and its likely environmental consequences, see Appendix F-10.

4.3.11 Data and Reporting Requirements

The MSA states that the collection of reliable data is essential to the effective conservation, management, and scientific understanding of the fishery resources of the United States. This qualitative analysis paper examines the effects of alternative approaches to data collection in the Alaska groundfish fisheries, focusing on the information collected from industry reporting requirements and VMS requirements for the groundfish fisheries. Alternative 1 and example FMP 2.2 would retain current reporting requirements. Example FMP 2.1 would eliminate measures requiring use of VMS and at-sea weighing of catch, except by catcher processors operating under the AFA. At present, the economic data collected on a routine basis are insufficient for a comprehensive regulatory analysis, and Alternatives 3 and 4 would create measures for the collection of economic data sufficient to give fishery managers a better understanding of socioeconomic issues. Alternatives 3 and 4 would also retain, expand, and improve upon existing reporting requirements. Example FMP 4.2, while it would effectively eliminate the need for reporting requirements, would create fishery-specific data-collection measures for those fisheries authorized to occur. For further detail on this FMP component and its likely environmental consequences, see Appendix F-11.

4.4 Summary of the Comparative Baseline

Chapter 3 of this document contains a comprehensive assessment of the human (physical, biological, and socioeconomic) environment potentially affected by the Alaska groundfish fisheries. For each of the resource categories used to analyze the impacts of the alternatives in this document, a comparative baseline has been developed. The baseline incorporates the state of the resource at a given point in time. In general, the baseline year is 2002 for physical and biological resources, and 2001 for socioeconomics. It is used to analyze the impacts of the alternatives.

The baseline does not represent a static 'snapshot' of the resource. Instead, it represents the trend of the resource, incorporating the past history of influences on the resource. The cumulative past effects of groundfish fishery activity, as well as effects external to the groundfish fishery such as other fishery impacts, human-induced impacts, and climatic events influencing the resource, all contribute to the state of the baseline condition.

In the table below, only those resource categories that were brought forward for alternatives impacts analysis are included. Some resource categories were identified in Chapter 3 as having in the past been impacted by the groundfish fisheries, but that interaction no longer occurs. More information on each resource category and the derivation of the baseline condition, can be accessed in the relevant section of Chapter 3.

The following is a list of tables containing information on resource categories and components:

Table number	Resource category	Components	Chapter 3 reference
4.4-1	Target groundfish species	Bering Sea and Aleutian Islands (BSAI) and Gulf of Alaska (GOA) walleye pollock, BSAI and GOA Pacific cod, BSAI and GOA sablefish, BSAI and GOA Atka mackerel, BSAI yellowfin sole, GOA shallow water flatfish, BSAI rock sole, BSAI and GOA flathead sole, BSAI and GOA arrowtooth flounder, BSAI Greenland turbot, GOA deepwater flatfish, BSAI Alaska plaice, BSAI other flatfish, GOA rex sole, BSAI and GOA Pacific ocean perch, GOA thornyhead rockfish, BSAI and GOA northern rockfish, BSAI and GOA shortraker/rougheye rockfish, BSAI other rockfish, GOA slope rockfish, GOA pelagic shelf rockfish, GOA demersal shelf rockfish	3.5.1
4.4-2	Prohibited species	Pacific halibut, Pacific salmon and steelhead trout, Pacific herring, crab	3.5.2
4.4-3	Other species, forage fish species, non-specified species	Other species category Forage fish category Grenadier	3.5.3, 3.5.4, 3.5.5
4.4-4	Habitat	BSAI, GOA	3.6
4.4-5	Seabirds	Black-footed albatross, Laysan albatross, short-tailed albatross, northern fulmar, shearwaters, storm-petrels, cormorants, spectacled eider, Steller's eider, jaegers, gulls, kittiwakes, terns, murres, guillemots, murrelets, auklets, puffins	3.7

Table number	Resource category	Components	Chapter 3 reference
4.4-6	Marine mammals	Steller sea lion, northern fur seal, Pacific walrus, harbor seal, spotted seal, bearded seal, ringed seal, ribbon seal, northern elephant, sea otter, blue whale, fin whale, sei whale, minke whale, humpback whale, gray whale, northern right whale, bowhead whale, sperm whale, beaked whales (Baird's, Cuvier's and Stejneger's), Pacific white-sided dolphin, killer whale, beluga whale, harbor porpoise, Dall's porpoise	3.8
4.4-7	Socioeconomics	Harvesting and processing Sector (catcher vessels [CVs], catcher processors [CPs], Inshore processors and motherships) Regional socioeconomic profiles (population, processing ownership and activity, CV ownership and activity, tax revenue, employment and income) Community development quota (CDQ) allocations Subsistence (subsistence use of groundfish, subsistence use of Steller sea lions, salmon subsistence fisheries, indirect subsistence factors: income and joint production) Environmental justice Market channels and benefits to United States consumers (product quantity, product year-round availability, product quality, product diversity) Non-market goods (benefits derived from marine ecosystems and associated species)	3.9.2 3.9.3 3.9.4 3.9.5 3.9.6 3.9.7 3.9.8
4.4-8	Ecosystem	Forage fish availability, spatial/temporal concentration of fisheries, introduction of non-native species, removal of top predators, energy redirection, energy removal, species diversity, guild diversity, genetic diversity	3.10

4.5 Alternative 1 Analysis

FMP 1 models status quo management, which has the goal of maintaining sustainable fisheries, protecting threatened and endangered species, and protecting, conserving, and restoring living marine resource habitats through existing institutions and processes. This alternative is described in detail in Section 2.6.

4.5.1 Target Groundfish Species Analysis

This section examines the potential direct, indirect, and cumulative effects that the implementation of FMP 1 is expected to have on the target groundfish species. The impact analyses start with the baseline (2002) status of the BSAI and GOA target groundfish stocks described in Section 3.5.1, including past trends that are likely to persist into the foreseeable future. Then, a computer-based analytic model is used to project how specific characteristics of the target groundfish stocks would respond directly and indirectly to management actions under FMP 1. These projections from the model are the predicted direct and indirect effects (impacts) of FMP 1 on the target groundfish stocks. Section 4.1.5 describes the analytic model and explains how it is applied.

The model output for each target groundfish stock is defined in terms of collected data and calculated measures that are standards used by fisheries managers to regulate the number of fish removed from the sea so that the fisheries will be sustainable over the long-term. These data and measures include the fishing mortality rate (F), the overfishing level (OFL), total and spawning biomass levels (B), the minimum stock size threshold (MSST), maximum sustainable yield (MSY), mean age of the stock in years, and the sex ratio of the stock (number of males compared to number of females). As discussed in the following subsections, relevant data are not always available for all stocks. When data gaps prevent application of the model to a specific stock, the projected direct or indirect effect is evaluated as unknown.

Each target groundfish stock is modeled with respect to the following direct and indirect effects:

Direct/Indirect Effects

Fishing Mortality: This is the rate at which the stock is depleted by direct mortality imposed by removing the fish from the sea.

Change in Biomass Level: This is the change over time in the biomass of the stock, as measured in metric tons (mt). Two measures are used: total biomass, which is the estimated biomass of the entire stock, and spawning biomass, which is the estimated biomass of all of the spawning females in the stock.

Spatial/Temporal Concentration of Catch: This is the degree to which the fishery will concentrate in a particular geographic area during a particular period of time each season. This pattern in space and time can affect fishing mortality and can also influence habitat suitability for spawning, rearing, and feeding.

Habitat Suitability: This is the degree to which habitat has the right characteristics to support the target stock at one or more life-history stages (spawning, rearing of juveniles, availability of food at all stages, availability of refuge areas to allow escape from predators at all stages). Habitat suitability can be affected directly, for example by mechanical damage from bottom trawling, or influenced indirectly, for example by the gradual depletion of corals that provide hard substrate.

Prey Availability: This is the extent to which prey species are present in the environment and available as food to the target stock. Like habitat suitability, this measure can be affected directly, for example by the direct removal of prey species by the fishery, or indirectly, for example by a change in the structure of the food web.

To determine their probable significance, the projected direct and indirect effects in each of the impact categories listed above are evaluated against significance criteria. The criteria are designed to be relevant and meaningful in terms of the target groundfish stocks. Each significance criterion includes a threshold value above (or below) which the projected effect would be considered significant. Each criterion also includes a definition of what would constitute a beneficial (positive, +) or adverse (negative, -) effect. The possible evaluations are significant and beneficial (S+), insignificant (I), significant and adverse (S-), and unknown (U). Evaluations of conditionally significant (CS + or -) are not made for projected direct and indirect effects on target groundfish species, because the model can show only whether the significance threshold is or is not exceeded. The significance criteria used for the target groundfish stocks are presented in Appendix A, Table 4.1-1.

Each of the following subsections presents the model results and rationale for the expected direct and indirect effects of FMP 1 on the target groundfish stocks. The significance ratings for these potential direct and indirect effects are presented in Appendix A, Table 4.5-83. Following the direct and indirect effects discussions on each stock, the expected cumulative effects on that stock are evaluated and discussed. The evaluation of potential cumulative effects builds on the direct and indirect effects evaluations as a starting point, and then brings in persistent past effects as well as reasonably foreseeable future natural events and human activities external to fisheries management. The cumulative effects assessment method uses the same impact categories and significance criteria discussed above for direct and indirect effects. This method is described further in Section 4.1.4.

4.5.1.1 Pollock

Numerous fishery management actions have been implemented that affect the pollock fisheries in the EBS and GOA. These actions are described in more detail in Sections 3.5.1.1 and 3.5.1.15 of this Programmatic SEIS. Pollock is managed as separate stocks in the BSAI and GOA, and falls under Tier 1 in both the BSAI and GOA groundfish FMPs.

Direct/Indirect Effects of FMP 1

The following discussions describe the analysis of potential direct and indirect impacts of FMP 1 on EBS and GOA pollock. As summarized in Table 4.5-83, all direct and indirect effects of FMP 1 on pollock are expected to be insignificant, as defined by the criteria in Table 4.1-1.

Fishing Mortality

The estimated fishing mortality for the EBS pollock stock in 2002 is 0.187. Model projections show this fishing mortality will increase by about 30 percent and average 0.228 for the period 2003-2007 (Table H.4-1 of Appendix H). These values are below the $F_{35\%}$ level of 0.448 and the $F_{40\%}$ level of 0.342, which are taken as proxies for F_{ABC} and F_{OFL}, respectively. This pattern in fishing mortality is due to the fact that the projected catch is expected to come closer to the actual ABC in future years. The proportion of SPR conserved under these mortality rates is 51 percent in 2003, decreasing to 48 percent by 2007; the average implied SPR rate of fishing from 2003-2007 is 49 percent. Fishing mortality for the Bogoslof and Aleutian Islands region is expected to remain at less than one percent under FMP 1 (Table H.4-2 of Appendix H). Because the projected changes are not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis, the effects of FMP 1 on fishing mortality for the EBS pollock stock are considered to be insignificant.

For the GOA, fishing mortality in 2002 is estimated at 0.174 with projections suggesting a decrease to 0.139 in 2003 followed by increases to 0.209 by 2007. The values for $F_{35\%}$ and $F_{40\%}$ are 0.350 and 0.294, respectively. The SPR rate in 2002 is estimated at 55 percent and averages about 56 percent for the period 2003-2007. This F pattern is due to the fact that under this FMP, the F_{ABC} is adjusted while the spawning stock is below $B_{40\%}$. Model projections for GOA fishing mortality are shown in Table H.4-23 of Appendix H. Because they are not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis, these changes in fishing mortality levels for GOA pollock are considered to be insignificant.

Change in Biomass Level

Total Biomass

Total biomass (ages 1 through 15+) of EBS pollock at the start of 2002 is estimated to be 12.97 million mt. Model projections of future total EBS pollock biomass are shown in Table H.4-1 of Appendix H. Under FMP 1, model projections indicate that EBS pollock biomass is expected to decrease to a value of about 11.3 million mt in 2004, then stabilize to about 11.6 million mt. The 2003-2007 average total biomass is projected to be 11.5 million mt. The direct effects of FMP 1 are considered insignificant, because the biomass levels estimated for 2003-2007 are expected to be above the biomass proxy value necessary to sustain maximum sustainable yield (B_{MSY}) and thus maintain the ability of the EBS stock to sustain itself above the MSST.

In the Aleutian Islands region, the assessments are based on trawl surveys that occur every other year. The most recent assessment indicates a biomass level of 175,000 mt. Given that under FMP 1 there is no directed fishing for pollock in this region (the exploitation level is quite low, less than 1 percent), the expectation is that the stock will remain stable or increase in the future. A similar pattern is expected for the Bogoslof Island pollock stock. For this reason, the direct effect of FMP 1 on the total biomass of the Aleutian Islands and Bogoslof Island pollock stocks is expected to be insignificant.

For GOA pollock, the age 2-10+ biomass is expected to increase under this FMP from a 2003 low of 800,000 mt to 1,210,000 mt by 2007. The average biomass over this period is expected to be 1,030,000 mt. This increase is anticipated primarily because recruitment is expected to improve from the recent series of relatively low levels. Model projections of future total GOA pollock biomass are shown in Table H.4-23 of Appendix H. The predicted direct effects of FMP 1 on GOA total pollock biomass are considered insignificant, because the biomass levels estimated for 2003-2007 are expected to maintain the ability of the GOA stock to sustain itself above the MSST.

Spawning Biomass

Female spawning biomass of EBS pollock in 2002 is estimated to be about 3.68 million mt. Model projections of future levels are shown in Table H.4-1 of Appendix H. Under FMP 1, projections indicate that EBS pollock spawning biomass will decrease to about 81 percent of the 2002 level by 2007. The projected average for 2003-2007 is 3.08 million mt. Because this level of decrease in female spawning biomass would not prevent the EBS pollock stock from sustaining itself at or above the MSST, the direct effect of FMP 1 on EBS pollock spawning biomass is considered to be insignificant.

In the Aleutian Islands region, spawning biomass is monitored by biannual trawl surveys. In the Bogoslof Island region, spawning stock is monitored by echo-integration trawl surveys. Since under FMP 1 these areas are kept at bycatch-only levels, we expect the spawning stock size to remain stable or increase in these regions. For this reason, the direct effect of FMP 1 on the spawning biomass of these stocks is expected to be insignificant.

The 2002 GOA female spawning biomass is estimated at about 136,000 mt and is anticipated to increase steadily to 228,000 mt by 2007 under FMP 1. This is above the estimated B_{MSY} level of 210,000 mt although the average from 2003-2007 is 183,000 mt. Model projections of future levels are shown in Table H.4-23 of Appendix H. Because the estimated increase in female spawning biomass is expected to maintain the ability of the GOA pollock stock to sustain itself above the MSST, this effect is considered to be insignificant.

Spatial/Temporal Concentration of Catch

The harvest of EBS pollock occurs largely along the western edge of the EBS shelf during the summer and around the southern areas east of 170°W during the winter season (January 20-March). Under FMP 1, an average of 1.4 million mt of EBS pollock is projected to be harvested annually from 2003-2007. The Bogoslof and Aleutian Island concentration of fishing mortality is anticipated to remain unchanged over this projection period. Because the spatial/temporal concentration of the catch under FMP 1 would not change notably from existing conditions, there is no evidence to suggest that harvest concentrations would be sufficient to alter genetic sub-populations or reproductive success in ways that affect the ability of the EBS pollock stock to sustain itself at or above the MSST. Therefore, this potential effect is considered to be insignificant.

Under FMP 1, an average of 87,300 mt of GOA pollock is projected to be harvested annually during 2003-2007 with the largest catch expected to be 133,000 mt in 2007. As the density and quotas of pollock change during this period, the concentration of the pollock fishery may change from the 2002 pattern. However, there is no indication that under FMP 1, harvest concentrations would change sufficiently to alter genetic sub-populations or reproductive success in ways that affect the ability of the GOA pollock stock to sustain itself at or above the MSST. Therefore, the direct effect of FMP 1 on the spatial and temporal concentration of the catch is expected to be insignificant relative to baseline conditions.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Given the similarity of FMP 1 to the status quo, however, it is unlikely that future levels of habitat disturbance would lead to a detectable change in spawning or rearing success sufficient to jeopardize the ability of the stocks to sustain themselves at or above the MSST. Therefore, the direct and indirect effects of FMP 1 on EBS and GOA pollock habitat suitability are expected to be insignificant.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. An evaluation of potential trophic interactions is presented in Section 3.10. Because of its similarity to the status quo, however, it is unlikely that FMP 1 would introduce changes in predator-prey interactions sufficient to affect the ability of pollock stocks to maintain themselves at or above the MSST. Therefore, the direct and indirect effects of FMP 1 on EBS and GOA pollock prey availability are expected to be insignificant.

Summary of Direct and Indirect Effects of FMP 1 on Pollock

The impact assessments discussed above indicate that the direct and indirect effects of FMP 1 on BSAI and GOA pollock would be insignificant for all of the effects categories (see Appendix A, Table 4.5-83). In addition, the fact that pollock would be fished at less than the OFL and above the MSST provides a separate rationale for considering the direct and indirect effects under FMP 1 to be insignificant. Fishing rates under this FMP would be well within accepted scientific standards, based on studies of population dynamics and estimates of natural variations in recruitment. Under these considerations, the spatial/temporal distribution of catch should have no significant direct impact on stock productivity. Based on extended 20-year projections (with the same model assumptions as used in the base 2003-2007 period), both the EBS and GOA pollock are expected to stabilize with catches lower than the expected long-term F_{ABC} catch levels and Bs above the B_{MSY} levels.

Status Determination from Modeling

Modeling projections for 2003-2007 indicate that under FMP 1, the future status of EBS and GOA pollock stocks would be as follows for key indicators.

Stock Size Relative to MSST

Under FMP 1, the ABC is set at a lower level than the OFL, creating a buffer between these two harvest regulations. Model projections of future catches of EBS pollock are below the ABC and OFL levels in all years. The EBS pollock are above their respective MSST in the year 2002 and in all subsequent projection years.

For FMP 1, GOA pollock spawning biomass is below the B_{MSY} (taken as $B_{35\%}$) in 2002 and remains below this level until 2007. However, based on 10-year status determinations projections, the stock is above the MSST for all years 2003-2007.

Age and Size Composition

Under FMP 1, the mean age of the EBS pollock stock at the end of 2007, as computed in model projections, is 2.53 years. This compares with a mean age in an equilibrium unfished stock of 3.16 years. For GOA pollock the 2007 value is 3.00 years compared with an unfished estimate of 3.60 years (note that the GOA pollock assessment is modeled from age 2-10+ while the EBS pollock is modeled from age 1-15). Model projections of EBS and GOA pollock age and size compositions are shown in Tables H.4-1 and H.4-23 of Appendix H.

Sex Ratio

In the models, the sex ratio of GOA and BSAI pollock are assumed to be 50:50. However, observer data and information from surveys are routinely collected and used to monitor the sex ratios of these stocks. Based on these data, it is unlikely that the sex ratio would be affected under FMP 1.

Cumulative Effects of FMP 1

External effects and the resultant cumulative effects associated with FMP 1 are shown in Tables 4.5-1 and 4.5-2. For further information regarding persistent past effects listed below in the text and in the tables, see Sections 3.5.1.1 and 3.5.1.15.

EBS Pollock

Mortality

- **Direct/Indirect Effects**. As described above under direct/indirect effects, the effect of fishing mortality on the EBS pollock stock is insignificant under FMP 1.

- **Persistent Past Effects.** The past effects of the foreign, Joint Venture (JV), and domestic fisheries are not expected for the EBS pollock stock. While large removals of pollock did occur in the past, there does not appear to be a lingering effect on the BSAI pollock populations (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** Removals of pollock occur in the Russian pollock fishery, and the catch is not accounted for in the annual harvest rates set for the U.S. fishery. Therefore, the removals can be considered a potential adverse effect on fishing mortality. Catch and bycatch of pollock in the State of Alaska pollock fisheries are not contributing factors since catch is accounted for. Marine pollution is also identified as having a reasonably foreseeable potential adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not identified as being contributors to pollock mortality.

- **Cumulative Effects.** The cumulative effects under FMP 1 is identified for mortality of EBS pollock, but the effect is judged to be insignificant. Pollock are fished at less than the OFL and are above the minimum stock size threshold (MSST). The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** As described above in Section 4.5.1.1, change in biomass of the EBS pollock stock is expected to be insignificant under FMP 1.

- **Persistent Past Effects.** While past large removals of pollock and other past effects on biomass have been identified (see Section 3.5.1.1), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects.** Future external effects on biomass are indicated due to removals in the Russian and State of Alaska pollock fisheries. However, the effects of any future removals are expected to be negligible and are not expected to affect the ability of the stock to maintain MSST. Marine pollution is identified as having a reasonably foreseeable potential adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not identified as being contributors to pollock mortality, and therefore would not directly affect biomass.

- **Cumulative Effects.** A cumulative effect on the change in biomass is identified; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently reduce the pollock biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1, the harvest of EBS pollock will continue to occur mostly along the western edge of the EBS shelf during the summer and around the southern areas east of 170°W longitude during the period (January 20 - March). Under these considerations, the spatial/temporal distribution of catch should have an insignificant effect on the genetic structure and reproductive success of the population.

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure since the past large removals of pollock and other past effects (see Section 3.5.1.1) have not had a lingering effect on the ability of the stock to sustain itself above MSST. However, since past fisheries could have had a beneficial effect on pollock recruitment by reducing the adult pollock biomass, lingering beneficial effects are identified for change in reproductive success. In addition, past commercial whaling and sealing also removed large predators of pollock, adding to the potential for reproductive success of the stock. Lingering past effects are also identified due to Climate Changes and Regime Shifts (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** The Russian and State of Alaska pollock fisheries have the potential to cause adverse effects. However, the removals are not expected to be sufficiently concentrated to alter the genetic structure of the population. On the other hand, removals in these fisheries could have a potential beneficial effect on pollock recruitment by reducing the adult pollock biomass. Cannibalism-related declines in pollock recruitment have been observed at high pollock spawning biomasses (see Section 3.5.1.1). Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events and also could result in reduced recruitment.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Any predation-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see above discussion of direct/indirect effects). However, it is determined that FMP 1 would have insignificant effects on pollock prey availability.

- **Persistent Past Effects.** While lingering population level effects from past foreign and domestic fisheries catch and bycatch of pollock prey species are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on pollock prey species (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** Past effects of climate changes and regime shifts on pollock prey species could have potential beneficial or potential adverse effects. A strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Likewise, a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. Marine pollution has also been identified as a reasonably foreseeable future external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The other fisheries shown on Table 4.5-1 are determined to be potential adverse contributors since catch and bycatch of prey species are likely to continue.

- **Cumulative Effects.** Cumulative effects are identified for prey availability; however, the effect is insignificant since the combination of internal and external removals of prey species is not expected to decrease prey availability such that the pollock stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, as with prey-mediated impacts, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see above discussion of direct/indirect effects). However, it is determined that FMP 1 would have insignificant effects on pollock habitat suitability.

- **Persistent Past Effects.** Past effects identified for EBS pollock stocks include past foreign, JV, and domestic fisheries, and climate changes and regime shifts (see Section 3.5.1.1). Intense bottom trawling for pollock in the past fisheries likely disrupted habitat in areas of the EBS. It is possible that some of these areas have not recovered from the intense efforts (see Section 3.6.4 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Future external are possible from the Russian and State of Alaska fisheries, since any of these may impact bottom habitat through use of fishing gear. Impacts on habitat from climate changes and regime shifts on the EBS pollock stock are unknown, although a strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Marine pollution has also been identified as a potential adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for habitat suitability; however, that effect on the EBS pollock stock is insignificant since the combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the pollock stock to sustain itself at or above MSST is jeopardized.

GOA Pollock

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA pollock stock is insignificant under FMP 1 (see Section 4.5.1.1 Direct/Indirect Effects discussion).

- **Persistent Past Effects.** Past effects of the foreign, JV, domestic, State of Alaska, and bait fisheries are not expected for the GOA pollock stock. While large removals of pollock did occur in the past, there does not appear to be a lingering effect on the GOA pollock populations (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** Catch and bycatch of pollock in the State of Alaska pollock fisheries, and State of Alaska shrimp fisheries, climate changes, and regime shifts are not considered to be contributors to fishing mortality in the cumulative case. Removals in these fisheries are accounted for when setting annual harvest levels for pollock and do not add additional fishing mortality. However, marine pollution could have a potential adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized.

- **Cumulative Effects.** A cumulative effect under FMP 1 is identified for mortality of GOA pollock, but the effect is judged to be insignificant. Pollock are fished at less than the OFL and are above the minimum stock size. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the GOA pollock stock is expected to be insignificant under FMP 1 (see Section 4.5.1.1).

- **Persistent Past Effects.** While past large removals of pollock and other past effects on biomass have been identified (see Section 3.5.1.1), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects.** Future external effects on biomass are indicated due to removals in the State of Alaska pollock fisheries. However, these removals are not expected to affect the ability of the stock to maintain MSST. Marine pollution is identified as having a potential adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not identified as being contributors to pollock mortality, thereby would not directly affect biomass.

- **Cumulative Effects.** A cumulative effect for change in biomass is identified; however, the combination of internal and external factors is not expected to sufficiently reduce the pollock biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch

- – Change in Genetic Structure of Population
- – Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1 in the GOA, impacts of the spatial/temporal changes should have an insignificant effect on the genetic structure and reproductive success of the population (see Section 4.5.1.1 Direct/Indirect Effects discussion).

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure since the past large removals of pollock and other past effects (see Section 3.5.1.1) have not had a lingering effect on the ability of the stock to sustain itself above MSST. However, there are lingering past effects due to Climate Changes and Regime Shifts (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** While there are potential adverse effects due to the State of Alaska pollock fisheries, and the State of Alaska shrimp fishery these fisheries are not sufficiently concentrated to alter the genetic structure of the population. Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration; however, the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Any predation-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see Section 4.5.1.1 Direct/Indirect Effects discussion). However, it is determined that FMP 1 would have insignificant effects on pollock prey availability.

- **Persistent Past Effects.** Lingering population level effects are not expected on these species from past foreign, state, and domestic fisheries catch and bycatch of pollock prey species, the effects of the *Exxon Valdez* Oil Spill (EVOS). However, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on pollock prey species (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** As described for BSAI pollock, climate changes and regime shifts could have beneficial or adverse effects depending on water temperature changes. Marine pollution is a potential contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The other fisheries shown on Table 4.5-2 are determined have potential adverse effects due to the removal of prey species as catch and bycatch. However, they are not likely to have population level effects on pollock.

- **Cumulative Effects.** Cumulative effects are identified for prey availability; however, the combination of internal and external removals of prey is not expected to decrease prey availability such that the pollock stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, as with prey-mediated impacts, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, it is determined that FMP 1 would have insignificant effects on pollock habitat suitability.

- **Persistent Past Effects.** Past effects on habitat suitability identified for GOA pollock stocks include past foreign, JV, State of Alaska, and domestic fisheries, EVOS, and climate changes and regime shifts (see Section 3.5.1.1). Intense bottom trawling for pollock in the past fisheries likely disrupted habitat in areas of the GOA. It is possible that some of these areas have not recovered from the intense efforts (see Section 3.6.4 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Future external effects are possible from the State of Alaska Pollock and Shrimp fisheries, since any of these may impact bottom habitat through use of fishing gear. Impacts on habitat from climate changes and regime shifts on the GOA pollock stock are unknown, although a strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Marine pollution has also been identified as a potential adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** Cumulative effects are identified for habitat suitability; however, that effect on the EBS pollock stock is insignificant since the combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the pollock stock to sustain itself at or above MSST is jeopardized.

4.5.1.2 Pacific Cod

Numerous fishery management actions have been implemented that affect the Pacific cod fisheries in the BSAI and GOA. These actions are described in more detail in Sections 3.5.1.2 and 3.5.1.16 of this Programmatic SEIS. Pacific cod is managed as separate stocks in the BSAI and GOA, both of which are managed under Tier 3a.

Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on BSAI and GOA Pacific cod. All direct and indirect effects of FMP 1 on Pacific cod are expected to be insignificant. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The F imposed on the BSAI Pacific cod stock in 2002 was estimated to be 0.228. Model projections of future BSAI Fs are shown in Table H.4-3 of Appendix H. Under FMP 1, model projections indicate that BSAI fishing mortality will increase to a value of 0.286 in 2003, decrease to a value of 0.269 in 2005, increase to a value of 0.274 in 2006,and then decrease to a value of 0.267 in 2007, with a 2003-2007 average of 0.275. These values are well below the F_{MSY} proxy value of 0.409, which is the rate associated with the overfishing level for stocks above $B_{40\%}$. The projected changes in the F are considered to be insignificant, because they would not jeopardize the capacity of the stock to produce MSY on a continuing basis.

The F imposed on the GOA Pacific cod stock in 2002 was estimated to be 0.255. Model projections of future GOA Fs are shown in Table H.4-24 of Appendix H. Under FMP 1, model projections indicate that GOA fishing mortality is expected to decrease steadily to a value of 0.204 in 2007, with a 2003-2007 average of 0.211. These values are well below the F_{MSY} proxy value of 0.421, which is the rate associated with the overfishing level for stocks above $B_{40\%}$. These projected changes in the F are also considered to be insignificant, because they would not jeopardize the capacity of the GOA stock to produce MSY on a continuing basis.

Change in Biomass Level

Total Biomass

Total (ages 1 through 12+) biomass of BSAI Pacific cod at the start of 2002 is estimated to be 1,933,000 mt. Model projections of future total BSAI biomasses are shown in Table H.4-3 of Appendix H. Under FMP 1, model projections indicate that total BSAI biomass is expected to increase steadily to a value of 2,118,000 mt in 2007, with a 2003-2007 average value of 2,086,000 mt. This projected increase is considered to be insignificant, because it would tend toward a level that would maintain the existing ability of the stock to sustain itself above the MSST.

Total (ages 1 through 12+) biomass of GOA Pacific cod at the start of 2002 is estimated to be 568,000 mt. Model projections of future total GOA biomasses are shown in Table H.4-24 of Appendix H. Under FMP 1, model projections indicate that total GOA biomass is expected to increase steadily to a value of 713,000 mt in 2007, with a 2003-2007 average value of 645,000 mt. This projected increase is considered to be insignificant, because it would tend toward a level that would maintain the existing ability of the stock to sustain itself above the MSST.

Spawning Biomass

Spawning biomass of female BSAI Pacific cod at the start of 2002 was estimated to be 404,500 mt. Model projections of future BSAI spawning biomasses are shown in Table H.4-3 of Appendix H. Under FMP 1, model projections indicate that BSAI spawning biomass is expected to decrease to a value of 403,000 mt in 2003, then increase to a value of 445,000 mt in 2006, then decrease to a value of 443,000 mt in 2007, with a 2003-2007 average value of 430,000 mt. Projected spawning biomass never dips below the B_{MSY} proxy value of 361,000 mt for the years 2003-2007. The projected fluctuations in B are considered to be insignificant, because they would tend toward levels that would maintain the existing ability of the stock to sustain itself above the MSST.

Spawning biomass of female GOA Pacific cod at the start of 2002 was estimated to be 97,900 mt. Model projections of future GOA spawning biomasses are shown in Table H.4-24 of Appendix H. Under FMP 1, model projections indicate that GOA spawning biomass is expected to decrease to a value of 86,400 mt in 2004, then increase to a value of 98,800 mt in 2007, with a 2003-2007 average value of 91,000 mt. Projected spawning biomass never dips below the B_{MSY} proxy value of 79,000 mt for the years 2003-2007. The projected fluctuations in B are considered to be insignificant, because they would tend toward levels that would maintain the existing ability of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch

Under FMP 1, it is likely that fishing for BSAI and GOA Pacific cod would tend, to some extent, to be concentrated in space and time so as to coincide with concentrations of spawning fish. Evaluating the effects of such concentrations of fishing mortality is problematic for two reasons: 1) Such concentrations of fishing mortality have already been in place for many years. Although the stocks currently appear to be healthy despite such concentrations, the absence of a "control" treatment makes it difficult to determine which population characteristics are attributable specifically to the existing spatial/temporal concentrations of fishing mortality. 2) Pacific cod undertake large migrations, and a high degree of genetic mixing appears to exist. In comparison to a sedentary species with readily identifiable genetic subunits, this means that the effects of spatial/temporal concentrations of fishing effort on Pacific cod are probably diluted to some extent, and also that their evaluation involves a larger number of difficult-to-estimate parameters. However, there is no indication that under FMP 1, harvest concentrations would change sufficiently to alter genetic sub-populations or reproductive success in ways that affect the ability of the GOA pollock stock to sustain itself at or above the MSST. Therefore, the direct effect of FMP 1 on the spatial and temporal concentration of the catch is expected to be insignificant relative to baseline conditions.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Because fishing practices under FMP 1 would be similar to the status quo, however, it is unlikely that future levels of habitat disturbance would lead to a detectable change in spawning or rearing success sufficient to jeopardize the ability of the stock to sustain itself at or above the

MSST. Therefore, the direct and indirect effects of FMP 1 on Pacific cod habitat suitability are expected to be insignificant.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Because of its similarity to the status quo, however, it seems unlikely that FMP 1 would introduce changes in predator-prey interactions sufficient to affect the ability of the Pacific cod stock to maintain itself at or above the MSST. Therefore, the direct and indirect effects of FMP 1 on prey availability for Pacific cod are expected to be insignificant.

Summary of Direct and Indirect Effects of FMP 1 on Pacific Cod

The criteria used to rate the significance of impacts of FMP 1 on the BSAI and GOA stocks of Pacific cod are identical to those used for the other groundfish stocks and are described in Appendix A, Table 4.1-1. Appendix A, Table 4.5-83 summarizes the expected effects of FMP 1 on Pacific cod. The rating of conditionally significant (either beneficial or adverse) is not applicable to any of the direct or indirect effects in this analysis, because the analytic model yields projections that can be classified only as significant (beneficial or adverse), insignificant, or unknown.

For the BSAI and GOA Pacific cod stocks, the impact of FMP 1 on fishing mortality and biomass is rated as insignificant, because the projection model indicates that fishing mortality would be less than the overfishing level and that biomass would be above the MSST throughout the period 2003-2007.

Because the existing spatial/temporal concentration of the catch does not appear to have led to changes in the genetic structure of the BSAI or GOA Pacific cod populations that materially affect either stock's ability to maintain itself at or above the MSST, and because the impacts of spatial/temporal concentration on genetic structure under FMP 1 are expected to be no greater than those of the existing concentration, the magnitude of this effect is rated as insignificant for both stocks.

Similarly, because the existing spatial/temporal concentration of the catch does not appear to have led to changes in the reproductive success of the BSAI or GOA Pacific cod populations that materially affect either stock's ability to maintain itself at or above the MSST, and because the impacts of spatial/temporal concentration on reproductive success under FMP 1 are expected to be no greater than those of the existing concentration, the magnitude of this effect is rated as insignificant for both stocks.

Because the existing level of groundfish harvest does not appear to have led to changes in prey availability for the BSAI or GOA Pacific cod populations that materially affect either stock's ability to maintain itself at or above the MSST, and because the level of groundfish harvest under FMP 1 is expected to be no greater than the existing level, the magnitude of this effect is rated as insignificant for both stocks.

Finally, because the existing level of habitat disturbance does not appear to have led to changes in spawning or rearing success in the BSAI or GOA Pacific cod populations that materially affect either stock's ability to maintain itself at or above the MSST, and because the level of habitat disturbance under FMP 1 is expected to be no greater than the existing level, the magnitude of this effect is rated as insignificant for both stocks.

Relationship to Comparative Baseline

The comparative baselines for BSAI and GOA Pacific cod are identical: neither stock is overfished, the biomass of each stock is below $B_{40\%}$ and has been decreasing for the last few years, and all catch and bycatch are accounted for in the management of both stocks. Under FMP 1, both stocks are projected to remain above MSST throughout the period 2003-2007; the biomass of the BSAI stock is projected to be above $B_{40\%}$ throughout the period 2003-2007 while the biomass of the GOA stock is projected to be below $B_{40\%}$ in 2003-2005, the biomass of each stock is expected to show an overall increase during the period 2003-2007 and beyond, and all catch and bycatch would continue to be accounted for in the management of both stocks.

Status Determination from Modeling

Modeling projections for 2003-2007 suggest that under FMP 1, the future status of the BSAI and GOA Pacific cod stocks would be as follows for key indicators.

Stock Size Relative to MSST

Model projections of future catches of BSAI and GOA Pacific cod are below their respective overfishing levels in all years under FMP 1 (Tables H.4-3 and H.4-24 of Appendix H). The BSAI and GOA Pacific cod stocks are projected to be above $B_{35\%}$ and therefore above their respective MSSTs in every year throughout the period 2003-2007.

Age and Size Composition

Under FMP 1, the projected mean age of the BSAI Pacific cod stock in 2008 is 2.8 years. This compares with a mean age in the equilibrium unfished BSAI stock of 3.2 years.

Under FMP 1, the projected mean age of the GOA Pacific cod stock in 2008 is 2.8 years. This compares with a mean age in the equilibrium unfished GOA stock of 3.2 years.

Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

The sex ratio of Pacific cod in both the BSAI and GOA is assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

External effects and the resultant cumulative effects associated with FMP 1 are depicted on Tables 4.5-3 and 4.5-4. For further information regarding persistent past effects listed below in the text and in the tables, see the past/present effects analysis section of Sections 3.5.1.2 and 3.5.1.16.

BSAI Pacific Cod

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI and Pacific cod stock is insignificant under FMP 1 (see the direct/indirect discussion above).

- **Persistent Past Effects.** Past effects of the foreign, JV, domestic, and State of Alaska bait fisheries are identified for the BSAI Pacific cod stock. Large removals of Pacific cod did occur in the past and could have a lingering effect on the present-day stock, the biomass of which is below $B_{40\%}$ (see above).

- **Reasonably Foreseeable Future External Effects.** While bycatch and removals of Pacific cod are predicted to continue in the International Pacific Halibut Commission (IPHC) longline fishery, State of Alaska crab fishery and subsistence/personal use fishery in the BSAI, these are not expected to be contributing factors to fishing mortality in the cumulative case. Removals in these fisheries are accounted for when setting annual harvest levels and do not add additional fishing mortality. Marine pollution is identified as having a reasonably foreseeable potential adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not identified as being contributors to Pacific cod mortality.

- **Cumulative Effects.** A cumulative effect under FMP 1 is identified for mortality of BSAI Pacific cod, but the effect is judged to be insignificant. Pacific cod are fished at less than the OFL and all catch and bycatch are accounted for in the management of the stock. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** As described in Section 4.5.1.2 direct/indirect effects, change in biomass of the BSAI Pacific cod stock is expected to be insignificant under FMP 1.

- **Persistent Past Effects.** While past large removals of Pacific cod and other past effects on biomass have been identified (see Section 3.5.1.2), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects.** Future external effects on biomass are indicated due to bycatch in the IPHC longline and State of Alaska crab fisheries and bycatch and removals in the subsistence/ personal use fishery in the BSAI. However, these removals are not expected to affect the ability of the stock to maintain MSST. Marine pollution is identified as having a reasonably foreseeable potential adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not identified as being contributors to Pacific cod mortality, thereby would not directly affect biomass.

- **Cumulative Effects.** A cumulative effect for change in biomass is identified; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently reduce the Pacific cod biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

<u>Spatial/Temporal Concentration of Catch</u>

- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1, the spatial/temporal distribution of catch should have an insignificant effect on the genetic structure and reproductive success of the population. Pacific cod are migratory species and a large degree of genetic mixing appears to exist. This likely means that the spatial/temporal concentration of fishing effort is diluted to some extent.

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure since the past large removals of Pacific cod and other past effects (see Section 3.5.1.2) have not had a lingering effect on the ability of the stock to sustain itself above MSST. However, since past fisheries could have had an adverse effect on Pacific cod recruitment, lingering effects are identified for change in reproductive success. Lingering past effects (either beneficial or adverse depending on the regime) are also identified due to Climate Changes and Regime Shifts (see Section 3.5.1.2).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline and State of Alaska crab fisheries, and subsistence use in the BSAI, have the potential to cause adverse effects. However, the removals are not expected to be sufficiently concentrated to alter the genetic structure of the population. Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** Any predation-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, it is determined that FMP 1 would have insignificant effects on Pacific cod prey availability (see the direct/indirect effects discussion).

- **Persistent Past Effects.** While lingering population level effects from past foreign and domestic and state fisheries catch and bycatch of Pacific cod prey species are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on Pacific cod prey species (see Section 3.5.1.2).

- **Reasonably Foreseeable Future External Effects.** Future external effects of climate changes and regime shifts on Pacific cod prey species are unknown; however, a strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Likewise, a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. Marine pollution has also been identified as a reasonably foreseeable future external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The other fisheries shown in Table 4.5-3 are determined to be potential adverse contributors since catch and bycatch of prey species are likely to continue.

- **Cumulative Effects.** Cumulative effects are identified for prey availability; however, the effects are insignificant since the combination of internal and external removals of prey is not expected to decrease prey availability such that the Pacific cod stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see above). Because the level of habitat disturbance under FMP 1 is expected to be no greater than the existing level, the effect is rated as insignificant.

- **Persistent Past Effects.** Past effects identified for BSAI Pacific cod stock include past foreign, JV, and domestic fisheries, the State of Alaska crab and bait fisheries, IPHC longline fishery, and climate changes and regime shifts (see Section 3.5.1.2). Previous Pacific cod fisheries likely disrupted habitat in areas of the BSAI. It is possible that some of these areas have not recovered (see Section 3.6.4 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Future external effects are possible from the State of Alaska fisheries, subsistence, and the IPHC fishery since any of these may impact bottom habitat through use of fishing gear. Impacts on habitat from climate changes and regime shifts on the BSAI Pacific cod stock are unknown, although a strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Marine pollution has also been identified as a potential adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for habitat suitability; however, the combination of internal and external impacts on habitat is not expected to jeopardize the Pacific cod stock such that it is unable to sustain itself at or above MSST.

GOA Pacific Cod

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA Pacific cod stock is insignificant under FMP 1 (see direct/indirect effects discussion above).

- **Persistent Past Effects.** Past effects of the foreign, JV, domestic, and State of Alaska bait fisheries are identified for the GOA Pacific cod stock. Additionally, the State of Alaska groundfish fishery contributed to past removals in the GOA. Large removals of Pacific cod did occur in the past and could have a lingering effect on the present-day stock, the biomass of which is below $B_{40\%}$ (see persistent past effects above).

- **Reasonably Foreseeable Future External Effects.** While bycatch and removals of Pacific cod are predicted to continue in the IPHC longline fishery, State of Alaska crab fishery, subsistence/personal use fishery, and in the State of Alaska groundfish fisheries in the GOA, these are not expected to be contributing factors to fishing mortality in the cumulative case. Removals in these fisheries are accounted for when setting annual harvest levels for pollock and do not add additional fishing mortality. Marine pollution is identified as having a reasonably foreseeable potential adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not identified as being contributors to Pacific cod mortality.

- **Cumulative Effects.** A cumulative effect under FMP 1 is identified for mortality of GOA Pacific cod, but the effect is judged to be insignificant. Pacific cod are fished at less than the OFL and all catch and bycatch are accounted for in the management of the stock. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the GOA Pacific cod stock is expected to be insignificant under FMP 1 (see Section 4.5.1.2 direct/indirect effects discussion).

- **Persistent Past Effects.** While past large removals of Pacific cod and other past effects on biomass have been identified (see Section 3.5.1.2), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects.** Future external effects on biomass are indicated due to bycatch in the IPHC longline and State of Alaska crab fisheries, and bycatch and removals in the subsistence/personal use fishery, and in the State of Alaska groundfish fisheries. However, these removals are not expected to affect the ability of the stock to maintain MSST. Marine pollution is identified as having a reasonably foreseeable potential adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not identified as being contributors to Pacific cod mortality, thereby would not directly affect biomass.

- **Cumulative Effects.** A cumulative effect for change in biomass is identified; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently reduce the Pacific cod biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch
- – Change in Genetic Structure of Population
- – Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1, the spatial/temporal distribution of catch should have an insignificant effect on the genetic structure and reproductive success of the population. Pacific cod are migratory species and a large degree of genetic mixing appears to exist. This likely means that the spatial/temporal concentration of fishing effort is diluted to some extent.

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure since the past large removals of Pacific cod and other past effects (see Section 3.5.1.2) have not had a lingering effect on the ability of the stock to sustain itself above MSST. However, since past fisheries could have had an adverse effect on Pacific cod recruitment particularly in the GOA where the state groundfish fishery is very localized, lingering effects are identified for change in reproductive success. Lingering past effects (either beneficial or adverse depending on the regime) are also identified due to Climate Changes and Regime Shifts (see Section 3.5.1.2).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline and State of Alaska crab fisheries, subsistence use, and State of Alaska groundfish fisheries have the potential to cause adverse effects. However, the removals are not expected to be sufficiently concentrated to alter the genetic structure of the population. Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Any predation-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see direct/indirect effects discussion). However, it is determined that FMP 1 would have insignificant effects on Pacific cod prey availability.

- **Persistent Past Effects.** While lingering population level effects from past foreign and domestic and state fisheries catch and bycatch of Pacific cod prey species are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on Pacific cod prey species (see Section 3.5.1.2).

- **Reasonably Foreseeable Future External Effects.** Future external effects of climate changes and regime shifts on Pacific cod prey species are unknown; however, a strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Likewise, a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. Marine pollution has also been identified as a reasonably foreseeable future external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The other fisheries shown on Table 4.5-4 are determined to be potential adverse contributors since catch and bycatch of prey species are likely to continue.

- **Cumulative Effects.** Cumulative effects are identified for prey availability; however, the effect is insignificant since the combination of internal and external removals of prey is not expected to decrease prey availability such that the Pacific cod stock is unable to sustain itself at or above MSST.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** Under FMP 1, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see Section 4.5.1.2 direct/indirect effects discussion above). Because the level of habitat disturbance under FMP 1 is expected to be no greater than the existing level, the effect is rated as insignificant.

- **Persistent Past Effects.** Past effects identified for GOA Pacific cod include past foreign, JV, and domestic fisheries, the State of Alaska crab and bait fisheries, IPHC longline fishery, and climate changes and regime shifts (see Section 3.5.1.2). Additionally, the State of Alaska groundfish fishery contributed to habitat impacts in the GOA. Past fishing for Pacific cod in the past fisheries likely disrupted habitat in areas of the GOA. It is possible that some of these areas have not recovered (see Section 3.6.4 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Future external effects are possible from the State of Alaska fisheries, subsistence, and the IPHC fishery since any of these may impact bottom habitat through use of fishing gear. Impacts on habitat from climate changes and regime shifts on the GOA Pacific cod stock are unknown, although a strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Marine pollution has also been identified as a potential adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for habitat suitability; however, the combination of internal and external impacts on habitat is not expected to jeopardize the ability of the Pacific cod stock to sustain itself at or above MSST.

4.5.1.3 Sablefish

This section provides the direct, indirect, and cumulative effects analyses for sablefish under FMP 1. Sablefish are managed as one stock in the BSAI and GOA under Tier 3b; therefore, BSAI and GOA areas are discussed together in this section.

Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on sablefish. All direct and indirect effects of FMP 1 on sablefish are expected to be insignificant. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1. Sections 3.5.1.3 and 3.5.1.17 provide additional information on the past/present effects analysis for BSAI and GOA sablefish.

Fishing Mortality

Under FMP 1, the fishing mortalities imposed on the sablefish stock are well below the F_{MSY} proxy value of 0.14 which is the rate associated with the OFL. Model projections of future BSAI and GOA fishing mortalities are shown in Tables H.4-11 and H.4-30 of Appendix H. The projected changes in the F are considered to be insignificant, because they would not jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

Total Biomass

FMP 1 is projected to have an insignificant impact on total biomass (age 2-31+) compared to the baseline. FMP 1 assumptions are intended to replicate baseline conditions, in which biomass tends toward levels that maintain the ability of the BSAI and GOA sablefish stocks to sustain themselves above the MSST. Total biomass increases from 2002-2007 under FMP 1 because long-term average recruitment (1977-present) is used to project biomass and is higher than most of the recent recruitments. Model projections of future BSAI and GOA total biomasses are shown in Tables H.4-11 and H.4-30 of Appendix H.

Spawning Biomass

FMP 1 is projected to have an insignificant impact on spawning biomass compared to the baseline. FMP 1 assumptions are intended to replicate baseline conditions, in which biomass tends toward levels that maintain the ability of the BSAI and GOA sablefish stocks to sustain themselves above the MSST. Spawning biomass decreases from 2002-2007 under FMP 1 because the strong 1997 year-class is decreasing in abundance and is the only strong year-class among recent recruitments.

Spawning biomass is projected to decrease from 2002-2007 while total biomass is projected to increase during the same interval. Total biomass includes ages 2-30+ while spawning biomass includes ages 6.5-30+ (initial age is average age of first spawning for females) so that spawning biomass trends due to changing recruitment lag total biomass trends. Spawning biomass will likely increase for a longer projection. Model projections of future BSAI and GOA spawning biomasses are shown in Tables H.4-11 and H.4-30 of Appendix H.

Spatial/Temporal Concentration of Catch

Sablefish fishing is concentrated along the upper continental slope and deepwater gullies. FMP 1 is projected to have an insignificant impact on the spatial/temporal concentration of fishing mortality compared to the baseline. FMP 1 assumptions are intended to replicate baseline conditions.

Habitat Suitability

Because fishing practices under FMP 1 would be similar baseline conditions, it is unlikely that future levels of habitat disturbance would lead to a detectable change in spawning or rearing success sufficient to jeopardize the ability of the BSAI and GOA sablefish stocks to sustain themselves at or above the MSST. Therefore, the direct and indirect effects of FMP 1 on sablefish habitat suitability are expected to be insignificant.

Prey Availability

It is unlikely that FMP 1 would introduce changes in predator-prey interactions sufficient to affect the ability of the BSAI and GOA sablefish stocks to maintain themselves at or above the MSST, because status quo fishing practices would continue under this FMP. Therefore, the direct and indirect effects of FMP 1 on prey availability for sablefish are expected to be insignificant.

Summary of Direct and Indirect Effects of FMP 1 on Sablefish

All direct and indirect effects are found to be insignificant for sablefish under FMP 1.

Status Determination from Modeling

Modeling projections for 2003-2007 suggest that under FMP 1, the future status of EBS and GOA sablefish stocks would be as follows for key indicators.

Catch Relative to ABC

FMP 1 is projected to have an insignificant impact on average sablefish yield compared to the baseline. Yields similar to current levels are projected because FMP 1 assumptions are intended to replicate baseline conditions. Under FMP 1, therefore, sablefish would not be overfished or approach an overfished condition.

Age and Size Composition

FMP 1 is projected to have an insignificant impact on sablefish mean age relative to the baseline. The mean ages actually observed in 2008 (as opposed to projections of mean ages) will be driven largely by incoming recruitment strengths during the intervening years.

BSAI mean age likely is overestimated. The model assumes that the lower exploitation rate for the BSAI compared to the GOA will translate into greater mean age for the BSAI. However, sablefish migration is substantial enough to erase the effects of differential exploitation rates between the BSAI and GOA. The mean age for the GOA best represents the mean age for the BSAI/GOA because sablefish abundance is much greater for the GOA.

Sex Ratio

The sex ratio of the adult population is 40 males: 60 females, based on sex ratio data collected during sablefish longline surveys. This FMP probably would have no significant effect on the sex ratio relative to the baseline.

Cumulative Effects of FMP 1

External effects and the resultant cumulative effects associated with FMP 1 are shown in Table 4.5-5.

<u>Mortality</u>

- **Direct/Indirect Effects.** The effect of fishing mortality on the sablefish stock is insignificant under FMP 1 (see Section 4.5.1.3 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects of the foreign, JV, domestic, and State of Alaska groundfish fisheries are identified for sablefish. Large removals of sablefish occurred, particularly in the JV, and domestic fisheries. Catches that were under-reported during the late 1980s may have contributed to abundance declines in the 1990s. (see Section 3.5.1.3).

- **Reasonably Foreseeable Future External Effects.** While bycatch and removals of sablefish are predicted to continue in the IPHC longline and State of Alaska groundfish fisheries, these are not expected to be contributing factors to fishing mortality in the cumulative case. Removals in these fisheries are accounted for when setting annual harvest levels and do not add additional fishing mortality. Due the highly migratory nature, Canadian fisheries fishing within Canadian waters could be harvesting sablefish considered to be part of the GOA population. These removals are not accounted for in the TAC setting process and can be considered as having a potential adverse contribution to the cumulative case. Likewise, marine pollution is identified as having a reasonably foreseeable potential adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality sufficient to jeopardize the capacity of the stock to produce MSY on a continuing basis. Climate changes and regime shifts are not identified as being contributors to direct sablefish mortality.

- **Cumulative Effects.** A cumulative effect under FMP 1 is identified for mortality of sablefish, but the effect is judged to be insignificant. Sablefish are fished at less than the OFL and all catch and bycatch are accounted for (with the exception of any fish taken in Canadian waters) in the management of the stock. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the sablefish stock is expected to be insignificant under FMP 1 (see Section 4.5.1.3 direct/indirect Effects discussion).

- **Persistent Past Effects.** While past large removals of sablefish and other past effects on biomass have been identified (see Section 3.5.1.3), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects.** Future external effects on biomass are indicated due to catch and bycatch in the IPHC longline and State of Alaska groundfish fisheries, and in the Canadian fisheries. Marine pollution is identified as having a reasonably foreseeable potential adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not identified as being contributors to sablefish mortality, thereby would not directly affect biomass.

- **Cumulative Effects.** A cumulative effect on the change in biomass is identified; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently reduce the sablefish biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch
  – Change in Genetic Structure of Population
  – Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1, the spatial/temporal distribution of catch should have an insignificant effect on the genetic structure and reproductive success of the population. Sablefish fishing is concentrated along the upper continental slope and deepwater gullies. FMP 1 is projected to have an insignificant impact on the spatial/temporal concentration of fishing mortality compared to the baseline. FMP 1 assumptions are intended to replicate baseline conditions.

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure or reproductive success. While spatial/temporal concentration of catch occurred in the state directed sablefish fisheries, there are no lingering effects due to the migratory nature of the fish (see Section 3.5.1.3).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline, State of Alaska groundfish, and Canadian fisheries all have the potential to cause adverse effects. However, the removals are not expected to be sufficiently concentrated to alter the genetic structure of the population or affect recruitment. Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Any predation-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, it is determined that the FMP would have insignificant effects on sablefish prey availability.

- **Persistent Past Effects.** While lingering population level effects from catch and bycatch of sablefish prey species in past foreign and domestic and state fisheries are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on sablefish prey species (see Section 3.5.1.3).

- **Reasonably Foreseeable Future External Effects.** Future external effects of climate changes and regime shifts on sablefish prey species are unknown; however, a strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Likewise, a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment (see Section 3.5.1.3). Marine pollution has also been identified as a reasonably foreseeable future external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The other fisheries shown on Table 4.5-5 are determined to be potential adverse contributors since catch and bycatch of prey species are likely to continue.

- **Cumulative Effects.** Cumulative effects are identified for prey availability; however, the effect is insignificant since the combination of internal and external removals of prey is not expected to decrease prey availability such that the sablefish stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, it is determined that the FMP would have insignificant effects on sablefish habitat suitability.

- **Persistent Past Effects.** Past effects identified for sablefish include past foreign, JV, and domestic fisheries, the State of Alaska crab and bait fisheries, IPHC longline fishery, and climate changes and regime shifts (see Section 3.5.1.3). Past fishing for sablefish in the past fisheries likely disrupted habitat in areas of the GOA and possibly the BSAI. It is possible that some of these areas have not recovered (see Section 3.6.4 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Future external effects are possible from the State of Alaska fisheries, and the IPHC fishery since any of these may impact bottom habitat through use of fishing gear. Impacts on habitat from climate changes and regime shifts on the sablefish stock are unknown, although a strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Marine pollution has also been identified as a potential adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** Cumulative effects are identified for habitat suitability; however, those effects on the sablefish stock are insignificant since the combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the sablefish stock to sustain itself at or above MSST is jeopardized.

4.5.1.4 Atka Mackerel

Numerous fishery management actions have been implemented that affect the Atka mackerel fisheries in the BSAI and GOA. These actions are described in more detail in Sections 3.5.1.4 and 3.5.1.18 of this Programmatic SEIS. Atka mackerel is managed as separate stocks in the BSAI and GOA; in the BSAI it falls under Tier 3a of the ABC and OFL definitions. However, in the GOA this target species is managed under Tier 6.

Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on BSAI and GOA Atka mackerel. All direct and indirect effects of FMP 1 on BSAI Atka mackerel are expected to be insignificant. The potential effects on the GOA stock are unknown. Significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Model projections of future BSAI Atka mackerel catch and biomass levels under FMP 1 assume the maximum permissible F according to Amendment 56 ABC/OFL definitions. Currently, BSAI Atka mackerel are harvested at a more conservative rate than the maximum allowable, but the rates have varied as set by the NPFMC. Given the difficulty in predicting the future ABC levels to be set by the NPFMC, the projections assume the default Amendment 56 values. Therefore, under FMP 1, projections may suggest higher than expected catches and lower than expected biomass levels, at least in the very short-term.

GOA Atka mackerel are managed in Tier 6 because current estimates of total and spawning biomass are unknown. Age-structured models were not available for evaluation of impacts for the GOA; therefore, model projections of future biomass levels were not produced.

<u>Fishing Mortality</u>

The average expected yield for BSAI Atka mackerel during the period 2003-2007 is 62,700 mt (Table H.4-17 of Appendix H). The catch and ABC values, which are nearly equivalent in the projections, are expected to decrease through 2006. The average fishing mortality imposed on the BSAI Atka mackerel stock in 2002 is 0.251. Model projections show this value will increase to 0.436 in 2004, then decrease in 2005 and increase to 0.401 in 2007. Overall, the projections show a 60 percent increase in the average fishing mortality from 2002 to 2007. These values are well below the F_{MSY} proxy ($F_{35\%}$) value of 0.564, which is the rate associated with the OFL. Therefore, the projected Fs for BSAI Atka mackerel under FMP 1 are considered to be insignificant, because they would not jeopardize the capacity of the stocks to produce MSY on a continuing basis.

The current GOA ABC and TAC level is 600 mt. This low level of TAC is intended to preclude a directed fishery and only provide for bycatch in other fisheries. This harvest strategy has been applied to GOA Atka mackerel since 1997 as a conservative measure to accommodate the lack of a reliable current estimate of biomass, and to recognize that GOA Atka mackerel may be particularly vulnerable to fishing pressure because of its patchy distribution and sporadic recruitment patterns (Lowe *et al.* 2002).

Projections of GOA Atka mackerel under FMP 1 indicate that catches will likely average 100 mt through 2007 (Table H.4-38 of Appendix H). Annual changes in the GOA Atka mackerel catches reflect shifts in catches of other species which catch Atka mackerel as bycatch (e.g. Pacific ocean perch, pollock, northern rockfish, and Pacific cod). Because data on which to establish a reliable current estimate of biomass for GOA Atka mackerel are lacking, the effects of fishing mortality on Atka mackerel under FMP 1 are unknown.

Change in Biomass Level

Total Biomass

Total (ages 1-15+) biomass of BSAI Atka mackerel at the start of 2002 is estimated to be 480,000 mt. Model projections of future total BSAI total biomasses are shown in Table H.4-17 of Appendix H. Under FMP 1, model projections indicate that total BSAI Atka mackerel is expected to decline to a value of 415,000 mt by 2005, then increase to a value of 442,000 mt by 2007, with a 2003-2007 average value of 435,000 mt. Overall, the projections show an 8 percent decrease in total biomass from 2002 to 2007 under FMP 1. This projected decrease is considered to be insignificant, because total Atka mackerel biomass in the BSAI would stay within a range that would maintain the existing ability of the stock to sustain itself above the MSST. Potential effects of FMP 1 on GOA Atka mackerel total biomass are unknown, because reliable estimates of the current total biomass are not available to support modeling.

Spawning Biomass

Spawning biomass of female BSAI Atka mackerel at the start of 2002 is estimated at 118,500 mt. Model projections of future BSAI spawning biomasses are shown in Table H.4-17 of Appendix H. Under FMP 1, model projections indicate that BSAI spawning biomass is expected to decline to a value of 78,500 mt by 2005, then increase to a value of 88,000 mt by 2007, with a 2003-2007 average value of 88,900 mt. Overall, the projections show about a 26 percent decrease in female spawning biomass from 2002 to 2007 under FMP 1. Projected spawning biomass exceeds the B_{MSY} proxy value ($B_{35\%}$) of 77,800 mt for the projection years (2003-2007). Although the BSAI Atka mackerel spawning biomass is projected to decline, it would stay within a range that would maintain the existing ability of the stock to sustain itself above the MSST. Therefore, this potential effect under FMP 1 is considered to be insignificant. Potential effects of FMP 1 on GOA Atka mackerel spawning biomass are unknown, because reliable estimates of the current spawning biomass are not available to support modeling.

Spatial/Temporal Concentration of Catch

Under FMP 1, the current network of spatial/temporal closed areas would remain in place. The closures designated in the Steller sea lion protection measures would probably have the largest impact relative to Atka mackerel.

The directed fishery for Atka mackerel is prosecuted by catcher processor bottom trawlers. The patterns of the fishery generally reflect the behavior of the species in that the fishery is highly localized, occurring in the same few locations each year, at depths that typically range between 100 and 200 m. The localized pattern of fishing for Atka mackerel apparently does not affect fishing success from one year to the next since local populations in the Aleutians appear to be replenished by immigration and recruitment. In addition, management measures are in place which have the effect of spreading out the harvest in time and space. The overall BSAI TAC is allocated to three management areas (Western, Central, and Bering Sea/Eastern Aleutians). The regional TACs are further allocated to two seasons, and there are limits to the amount of catch that can be taken inside of Steller sea lion critical habitat. Because Steller sea lion critical habitat overlaps significantly with Atka mackerel habitat, these measures provide protection to Atka mackerel by reducing the risk of localized depletion through effort limitations and reductions. The temporal/spatial concentration of the catch under FMP 1 does not appear to affect the sustainability of the stock either through changes in the genetic structure of the population or changes in reproductive success, as measured by the ability of the stock to maintain itself above its MSST. Under FMP 1, therefore, the spatial and temporal pattern of catch concentration would have an insignificant effect on BSAI Atka mackerel relative to the baseline.

Because population data are lacking on the GOA Atka mackerel stock, its MSST is unknown. Therefore, the potential effects of the spatial and temporal pattern of catch on this stock under FMP 1 are unknown.

Habitat Suitability

Because Steller sea lion critical habitat overlaps significantly with BSAI Atka mackerel habitat, Steller sea lion protection measures may provide habitat protection for Atka mackerel through effort limitations and reductions. The level of habitat disturbance caused by the fishery under FMP 1 does not appear likely to affect the sustainability of the stock as measured by the ability of the stock to maintain itself above its MSST. Therefore, impacts on habitat suitability for BSAI Atka mackerel would be insignificant under FMP 1. It is not known what effect implementation of FMP 1 would have on habitat suitability for GOA Atka mackerel, although fishing practices would be similar to those under the status quo.

Prey Availability

The trophic interactions of Atka mackerel are governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next five years under FMP 1. In a study conducted by Yang (1996), more than 90 percent of the total stomach contents weight of Atka mackerel in the study was made up of invertebrates, with less than 10 percent made up of fish. The current levels and distribution of harvest do not appear to affect prey availability in ways that impair the ability of the stock to maintain itself above its MSST. Therefore, it is likely that potential effects of FMP 1 on prey availability for BSAI and GOA Atka mackerel would be insignificant.

Summary of Direct and Indirect Effects of FMP 1 on Atka Mackerel

The criteria used to estimate the significance of potential effects of the FMPs on the BSAI and GOA stocks of Atka mackerel are outlined in Section 4.1.1.1. The expected direct and indirect effects of FMP 1 on BSAI and GOA Atka mackerel are summarized in Appendix A, Table 4.5-83. Potential direct and indirect impacts of FMP 1 on the BSAI and GOA Atka mackerel stocks are rated as either insignificant or unknown. The ratings of conditionally significant (either beneficial or adverse) are not applicable in this analysis, as the model projections could yield only results that were deemed significant (beneficial or adverse), insignificant, or unknown.

The ratings use the overF (F_{OFL}), the MSST for the fishing mortality effect, and the MSST for all other effects as the bases for evaluating the potential impacts of FMP 1 on Atka mackerel. Because the mean projected BSAI Atka mackerel Fs are below the overF, and the spawning stock is above its MSST in each of the projection years (2003-2007), the fishing mortality effect of FMP 1 is rated as insignificant. As noted above, the spawning stock biomass of BSAI Atka mackerel in each of the projection years (2003-2007) is above $B_{35\%}$ (B_{MSY} proxy), and therefore the BSAI Atka mackerel stock is determined to be above its MSST under FMP 1. For all other direct and indirect effects, it was determined that FMP 1 would not jeopardize the ability of the BSAI Atka mackerel stock to sustain itself at or above its MSST, and the effects were accordingly rated as insignificant.

Relative to the comparative baseline under FMP 1, the BSAI Atka mackerel stock is not overfished. Spawning biomass declines through 2005, after which biomass increases. Long-term projections (10- and 20-year projections) of spawning biomass show a very stable trend in biomass after 2007, with levels just above the 2007 level of 88,000 mt.

The F and the MSST for GOA Atka mackerel are unknown, and thus the effect of fishing mortality is unknown under FMP 1. As the MSST cannot be estimated for GOA Atka mackerel, which are in Tier 6, the significance of the spatial/temporal concentration and habitat suitability effects is also unknown under FMP 1. Although the MSST cannot be estimated for GOA Atka mackerel, due to the low proportion of fish found in the diet of Atka mackerel, it is presumed that FMP 1 will not affect prey availability for BSAI or GOA Atka mackerel, and the potential impact on prey availability is considered to be insignificant.

Relative to the baseline, the GOA Atka mackerel stock under FMP 1 is likely to remain at a low abundance with continued low exploitation as a bycatch fishery only.

Status Determination from Modeling

Modeling projections for 2003-2007 suggest that under FMP 1, the future status of EBS and GOA atka mackerel stocks would be as follows for key indicators.

Stock Size Relative to MSST

Model projections of future catches of BSAI Atka mackerel are below the overfishing level in all years under FMP 1 (Table H.4-17 of Appendix H). Female spawning biomass in each of the projection years (2003-2007), is above $B_{35\%}$ (B_{MSY} proxy). These indicators suggest that the BSAI Atka mackerel stock is not overfished and is above its MSST under FMP 1.

GOA Atka mackerel are in Tier 6, and the MSST is unknown. Therefore, a status determination cannot be made for this stock.

Age and Size Composition

Under FMP 1, the mean age of BSAI Atka mackerel in 2007, as computed in model projections, is 2.74 years. This compares with a mean age in the equilibrium unfished BSAI stock of 3.82 years. Note that the mean ages and sizes actually observed in 2007 (as opposed to the model projections of mean age in 2007) will be driven largely by the strengths of incoming recruitments during the intervening years. The selectivity of the fishery has cumulative impacts on the age composition due to fishing mortality, and the current composition is also the result of its being a fished population with a greater than 30-year catch history. In the short-term, however, the impacts of the current fishing mortality levels on the stock would be overshadowed by the magnitude of incoming year-classes, which in turn are highly dependent on environmental conditions. The cumulative long-term impacts of the Fs could cause a shift in the age and size compositions.

Because the level of catch of GOA Atka mackerel is very low and projected to remain at the same low level under FMP 1, it is unlikely that the age and size compositions would change in the future under this FMP. Changes in the age and size compositions of GOA Atka mackerel are more likely driven by variations in recruitment than by the effects of fishing.

Sex Ratio

A 50:50 sex ratio is assumed for the BSAI Atka mackerel stock assessment and model projections. It is unknown what the true population sex ratio is, and what change, if any, would occur in the future under FMP 1. The current population sex ratio of GOA Atka mackerel is unknown. The true GOA population sex ratio and what changes, if any, would occur in the future under FMP 1 are unknown.

Cumulative Effects of FMP 1

External effects and the resultant cumulative effects associated with FMP 1 are shown in Tables 4.5-6 and 4.5-7. For further information regarding persistent past effects listed below in the text and in the tables, see the past/present effects analysis section of Sections 3.5.1.4 and 3.5.1.18.

BSAI Atka Mackerel

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI Atka mackerel stock is insignificant under FMP 1 (see Section 4.5.1.4 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects of the foreign, JV, and domestic fisheries are not expected for the BSAI Atka mackerel stock. While large removals of Atka mackerel did occur in the past, there does not appear to be a lingering effect on the BSAI Atka mackerel populations (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Marine pollution has been identified as the only external event that could cause effects on the BSAI Atka mackerel population. Acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not identified as being contributors to Atka mackerel mortality.

- **Cumulative Effects.** A cumulative effect under FMP 1 is identified for mortality of BSAI Atka mackerel, but the effect is judged to be insignificant. Atka mackerel are fished at less than the OFL and are above the MSS. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

<u>Change in Biomass</u>

- **Direct/Indirect Effects.** Change in biomass of the BSAI Atka mackerel stock is expected to be insignificant under FMP 1 (see Section 4.5.1.4 direct/indirect effects discussion).

- **Persistent Past Effects.** While past large removals of Atka mackerel and other past effects on biomass have been identified (see Section 3.5.1.4), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as having a reasonably foreseeable potential adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not identified as being contributors to Atka mackerel mortality, and therefore would not directly affect biomass.

- **Cumulative Effects.** A cumulative effect for change in biomass is identified; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently reduce the Atka mackerel biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

<u>Spatial/Temporal Concentration of Catch</u>
- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** As described under the internal effects section, the temporal/spatial concentration of the catch under FMP 1 does not appear to affect the sustainability of the stock either through changes in the genetic structure of the population or changes in reproductive success, as measured by the ability of the stock to maintain itself above its MSST.

- **Persistent Past Effects.** Since the Atka mackerel fishery was highly localized, past foreign, JV, and domestic fisheries are found to have had lingering effects on the spatial/temporal distribution of the fish. However, the effect of this change in distribution on genetic structure is unknown. Past commercial whaling and sealing removed large predators of Atka mackerel adding to the potential for reproductive success of the stock. Lingering past effects are also identified due to climate changes and regime shifts (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment. Climate changes and regime shifts could have potential beneficial or potential adverse effects on Atka mackerel reproductive success. A shift toward colder waters favors recruitment and survival of Atka mackerel. Conversely, warmer waters are potentially adverse.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** As described above under the direct/indirect effects section, the current levels and distribution of harvest do not appear to impact prey availability such that it affects the sustainability of the stock as measured by the ability of the stock to maintain itself above its MSST and the effect is judged insignificant.

- **Persistent Past Effects.** While lingering population level effects from past foreign and domestic fisheries catch and bycatch of Atka mackerel prey species are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on Atka mackerel prey species (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Climate changes and regime shifts could have potential beneficial or potential adverse effects on Atka mackerel reproductive success. A shift toward colder waters favors recruitment and survival of Atka mackerel. Conversely, warmer waters are potentially adverse. Marine pollution has also been identified as a reasonably foreseeable future external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** Cumulative effects are identified for prey availability; however, the effect is insignificant since the combination of internal and external removals of prey species is not expected to decrease prey availability such that the Atka mackerel stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** As described in the direct/indirect effects section above, the level of habitat disturbance caused by the fishery under FMP 1 does not appear to affect the sustainability of the stock as measured by the ability of the stock to maintain itself above its MSST, and the effect is judged insignificant.

- **Persistent Past Effects.** Past effects are identified for BSAI Atka mackerel stocks include past foreign, JV, and domestic fisheries, and climate changes and regime shifts (see Section 3.5.1.4). Intense bottom trawling for Atka mackerel in the past fisheries likely disrupted habitat in areas of the BSAI. It is possible that some of these areas have not recovered from the intense efforts (see Section 3.6.4 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Impacts on habitat from the climate changes and regime shifts could be either beneficial or adverse. Marine pollution has also been identified as a potential adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for habitat suitability; however, that effect on the BSAI Atka mackerel stock is insignificant since the combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the Atka mackerel stock to sustain itself at or above MSST is jeopardized.

GOA Atka Mackerel

GOA Atka mackerel are managed in Tier 6 because current estimates of total and spawning biomass are unknown for GOA Atka mackerel. Age structured models were not available for evaluation of impacts for the GOA; therefore model projections of future biomass levels were not produced.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA Atka mackerel stock is unknown under FMP 1. The F and the MSST for GOA Atka mackerel are unknown; thus the effect of fishing mortality is unknown under FMP 1 (see Section 4.5.1.4, direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects of the past foreign, JV, and domestic, fisheries are likely for the GOA Atka mackerel stock. Large, concentrated removals of Atka mackerel occurred in the foreign, domestic, and JV fisheries and have had a lingering effect on the GOA Atka mackerel population, which has not yet recovered (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as having a potential adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the population is jeopardized. Climate changes and regime shifts are not identified as being contributors to Atka mackerel mortality.

- **Cumulative Effects.** A cumulative effect under FMP 1 is identified for mortality of GOA Atka mackerel, but the significance of the effect is unknown. GOA Atka mackerel are in Tier 6 and its MSST is unknown; therefore a status determination cannot be made.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the GOA Atka mackerel stock is unknown FMP 1. Current reliable estimates of total and spawning biomass are unknown for GOA Atka mackerel (see Section 4.5.1.4, direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects of the past foreign, JV, and domestic, fisheries are likely for the GOA Atka mackerel stock. Large, concentrated removals of Atka mackerel occurred in the foreign, domestic, and JV fisheries and have had a lingering effect on the GOA Atka mackerel population which has not yet recovered (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as having a potential adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the population is affected. Climate changes and regime shifts are not identified as being contributors to Atka mackerel mortality, thereby would not directly affect biomass.

- **Cumulative Effects.** A cumulative effect for change in biomass is identified; however, the significance of the effect is unknown.

Spatial/Temporal Concentration of Catch

- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** As the MSST cannot be estimated for GOA Atka mackerel which are in Tier 6, the significance of the spatial temporal concentration effects is also unknown under FMP 1 (see Section 4.5.1.4, direct/indirect effects discussion).

- **Persistent Past Effects.** Since the Atka mackerel fishery was highly localized, past foreign, JV, and domestic fisheries are found to have had lingering effects on the spatial/temporal distribution of the fish. However, the effect of this change in distribution on genetic structure is unknown. The past highly localized fisheries are found to have had lingering effects on the spatial/temporal distribution of the fish. Also, there are lingering past effects due to Climate Changes and Regime Shifts (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment. Also, climate changes and regime shifts could impact spawning success since a shift toward colder waters favors recruitment and survival of Atka mackerel. Conversely, warmer waters are potentially adverse.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration; however, the significance of the effect is unknown.

Change in Prey Availability

- **Direct/Indirect Effects.** Although the MSST cannot be estimated for GOA Atka mackerel, due to the low proportion of fish found in the diet of Atka mackerel, it is presumed that FMP 1 will not impact prey availability for BSAI Atka mackerel and the impact to the prey availability effect is determined to be insignificant (see Section 4.5.1.4, direct/indirect effects discussion).

- **Persistent Past Effects.** While lingering population level effects on the invertebrate prey of Atka mackerel from past foreign, state, and domestic fisheries, and the effects of EVOS on these species, are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on Atka mackerel prey species (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Future external effects of climate changes and regime shifts on Atka mackerel prey species could be either beneficial or adverse depending on the direction of change. Marine pollution has also been identified as a reasonably foreseeable future external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** A cumulative effect is not identified for prey availability; however, the effects are unknown since the direction of external effects is unknown.

Change in Habitat Suitability

- **Direct/Indirect Effects.** As the MSST cannot be estimated for GOA Atka mackerel, which are in Tier 6, the significance of the habitat suitability effects is also unknown under FMP 1 (see Section 4.5.1.4, direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on habitat suitability identified for GOA Atka mackerel stocks include past foreign, JV, and domestic fisheries, EVOS, and climate changes and regime shifts (see Section 3.5.1.4). Intense bottom trawling for Atka mackerel in the past fisheries likely disrupted habitat in areas of the GOA. It is possible that some of these areas have not recovered from the intense efforts (see Section 3.6.4 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Impacts on habitat from climate changes and regime shifts on the GOA Atka mackerel could be either favorable or unfavorable depending on the direction of change. Marine pollution has also been identified as a potential adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** Cumulative effects are identified for habitat suitability; however, their significance on the GOA Atka mackerel stock is unknown.

4.5.1.5 Yellowfin Sole and Shallow Water Flatfish

Numerous fishery management actions have been implemented that affect the yellowfin sole fisheries in the BSAI. These actions are described in more detail in Sections 3.5.1.5 and 3.5.1.19 of this Programmatic SEIS. Yellowfin sole is managed as its own stock under the BSAI groundfish FMP in the Tier 3 management category; thus MSSTs are defined for these species by the National Standard Guidelines.

Eight flatfish species inhabit shallow waters and are managed in the shallow water flatfish assemblage in the GOA. Yellowfin sole is included in this group, along with northern and southern rock sole, starry flounder, butter sole, English sole, Alaska plaice, and sand sole. Survey results from 2001 indicate that over half of the estimated biomass (54 percent) of this assemblage are northern and southern rock sole (Turnock *et al.* 2001). The shallow water group is managed as Tier 4 and Tier 5 species in the GOA.

As discussed in the following subsections, all potential direct and indirect effects of FMP 1 on this group are expected to be insignificant. External effects associated with the FMP 1 are shown in Tables 4.5-8 and 4.5-9 of Appendix A. For further information regarding persistent past effects listed below in the text and in Tables 4.5-8 and 4.5-9, see the past/present effects analysis discussion in Sections 3.5.1.5 and 3.5.1.19.

BSAI Yellowfin Sole – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on BSAI yellowfin sole. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The average annual fishing mortality imposed on the yellowfin sole stock in 2002 is 0.064. Model projections show that under FMP 1, this value would increase to 0.099 in 2006 and 2007 (Table H.4-4 of Appendix H). This value is well below the F_{MSY} proxy value of 0.138, the rate associated with the overfishing level. Because the capacity of the stock to produce MSY on a continuing basis would not be jeopardized under these conditions, the direct effect of FMP 1 on the mortality rate of BSAI yellowfin sole from fishing is expected to be insignificant.

Change in Biomass Level

Total Biomass

The total biomass of yellowfin sole at the start of 2002 is estimated to be 1,552,000 mt. Model projections of future total BSAI biomass estimates are shown in Table H.4-4 of Appendix H. Under FMP 1, model projections indicate that the total BSAI biomass is expected to decline by slightly more than 2 percent of the 2002 value to 1,520,000 mt by 2007, with a 2003-2007 average value of 1,531,000 mt. This projected decrease is considered to be insignificant, because total yellowfin sole biomass in the BSAI would stay within a range that would maintain the existing ability of the stock to sustain itself above the MSST.

Spawning Biomass

Spawning biomass of female yellowfin sole at the start of 2002 is estimated to be 450,700 mt. Model projections of future yellowfin sole spawning biomass estimates are shown in Table H.4-4 of Appendix H. Under FMP 1, model projections indicate that female spawning biomass is expected to decline by nearly 10 percent of the 2002 value to 409,000 mt by 2007, with a 2003-2007 average value of 433,500 mt. Projected female spawning biomass is estimated to be above the B_{MSY} proxy value of 336,900 mt throughout the five-year projection. Although the BSAI yellowfin sole spawning biomass is projected to decline, it would stay within a range that would maintain the existing ability of the stock to sustain itself above the MSST. Therefore, this potential effect under FMP 1 is considered to be insignificant.

Spatial/Temporal Concentration of Catch

The spatial/temporal characteristics of the annual BSAI yellowfin sole harvest, relative to the 2002 baseline, would not be affected under FMP 1. Therefore, this potential impact is considered to be insignificant, because it is not likely to cause changes in genetic structure or reproductive success that would jeopardize the ability of the stock to maintain itself at or above the MSST.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next five years under this FMP. Because fishing practices under FMP 1 would be similar to the status quo, however, it is unlikely that future levels of habitat disturbance would lead to a detectable change in spawning or rearing success sufficient to jeopardize the ability of the stock to sustain itself at or above the MSST. Therefore, any direct or indirect effects of FMP 1 on BSAI yellowfin sole habitat suitability are expected to be insignificant.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 on BSAI yellowfin sole would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next five years under FMP 1. The current levels and distribution of harvest do not appear to affect prey availability in ways that impair the ability of the stock to maintain itself above its MSST, however, it is likely that potential effects of FMP 1 on prey availability for BSAI yellowfin sole would be insignificant.

Summary of Direct and Indirect Effects of FMP 1 on BSAI Yellowfin Sole

Appendix A, Table 4.5-83 summarizes the expected effects of FMP 1 on BSAI yellowfin sole. The rating of conditionally significant (either beneficial or adverse) is not applicable in this analysis, because the model yields projections that can be classified only as significant (beneficial or adverse), insignificant, or unknown.

The ratings utilize F_{OFL} and the MSST as a basis for predicting beneficial or adverse impacts on fishing mortality and reproductive success, respectively, for each FMP. A thorough description of the rationale for the MSST can be found in the National Standard Guidelines, 50 CFR Part 600 (FR Vol. 63, No. 84, 24212-24237). Under FMP 1, the spawning stock biomass of BSAI yellowfin sole is expected to be above the MSST. The fishing mortality does not exceed F_{OFL}, and the female spawning stock is currently above the MSST; therefore, the expected changes under this FMP would not be substantial enough to change the genetic diversity or reproductive success of the spawning stocks. For this reason, the potential indirect and direct effect sof this FMP on BSAI yellowfin sole are considered insignificant.

Relative to the 2002 comparative baseline, the yellowfin sole stock is not projected to be continually overfished under this FMP. The 20-year projection indicates that the female spawning stock would decline to B_{ABC} levels until 2010 and increase thereafter through the end of the projection in 2023.

Status Determination from Modeling

Model projections for 2003-2007 indicate that under FMP 1, the future status of the BSAI yellowfin sole stock would be as follows for key indicators.

Stock Size Relative to MSST

Model projections of future catches of BSAI yellowfin sole are below the OFLs in all years under FMP 1. The yellowfin sole stock is above the MSST level in 2002 (Table H.4-4 of Appendix H).

Age and Size Composition

Under FMP 1, the mean age of the BSAI yellowfin sole stock in 2008, as computed in model projections (Table H.4-4 of Appendix H), is 6.2 years. This compares with a mean age in the equilibrium unfished BSAI stock of 8.0 years. Note that the mean age and size actually observed in 2008 (as opposed to the model projections) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

The sex ratio of yellowfin sole in the BSAI is assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

External effects and the resultant cumulative effects associated with FMP 1 are shown in Table 4.5-8.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI yellowfin sole is rated as insignificant under FMP 1 (see the direct/indirect effects discussion above).

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI yellowfin sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potential adverse contributions of marine pollution since acute and/or chronic pollution events could cause yellowfin sole mortality. Climate changes and regime shifts are considered non-contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of yellowfin sole.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI yellowfin sole, and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

- **Direct/Indirect Effects.** As described in the direct/indirect effects section, it is not expected that FMP 1 will result in any significant adverse impact to these stocks.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI yellowfin sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to the potential adverse contributions of marine pollution since acute and/or chronic pollution events could cause yellowfin sole mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse contributions on the yellowfin sole biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. For more information on climate changes and regime shifts, see Sections 3.5.1.5 and 3.10.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI yellowfin sole, but is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock and the spawning biomass is above the B_{MSY} value. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch

- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1 the effect of the spatial/temporal concentration of catch is considered insignificant for the stock (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects are not identified for spatial/temporal concentration of BSAI yellowfin sole catch.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of yellowfin sole due to climate changes and regime shifts are potentially beneficial or adverse. A strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Likewise, a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. Marine pollution has also been identified as a potential adverse contribution since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of BSAI yellowfin sole.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the yellowfin sole catch; however, this effect is ranked as insignificant. The spatial/temporal distribution of yellowfin sole catch is not expected to change significantly. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under FMP 1, the change in prey availability for the BSAI yellowfin sole is ranked as insignificant (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects are identified for the change in prey availability of the BSAI yellowfin sole stock and include climate changes and regime shifts. Crab and shrimp have shown variation in abundance associated with changes in climate and water temperatures. However, studies on most benthic invertebrates have not been conducted. See Sections 3.5.1.5 and 3.10 for more information on climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI yellowfin sole stock are potentially beneficial or adverse. A strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Likewise, a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. Marine pollution has also been identified as a potential adverse contribution since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** Cumulative effects are identified for change in prey availability; however, these effects are considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** Under FMP 1, the change in habitat suitability for the BSAI yellowfin sole is ranked as insignificant. Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, it is determined that FMP 1 would have insignificant effects on yellowfin sole habitat suitability (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects identified for BSAI yellowfin sole include climate changes and regime shifts. In the past, when the Aleutian Low was strong and water temperatures warm, catch tended to be dominated by flatfish species, implying increased recruitment. In contrast, when the Aleutian Low was weak and water temperatures cooler, catch tended to be dominated by shrimp. Persistent past effects of the foreign, JV, and domestic fisheries gear impacts are described in Sections 3.5.1.5 and 3.6.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI yellowfin sole stock are potentially beneficial or adverse. A strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Marine pollution has also been identified as a potential adverse contribution since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** Cumulative effects are identified for BSAI yellowfin sole habitat suitability; however, these effects are considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the yellowfin sole stock to sustain itself at or above the MSST is jeopardized.

GOA Shallow Water Flatfish – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on the GOA shallow water flatfish complex. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

<u>Fishing Fishing Mortality</u>

The catch of GOA shallow water flatfish in 2002 was estimated to be 6,800 mt. Model projections of future catch are shown in Table H.4-27 of Appendix H. Under FMP 1, model projections indicate that the catch is expected to decrease from the 2002 value to 5,400 mt in 2003-2006 and to 5,100 mt in 2007. The 2003-2007 average catch is projected to be 5,300 mt under FMP 1. Although information necessary to determine MSY is lacking for shallow water flatfish, the projected decrease in catch under this FMP suggests that effects of fishing mortality are likely to be insignificant, because they would not be expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

<u>Change in Biomass Level</u>

No reliable estimates for total or spawning biomass are available for GOA shallow water flatfish. Therefore, potential effects of FMP 1 relating to changes in biomass are unknown for this group.

<u>Spatial/Temporal Concentration of Catch</u>

The spatial/temporal characteristics of the annual GOA shallow water flatfish harvest under FMP 1 would be similar to baseline conditions. However, evidence is insufficient to conclude whether spatial and temporal patterns of harvest concentration would lead to a detectable change in genetic diversity or reproductive success, and MSSTs have not been established for the species in this group. Therefore, any potential effects of the spatial/temporal concentration of the catch on shallow water flatfish under this FMP are unknown.

<u>Habitat Suitability</u>

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next five years under this FMP, and MSSTs have not been defined for the shallow water flatfish species. Therefore, potential effects of FMP 1 on habitat suitability for this group are unknown.

<u>Prey Availability</u>

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 on shallow water flatfish would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next five years under FMP nor have MSSTs been defined for the shallow water flatfish species. Therefore, potential effects of FMP 1 on prey availability for this group are unknown.

Summary of Direct and Indirect Effects of FMP 1 on GOA Shallow Water Flatfish

The direct and indirect effects of FMP 1 on GOA shallow water flatfish cannot be determined from the MSST criteria used for stocks in Management Category Tiers 1-3. Available information is insufficient to estimate female spawning biomass of these stocks over the five-year projection and what level of fishing mortality would correspond to the modeled catch estimated under this FMP. Because catch volumes are predicted to decline moderately over the five-year period, the effect of FMP 1 on fishing mortality is likely to be insignificant. All other direct and indirect effects of FMP 1 on the shallow water flatfish complex are unknown, because available information on the stocks is insufficient to determine MSSTs.

Status Determination from Modeling

Stock Size Relative to MSST

The available information for flatfish species in the shallow water complex requires that they be classified into either the Tier 4 or Tier 5 management category. As a result, no MSSTs are defined for these species in the National Standard Guidelines. Therefore, it is not possible to determine the status of their stocks relative to MSST.

Age and Size Composition

Under FMP 1, the mean age of the GOA shallow water flatfish stock in 2008, as computed in model projections, is 4.7 years. This compares with a mean age in the equilibrium unfished GOA stock of 5.9 years. Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

The sex ratio of shallow water flatfish in the GOA is assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

Table 4.5-9 summarizes the cumulative effects analysis for GOA shallow water flatfish.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA shallow water flatfish is rated as insignificant under FMP 1 (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past, JV, and domestic fisheries have been identified as having lingering past adverse effects on th GOA shallow water flatfish complex. See Section 3.5.1.19 for more information.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potential adverse contributions of marine pollution, since acute and/or chronic pollution events could cause shallow water flatfish species mortality. Climate changes and regime shifts are considered non-contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of shallow water flatfish. The State of Alaska scallop fishery is identified as a non-contributing factor since shallow water flatfish species by catch is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for mortality of GOA shallow water flatfish, but is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to maintain current population levels.

Change in Biomass

- **Direct/Indirect Effects.** Since the total and spawning biomass estimates for GOA shallow water species is unavailable, the effects of FMP 1 on change in biomass are unknown (see the direct/indirect effects discussion).

- **Persistent Past Effects.** The past, JV, and domestic fisheries are identified as having past lingering adverse effects on the biomass levels of GOA shallow water flatfish. See Section 3.5.1.19 for more information.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to the potential adverse contributions of marine pollution; acute and/or chronic pollution events could cause shallow water flatfish species mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse contributions on the shallow water flatfish species biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. For more information on climate changes and regime shifts, see Sections 3.5.1.19 and 3.10. The State of Alaska scallop fishery is identified as a non-contributing factor since bycatch of shallow water flatfish species is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for change in biomass of GOA shallow water flatfish, but is rated as unknown. Fishing mortality at projected levels is well below the OFL for this stock. It is unknown if the combined effects of internal and external removals are likely to jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch
- – Change in Genetic Structure of Population
- – Change in Reproductive Success

- **Direct/Indirect Effects.** The spatial/temporal distribution of the annual GOA shallow water flatfish harvest will not be affected under FMP 1, relative to the 2002 baseline year. However, little is known about the spatial/temporal characteristics of GOA shallow water flatfish, therefore the effects of FMP 1 are rated as unknown (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects have not been identified for the change in genetic structure or the change in reproductive success of GOA shallow water flatfish (see Section 3.5.1.19).

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of shallow water flatfish species due to climate changes and regime shifts are potentially beneficial or adverse. A strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock complex. Likewise, a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. Marine pollution has also been identified as a potential adverse contribution since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of GOA shallow water flatfish. The State of Alaska scallop fishery has been identified as a non-contributing factor to the change in genetic structure and reproductive success since bycatch of shallow water flatfish species is not expected to occur in this fishery.

- **Cumulative Effects.** Cumulative effects are possible for change in genetic structure and reproductive success of GOA shallow water flatfish, but are rated as unknown. It is unknown if the combined effects of internal removals and removals due to reasonably foreseeable future external events are likely to jeopardize the capacity of the stock to maintain current population levels.

Change in Prey Availability

- **Direct/Indirect Effects.** Under FMP 1, the change in prey availability for the GOA shallow water flatfish is determined to be unknown (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects are identified for the change in prey availability of the GOA shallow water flatfish stock complex and include climate changes and regime shifts. Crab and shrimp have shown variation in abundance associated with changes in climate and water temperatures. However, studies on most benthic invertebrates have not been conducted. See Sections 3.5.1.19 and 3.10 for more information on climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA shallow water flatfish stock complex are potentially beneficial or adverse. A strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Likewise, a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. Marine pollution has also been identified as a potential adverse contribution since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The State of Alaska scallop fishery is identified as a non-contributing factor since by catch of shallow water flatfish prey species is not expected to occur in this fishery.

- **Cumulative Effects.** Cumulative effects for change in prey availability are unknown. The predation-mediated impacts of FMP 1 on shallow water flatfish are governed by a complex web of indirect interactions which are currently difficult to quantify.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, the change in habitat suitability for the GOA shallow water flatfish complex is considered to be unknown. Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects identified for GOA shallow water flatfish include climate changes and regime shifts. In the past, when the Aleutian Low was strong and water temperatures warm, catch tended to be dominated by flatfish species, implying increased recruitment. In contrast, when the Aleutian Low was weak and water temperatures cooler, catch tended to be dominated by shrimp. Persistent past effects of the foreign, JV, and domestic fisheries gear impacts are described in Sections 3.5.1.19 and 3.6.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA shallow water flatfish stock complex are potentially beneficial or adverse. A strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Marine pollution has also been identified as a potential adverse contribution since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. The State of Alaska scallop fishery is also identified as a potential adverse contributor to GOA shallow water flatfish habitat suitability. See Section 3.6.4 for information of the impacts of fishery gear on EFH.

- **Cumulative Effects.** Cumulative effects are identified for GOA shallow water flatfish habitat suitability; however, these effects are unknown. It is unknown if the combination of internal and external habitat disturbances will to lead to a detectable change in spawning or rearing success such that the ability of the GOA shallow water flatfish stock to maintain current population levels is jeopardized.

4.5.1.6 Rock Sole

Numerous fishery management actions have been implemented that affect the rock sole fisheries in the BSAI. These actions are described in more detail in Section 3.5.1.6 of this Programmatic SEIS. Rock sole is managed as its own stock under the BSAI groundfish FMP as a Tier 3 management category; therefore, an MSST is defined for this species.

Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on BSAI rock sole. As discussed below, all potential direct and indirect effects of FMP 1 on this group are expected to be insignificant. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The average annual fishing mortality imposed on the rock sole stock in 2002 is 0.055. Model projections suggest this value will increase to 0.137 in 2007 (Table H.4-7 of Appendix H). These values are well below the F_{MSY} proxy value of 0.21, the rate associated with the OFL. Therefore, the projected Fs for BSAI rock sole under FMP 1 are considered to be insignificant, because they would not jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

Total Biomass

The total biomass of rock sole at the start of 2002 is estimated to be 970,000 mt. Model projections of future total BSAI biomass estimates are shown in Table H.4-7 of Appendix H. Under FMP 1, the model projections indicate that the total BSAI biomass is expected to decline 30 percent of the 2002 value to 680,000 mt by 2007, with a 2003-2007 average value of 765,000 mt. This projected decrease is considered to be insignificant, because total rock sole biomass in the BSAI would stay within a range that would maintain the existing ability of the stock to sustain itself above the MSST.

Spawning Biomass

Spawning biomass of female rock sole at the start of 2002 is estimated to be 331,000 mt. Model projections of future rock sole spawning biomass estimates are shown in Table H.4-7 of Appendix H. Under FMP 1, model projections indicate that female spawning biomass is expected to decline to 53 percent of the 2002 value to 175,900 mt by 2007, with a 2003-2007 average value of 238,100 mt. Projected female spawning biomass is estimated to be above the B_{MSY} proxy value of 136,700 mt throughout the five-year projection. Although spawning biomass for BSAI rock sole is projected to decline, it would stay within a range that would maintain the existing ability of the stock to sustain itself above the MSST. Therefore, this potential effect under FMP 1 is considered to be insignificant.

Spatial/Temporal Concentration of Catch

The spatial/temporal characteristics of the annual BSAI rock sole harvest, relative to the 2002 baseline year, would not be affected under FMP 1. The temporal/spatial concentration of the catch under baseline conditions does not appear to affect the sustainability of the stock either through changes in the genetic structure of the population or changes in reproductive success, as measured by the ability of the stock to maintain itself above its MSST. Under FMP 1, therefore, the spatial and temporal pattern of catch concentration would have an insignificant effect on BSAI rock sole relative to the baseline.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 on BSAI rock sole would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat- mediated impacts would undergo significant qualitative change during the next five years under this FMP. The level of habitat disturbance caused by the fishery under baseline conditions does not appear to affect the sustainability of the stock as measured by the ability of the stock to maintain itself above its MSST. Therefore, impacts on habitat suitability for BSAI rock sole are expected to be insignificant under FMP 1.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 on rock sole would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next five years under FMP 1. The current levels and distribution of harvest do not appear to affect prey availability in ways that impair the ability of the rock sole stock to maintain itself above its MSST. Therefore, it is likely that potential effects of FMP 1 on prey availability for BSAI rock sole would be insignificant.

Summary of Direct and Indirect Effects of FMP 1 on BSAI Rock Sole

Appendix A, Table 4.5-83 summarizes the expected direct and indirect effects of FMP 1 on BSAI rock sole. The rating of conditionally significant (either beneficial or adverse) is not applicable in this analysis, because the model projections yielded results that could be evaluated only as significant (beneficial or adverse), insignificant, or unknown.

The ratings utilize F_{OFL} and MSST as the bases for identifying potentially beneficial or adverse impacts on fishing mortality and reproductive success under each FMP. A thorough description of the rationale for the MSST can be found in the National Standard Guidelines, 50 CFR Part 600 (FR Vol. 63, No. 84, 24212-24237). Under FMP 1, the spawning stock biomass of BSAI rock sole is expected to be above the MSST. Since the F would not exceed F_{OFL} and the stock is expected to remain above the MSST, the expected changes under this FMP would not be substantial enough that the genetic diversity or reproductive success of the spawning stocks would be likely to change under the new management regime. Therefore, the potential direct and indirect effects on BSAI rock sole under this FMP are considered insignificant.

Relative to the 2002 comparative baseline, the rock sole stock is projected to continue not to be overfished under this FMP. The 20-year projection indicates that the female spawning stock is expected to decline to a level just less than B_{MSY} in 2010, then increase to above B_{ABC} levels by 2015, and continue to increase through the end of the projection in 2023.

Status Determination from Modeling

Model projections for 2003-2007 suggest that under FMP 1, the future status of the BSAI rock sole stock would be as follows for key indicators.

Stock Size Relative to MSST

Model projections of future catches of BSAI rock sole are below the OFLs in all years under FMP 1, and the female spawning stock is above the MSST. The rock sole stock is projected to be above the MSST level in 2002.

Age and Size Composition

Under FMP 1, the mean age of the BSAI rock sole stock in 2008, as computed in model projections (Table H.4-7 of Appendix H), is 4.7 years. This compares with a mean age in the equilibrium unfished BSAI stock of 5.9 years. Note that the mean age and size actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

The sex ratio of rock sole in the BSAI is assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

Table 4.5-10 summarizes the cumulative effects analysis for BSAI rock sole.

Mortality

- **Direct/Indirect Effects.** As stated above in the direct/indirect effects section, the effect of fishing mortality on the BSAI rock sole is rated as insignificant under FMP 1.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI rock sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potential adverse effects of marine pollution; acute and/or chronic pollution events could cause rock sole mortality. Climate changes and regime shifts are considered non-contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of rock sole.

- **Cumulative Effects.** A cumulative effect is possible for mortality of BSAI rock sole, and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of the fisheries on BSAI rock sole biomass is rated as insignificant.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI rock sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are indicated due to the potential adverse contribution of marine pollution; acute and/or chronic pollution events could cause rock sole mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the rock sole biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. For more information on climate changes and regime shifts, see Sections 3.5.1.6 and 3.10.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI rock sole, and is rated as insignificant. The spawning biomass is above the B_{MSY} value for all years. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of the spatial/temporal concentration of catch is considered insignificant for the stock.

- **Persistent Past Effects.** Past effects are not identified for the change in genetic structure of the BSAI rock sole. Climate changes and regime shifts have been identified as having a persistent past effect on the reproductive success of BSAI rock sole. Climate changes and regime shifts and corresponding water temperature variation could affect prey availability and habitat suitability, which in combination could affect the reproductive success of the rock sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of rock sole due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse contribution since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of BSAI rock sole.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the rock sole catch, and is ranked as insignificant. The spatial/temporal distribution of rock sole catch is not expected to change significantly. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the change in prey availability for the BSAI rock sole is ranked as insignificant.

- **Persistent Past Effects.** Past effects include climate changes and regime shifts. Climate changes and regime shifts and corresponding water temperature variation do affect the availability of some forage species (i.e. capelin); however, studies on benthic invertebrates have not been conducted. See Section 3.5.1.6 for more information.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI rock sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** A cumulative effect is identified for the change in prey availability, and is considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the change in habitat suitability for the BSAI rock sole is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified for BSAI rock sole include climate changes and regime shifts. Persistent past effects of the foreign, JV, and domestic fisheries are described in Section 3.5.1.6.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI rock sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for BSAI rock sole habitat suitability; however, this effect is considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the rock sole stock to sustain itself at or above the MSST is jeopardized.

4.5.1.7 Flathead Sole

Numerous fishery management actions have been implemented that affect the flathead sole fisheries in the BSAI and GOA. These actions are described in more detail in Sections 3.5.1.7 and 3.5.1.20 of this Programmatic SEIS. Flathead sole is managed as its own stock under the BSAI groundfish FMP within the Tier 3 management category; therefore, an MSST is defined for this species by the National Standard Guidelines. Beginning in 2002, flathead sole were managed independently of the other flatfish species in the GOA. Until recently, GOA flathead sole were evaluated under the Tier 4 management category; beginning in 2004, flathead sole will be managed under Tier 3. GOA flathead sole were modeled under the Tier 4 category for this analysis.

BSAI Flathead Sole – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the analyses of direct and indirect impacts of FMP 1 on BSAI flathead sole. As discussed below, all of these potential effects are expected to be insignificant. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The projected fishing mortality imposed on the BSAI flathead sole stock in 2003 is 0.047. Model projections suggest that under FMP 1, this fishing mortality would increase to 0.086 in 2008, with an average fishing mortality of 0.063 from 2003-2008 (Table H.4-8 of Appendix H). These values are below the $F_{35\%}$ level of 0.355 and the $F_{40\%}$ level of 0.286, which are taken as proxies for F_{ABC} and F_{OFL}, respectively. The proportion of spawner biomass per recruit conserved under these mortality rates is 80 percent in 2003, decreasing to 70 percent in 2008; the average implied spawner biomass per recruit (SPR) rate of fishing from 2003-2008 is 76 percent. These projections indicate that the expected effects of FMP 1 on BSAI flathead sole mortality are likely to be insignificant, because they would not jeopardize the capacity of the stocks to produce MSY on a continuing basis.

Change in Biomass Level

Total Biomass

Total biomass (ages 3 through 21+) of BSAI flathead sole at the start of 2003 is estimated to be 513,000 mt. Model projections of future BSAI total flathead sole biomass are shown in Table H.4-8 of Appendix H. Under FMP 1, model projections indicate that BSAI flathead sole biomass is expected to decrease to a value of 490,000 mt in 2006, then increase to 498,000 mt in 2008. The 2003-2008 projected average total biomass is 497,000 mt. These projections indicate that the total flathead sole biomass in the BSAI would stay within a range that would maintain the existing ability of the stock to sustain itself above the MSST. For this reason, the impact of FMP 1 on BSAI flathead sole total biomass is expected to be insignificant.

Spawning Biomass

Spawning biomass of BSAI flathead sole at the start of 2003 is estimated to be 231,200 mt. Model projections of future total BSAI flathead sole spawning biomass are shown in Table H.4-8 of Appendix H. Under FMP 1, model projections indicate that BSAI flathead sole spawning biomass would increase to a value of 164,600 mt in 2008, with a 2003-2008 average value of 196,000 mt. Under FMP 1, therefore, impacts on BSAI flathead sole spawning biomass are expected to be insignificant, because the existing ability of the stock to sustain itself above the MSST would be maintained.

Spatial/Temporal Concentration of Catch

The harvest of flathead sole occurs largely along the western edge of the EBS shelf; little harvest occurs in the Aleutian Islands. Although some directed fishing for flathead sole exists, a considerable amount of harvest occurs as bycatch in other target fisheries. Under FMP 1, an average of 12,900 mt is projected to be harvested annually from 2003-2008, almost entirely from the EBS. The EBS Pacific cod and yellowfin sole fisheries account for 3,240 mt (25 percent) and 2,530 mt (19 percent) of the average annual harvest, whereas the directed flathead sole fishery accounts for 1,910 mt (15 percent). Recent observer data indicate that the harvest of flathead sole occurs year-round, and is determined largely from the seasonal allocations of the Pacific halibut prohibited species bycatch limits for flatfish trawl fisheries (Spencer *et al.* 2001). Because these patterns would be maintained under FMP 1, the temporal/spatial concentration of the catch would not be likely to affect the sustainability of the stock either through changes in the genetic structure of the population or changes in reproductive success, as measured by the ability of the stock to maintain itself above its MSST. Therefore, this potential impact is considered to be insignificant.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change under this FMP 1. Therefore, the effects of FMP 1 on BSAI flathead sole habitat suitability are expected to be insignificant, because the present ability of the stock to maintain itself above the MSST would not be impaired.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that trophic interactions would undergo significant qualitative change under this FMP. Since the current levels and distribution of harvest have not been shown to affect prey availability in ways that impair the ability of the stock to maintain itself above its MSST, potential future effects of FMP 1 on prey availability for BSAI flathead sole are likely to be insignificant.

Summary of Direct and Indirect Effects of FMP 1 on BSAI Flathead Sole

Because BSAI flathead sole are fished at less than the OFL and are above the MSST, the direct and indirect effects of FMP 1 on this stock are considered insignificant. Fishing rates are well within accepted scientific standards based on studies of population dynamics and estimates of natural variations in recruitment. Therefore, the spatial/temporal distribution of catch should have no significant direct impact on stock productivity.

Relative to the 2002 comparative baseline, the flathead sole stock is projected to continue not tot be overfished under this FMP. The 20-year projection indicates that the female spawning stock would decrease until 2009, then begin to increase steadily through the end of the projection. The female spawning stock is estimated to remain above B_{ABC} throughout the projection.

Status Determination from Modeling

Stock Size Relative to MSST

Under FMP 1, the ABC is set at a lower level than the OFL, creating a buffer between these two harvest regulations. Model projections of future catches of BSAI flathead sole are below the ABC and OFL levels in all years. The BSAI flathead sole are above their MSST in the year 2002.

Age and Size Composition

Under FMP 1, the mean age of the BSAI flathead sole stock in 2008, as computed in model projections, is 4.53 years. This compares with a mean age in the equilibrium unfished stock of 5.39 years.

Sex Ratio

The sex ratio of BSAI flathead sole is assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

Table 4.5-11 summarizes the cumulative effects analysis for BSAI flathead sole.

<u>Mortality</u>

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI flathead sole is rated as insignificant under FMP 1.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI flathead sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potential adverse effects of marine pollution; acute and/or chronic pollution events could cause flathead sole mortality. Climate changes and regime shifts are considered non-contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of flathead sole.

- **Cumulative Effects.** A cumulative effect is possible for mortality of BSAI flathead sole, and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

<u>Change in Biomass Level</u>

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of the fishing on the flathead sole biomass is insignificant.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI flathead sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are indicated due to the potential adverse effects of marine pollution; acute and/or chronic pollution events could cause flathead sole mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the flathead sole biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. For more information on climate changes and regime shifts, see Sections 3.5.1.7 and 3.10.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI flathead sole, and is rated as insignificant. Fishing mortality at projected levels is well below the

OFL for this stock and the spawning biomass is above the B_{MSY} value. The combined effect of internal removals and removals due to reasonable foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1 the effect of the spatial/temporal concentration of catch is considered insignificant for the stock.

- **Persistent Past Effects.** Past effects are not identified for spatial/temporal concentration of BSAI flathead sole catch.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of flathead sole due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of BSAI flathead sole.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the flathead sole catch, and is ranked as insignificant. The spatial/temporal distribution of flathead sole catch is not expected to change significantly. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under FMP 1, the change in prey availability for the BSAI flathead sole is ranked as insignificant.

- **Persistent Past Effects.** Past effects are not identified for the change in prey availability of the BSAI flathead sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI flathead sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability, and is considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, the change in habitat suitability for the BSAI flathead sole is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified for BSAI flathead sole include climate changes and regime shifts. Persistent past effects of the foreign, JV, and domestic fisheries are described in Section 3.5.1.7.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI flathead sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for BSAI flathead sole habitat suitability, and is considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the flathead sole stock to sustain itself at or above the MSST is jeopardized.

GOA Flathead Sole – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the analyses of direct and indirect impacts of FMP 1 on GOA flathead sole. The effect of fishing mortality on this stock is expected to be insignificant, whereas the significance of other potential direct and indirect effects is unknown. Significance ratings are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The catch of GOA flathead sole in 2002 was estimated to be 2,000 mt. Model projections of future catch are shown in Table H.4-28 of Appendix H. Under FMP 1, model projections indicate that the catch would decrease from the 2002 value to 1,700 mt in 2003 and then further decline to 1,500 mt in 2007 (75 percent of 2002 catch). The 2003-2007 average catch is 1,600 mt. Therefore, the projected Fs for GOA flathead sole under FMP 1 are considered to be insignificant, because they would not jeopardize the capacity of the stocks to produce MSY on a continuing basis.

Change in Biomass Level

Estimates of total and spawning biomass are not available for this species. Therefore, the potential effects of FMP 1 on biomass levels, and any resulting impact on the stock's ability to maintain itself above the MSST, are unknown.

Spatial/Temporal Concentration of Catch

The spatial/temporal characteristics of the annual GOA flathead sole harvest would not be affected under FMP 1, relative to the 2002 baseline year. However, the effects of the temporal/spatial concentration of the catch on this stock under baseline conditions are unknown. Therefore, the potential effects of FMP 1 to affect the stock's genetic structure or reproductive success must also be considered unknown.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 on GOA flathead sole would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat- mediated impacts would undergo significant qualitative change during the next five years under this FMP. Because habitat-mediated impacts under baseline conditions are unknown, however, the potential habitat-mediated effects of FMP 1 on the stock's ability to maintain itself above the MSST must also be considered unknown.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 on GOA flathead sole would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next five years under FMP 1. Because data on prey availability under baseline conditions are not available, however, potential predation-mediated impacts of FMP 1 on the ability of the GOA flathead sole stock to sustain itself at or above the MSST are unknown.

Summary of Direct and Indirect Effects of FMP 1 on GOA Flathead Sole

Because the GOA flathead sole catch is projected to decrease moderately during the 2003-2007 period, the effect of FMP 1 on fishing mortality is expected to be insignificant. All other direct and indirect effects of FMP 1 on GOA flathead sole are unknown, because they cannot be determined from the MSST criteria used for stocks in Management Category Tiers 1-3. It is unknown what the estimate of female spawning biomass of these stocks would be over the five-year projection and what level of fishing mortality would correspond to the modeled catch estimated under this FMP.

Status Determination from Modeling

Stock Size Relative to MSST

The available information for flathead sole requires that this species be classified into the Tier 4 management category. As a result, no MSSTs are defined for flathead sole, and it is not possible to determine the status of the stock size relative to MSST.

Age and Size Composition

Age and size composition estimates are not available for this species.

Sex Ratio

The sex ratio of flathead sole in the GOA is assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

Table 4.5-12 summarizes the cumulative effects analysis for GOA flathead sole.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA flathead sole is rated as insignificant under FMP 1.

- **Persistent Past Effects.** Past effects have been identified for fishing mortality in the GOA flathead sole stock and include past, JV, and domestic fisheries. Removals by these fisheries have had a lingering adverse effect on GOA flathead sole. For more information, see Section 3.5.1.20.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potential adverse effects of marine pollution; acute and/or chronic pollution events could cause flathead sole mortality. Climate changes and regime shifts are considered non-contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of flathead sole. The State of Alaska scallop fishery has also been identified as a non-contributing factor since GOA flathead sole bycatch is not expected in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for mortality of GOA flathead sole, and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonable foreseeable future external events is unlikely to jeopardize the capacity of the stock to maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under FMP 1, the change in biomass level is rated as unknown since MSST is unable to be determined at this time.

- **Persistent Past Effects.** Past effects have been identified for fishing mortality in the GOA flathead sole stock and include past, JV, and domestic fisheries. Large removals of flathead sole by these fisheries is determined to have had a lingering effect on the GOA flathead sole stock (see Section 3.5.1.20).

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are indicated due to the potential adverse effects of marine pollution; acute and/or chronic pollution events could cause flathead sole mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the flathead sole biomass level. For more information on climate changes and regime shifts, see Sections 3.5.1.20 and 3.10. The State of Alaska scallop fishery is identified as a non-contributing factor for change in biomass level since flathead sole bycatch is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of GOA flathead sole, but is unknown. The MSST is not able to be determined and the total and spawning biomass estimates are currently unavailable. It is unknown whether the combined effect of internal and external removals are likely to jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1 the effect of the spatial/temporal concentration of catch is unknown since the MSST is unable to be determined.

- **Persistent Past Effects.** Past effects are not identified for the change in genetic structure of the GOA flathead sole stock. However, climate changes and regime shifts have been identified as having a beneficial or adverse effect on GOA flathead sole reproductive success. See Section 3.5.1.20 for more information on the effects of climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of flathead sole due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of GOA flathead sole. The State of Alaska scallop fishery has been identified as a non-contributing factor to change in genetic structure and change in reproductive success since GOA flathead sole bycatch is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the flathead sole catch; however, this effect is unknown. It is unknown whether the combined effect of internal and external removals are likely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain current population levels is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under FMP 1, the change in prey availability for the GOA flathead sole is unknown.

- **Persistent Past Effects.** Past effects are identified for the change in prey availability of the GOA flathead sole stock and include climate changes and regime shifts. For more information on the effects of climate changes and regime shifts on the GOA flathead sole stock, see Section 3.5.1.20.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA flathead sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The State of Alaska scallop fishery is identified as a potential adverse contributor to GOA flathead sole prey availability. The State of Alaska scallop fishery gear could impact flathead sole benthic prey availability and/or quality.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability; however, this effect is unknown. It is unknown whether the combination of internal and external removals of prey is expected to jeopardize the ability of the stock to sustain itself at current population levels.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, the change in habitat suitability for the GOA flathead sole is unknown. Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify.

- **Persistent Past Effects.** Past effects identified for GOA flathead sole include climate changes and regime shifts. Persistent past effects of the foreign, JV, and domestic fisheries are described in Section 3.5.1.20.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA flathead sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. The State of Alaska scallop fishery is identified as a potential adverse contributor to GOA flathead sole habitat suitability. For information on the effects of fishery gear on EFH, see Section 3.6.4.

- **Cumulative Effects.** A cumulative effect is identified for GOA flathead sole habitat suitability; however, this effect is unknown. It is unknown whether the combination of internal and external habitat disturbances is expected to lead to a detectable change in spawning or rearing success such that the ability of the flathead sole stock to sustain itself at current population levels.

4.5.1.8 Arrowtooth Flounder

Numerous fishery management actions have been implemented that affect the arrowtooth flounder fisheries in the BSAI and GOA. These actions are described in more detail in Sections 3.5.1.8 and 3.5.1.21 of this Programmatic SEIS. Arrowtooth flounder is managed as its own stock under the BSAI and GOA groundfish FMPs as part of the Tier 3 management category. Therefore, MSSTs are defined for these stocks.

BSAI Arrowtooth Flounder – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on BSAI arrowtooth flounder. All of these potential effects are expected to be insignificant. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The average annual fishing mortality imposed on the BSAI arrowtooth flounder stock in 2002 is 0.015. Model projections show this value will increase to 0.26 in 2007. These values are well below the F_{MSY} proxy value of 0.38, the rate associated with the overfishing level. This impact is expected to be insignificant, because it is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

Total Biomass

The total biomass of BSAI arrowtooth flounder at the start of 2002 is estimated to be 811,000 mt. Model projections of future total BSAI biomass estimates are shown in Table H.4-6 of Appendix H. Under FMP 1, model projections indicate that the total BSAI biomass is expected to decline 26 percent of the 2002 value to 597,000 mt by 2007, with a 2003-2007 average value of 675,000 mt. Because total biomass would tend toward levels that would maintain the ability of the stock to sustain itself above the MSST, this effect would be insignificant under FMP 1.

Spawning Biomass

Spawning biomass of female BSAI arrowtooth flounder at the start of 2002 is estimated to be 475,900 mt. Model projections of future arrowtooth flounder spawning biomass estimates are shown in Table H.4-6 of Appendix H. Under FMP 1, model projections indicate that female spawning biomass is expected to decline to 30 percent of the 2002 value to 329,500 mt by 2007, with a 2003-2007 average value of 387,900 mt. Projected female spawning biomass is estimated to be above the B_{MSY} proxy value of 182,900 mt throughout the five-year projection. Because spawning biomass would tend toward levels that would maintain the ability of the stock to sustain itself above the MSST, this effect would be insignificant under FMP 1.

Spatial/Temporal Concentration of Catch

The spatial/temporal characteristics of the annual BSAI arrowtooth flounder harvest, relative to the 2002 baseline, would not be affected under FMP 1. This impact is expected to be insignificant, because the concentration of harvest would not be sufficient to alter the genetic sub-population structure or reproductive success such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next five years under this FMP. Therefore, the effects of FMP 1 on habitat suitability are expected to be insignificant, because future levels of habitat disturbance would not lead to a detectable change in spawning or rearing success such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 on BSAI arrowtooth flounder would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next five years under FMP 1. Therefore, this impact is expected to be insignificant, because there is no evidence that future FMP 1 harvest levels or distribution of harvest would lead to a change in prey availability such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Summary of Direct and Indirect Effects of FMP 1 on BSAI Arrowtooth Flounder

Under FMP 1, the spawning stock biomass of BSAI arrowtooth flounder is expected to be above the MSST. Since the F does not exceed F_{OFL} and the female spawning stocks are expected to remain above the MSST, the expected changes under this FMP are not substantial enough to expect that the genetic diversity or the reproductive success of the spawning stocks would change under the new management regime. Thus, the indirect and direct effects under this FMP are considered insignificant.

Relative to the 2002 comparative baseline, the BSAI arrowtooth flounder stocks are projected to continue to not be overfished under this FMP. The 20-year projection indicates that the female spawning stock in both areas is expected to remain above B_{ABC} levels through the end of the projection in 2023.

Status Determination from Modeling

Modeling projections for 2003-2007 indicate that under FMP 1, the future status of BSAI arrowtooth flounder would be as follows for key indicators.

Stock Size Relative to MSST

Model projections of future catches of BSAI arrowtooth flounder are below the overfishing levels in all years under FMP 1. The arrowtooth flounder female spawning biomass is above the MSST level in 2002.

Age and Size Composition

Under FMP 1, the mean age of the BSAI arrowtooth flounder stock in 2008, as computed in model projections (Table H.4-6 of Appendix H), is 4.8 years. This compares with a mean age in the equilibrium unfished BSAI stock of 5.4 years. Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

Fishery-independent resource assessment surveys in the BSAI have found that populations of arrowtooth flounder are comprised of a higher percentage of females than males. It is believed that this is a function of a higher natural mortality rate for males than females. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

Table 4.5-13 summarizes the cumulative effects analysis for BSAI arrowtooth flounder.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI arrowtooth flounder is rated as insignificant under FMP 1.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI arrowtooth flounder stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potential adverse effects of marine pollution; acute and/or chronic pollution events could cause arrowtooth flounder mortality. Climate changes and regime shifts are considered non-contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of arrowtooth flounder. The IPHC longline fishery is identified as a potential adverse contributor to BSAI arrowtooth flounder mortality since arrowtooth flounder are caught as bycatch in this fishery. Finally, the State of Alaska herring fishery is identified as a non-contributing factor to BSAI arrowtooth flounder mortality since bycatch is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for mortality of BSAI arrowtooth flounder, and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of the fisheries on the BSAI arrowtooth flounder biomass is insignificant.

- **Persistent Past Effects.** Past effects have not been identified for the change in biomass level in the BSAI arrowtooth flounder stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in biomass level are indicated due to the potential adverse effects of marine pollution; acute and/or chronic pollution events could cause arrowtooth flounder mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the arrowtooth flounder biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. For more information on climate changes and regime shifts, see Sections 3.5.1.8 and 3.10. The IPHC longline fishery has been identified as a potential adverse contributor to BSAI arrowtooth flounder biomass level since bycatch is expected to occur in this fishery. Finally, the State of Alaska herring fishery is identified as a non-contributing factor since arrowtooth flounder bycatch is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI arrowtooth flounder, and is rated as insignificant. The spawning biomass is above the B_{MSY} value for all years. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1 the effect of the spatial/temporal concentration of catch is considered insignificant for the stock.

- **Persistent Past Effects.** Past effects are not identified for the change in genetic structure of BSAI arrowtooth flounder. Climate changes and regime shifts are identified as having had potential adverse or beneficial effects on the reproductive success of BSAI arrowtooth flounder (see Section 3.5.1.8 for more information).

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of arrowtooth flounder due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of BSAI arrowtooth flounder. The IPHC longline fishery is identified as a non-contributing factor to the genetic structure and reproductive success of BSAI arrowtooth flounder since the removals are not expected to be significant. The State of Alaska herring fishery is also identified as a non-contributing factor to the genetic structure and reproductive success of BSAI arrowtooth flounder since bycatch is not expected in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the arrowtooth flounder catch, and is ranked as insignificant. The spatial/temporal distribution of arrowtooth flounder catch is not expected to change significantly. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under FMP 1, the change in prey availability for the BSAI arrowtooth flounder is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified include the past foreign, JV, domestic fisheries, State of Alaska groundfish fisheries, State of Alaska herring fisheries, and climate changes and regime shifts. See Section 3.5.1.8 for more information.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI arrowtooth flounder stock are potentially beneficial or adverse. Some forage species (i.e. capelin and herring), shrimp and pollock respond to variations in water temperatures which vary with the climate. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The IPHC longline fishery is identified as a non-contributing factor to prey availability since the bycatch of prey species is not expected in this fishery. The State of Alaska herring fishery is identified as a potential adverse contributor to prey availability by reducing the availability of herring.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability, and is considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, the change in habitat suitability for the BSAI arrowtooth flounder is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified for BSAI arrowtooth flounder include climate changes and regime shifts. Persistent past effects of the foreign, JV, and domestic fisheries are described in Section 3.5.1.8.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI arrowtooth flounder stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. The IPHC longline fishery and the State of Alaska herring fishery are both identified as non-contributing factors to BSAI arrowtooth flounder habitat suitability. The impacts from the fishery gear is expected to be minimal.

- **Cumulative Effects.** A cumulative effect is identified for BSAI arrowtooth flounder habitat suitability, and is considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the arrowtooth flounder stock to sustain itself at or above the MSST is jeopardized.

GOA Arrowtooth Flounder – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on GOA arrowtooth flounder. All of these potential effects are expected to be insignificant. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The average annual fishing mortality imposed on the GOA arrowtooth flounder stock in 2002 is 0.017. Model projections show this value will decrease to 0.009 in 2007. These values are well below the F_{MSY} proxy value of 0.165, the rate associated with the overfishing level. This impact is expected to be insignificant, because it is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

Total Biomass

The total biomass of GOA arrowtooth flounder at the start of 2002 is estimated to be 1,816,000 mt. Model projections of future total GOA biomass estimates are shown in Table H.4-29 of Appendix H. Under FMP 1, model projections indicate that the total GOA biomass is expected to increase 15 percent of the 2002 value to 2,086,000 mt by 2007, with a 2003-2007 average value of 1,982,000 mt. Because total biomass would tend toward levels that would maintain the ability of the stock to sustain itself above the MSST, this effect would be insignificant under FMP 1.

Spawning Biomass

Spawning biomass of female GOA arrowtooth flounder at the start of 2002 is estimated to be 1,113,800 mt. Model projections of future GOA arrowtooth flounder spawning biomass estimates are shown in Table H.4-29 of Appendix H. Under FMP 1, model projections indicate that female spawning biomass is expected to increase 4 percent of the 2002 value to 1,115,700 mt by 2007, with a 2003-2007 average value of 1,142,300 mt. Projected female spawning biomass is estimated to be above the B_{MSY} proxy value of 432,700 mt throughout the five-year projection. Because spawning biomass would tend toward levels that would maintain the ability of the stock to sustain itself above the MSST, this effect would be insignificant under FMP 1.

Spatial/Temporal Concentration of Catch

The spatial/temporal characteristics of the annual GOA arrowtooth flounder harvest, relative to the 2002 baseline, would not be affected under FMP 1. Therefore, this impact is expected to be insignificant, because the concentration of harvest would not be sufficient to alter the genetic sub-population structure or reproductive success such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next five years under this FMP. Therefore, the effects of FMP 1 on habitat suitability are expected to be insignificant, because future levels of habitat disturbance would not lead to a detectable change in spawning or rearing success such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 on GOA arrowtooth flounder would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next five years under FMP 1. Therefore, this impact is expected to be insignificant, because there is no evidence that future FMP 1 harvest levels or distribution of harvest would lead to a change in prey availability such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Summary of Direct and Indirect Effects of FMP 1 on GOA Arrowtooth Flounder

Under FMP 1, the spawning stock biomass of GOA arrowtooth flounder is expected to be above the MSST. Since the F does not exceed F_{OFL} and the female spawning stocks are expected to remain above the MSST, the expected changes under this FMP are not substantial enough to expect that the genetic diversity or the reproductive success of the spawning stocks would change under the new management regime. Therefore, the indirect and direct effects under this FMP are considered insignificant.

Relative to the 2002 comparative baseline, the GOA arrowtooth flounder stocks are projected to continue not to be overfished under this FMP. The 20-year projection indicates that the female spawning stock in both areas is expected to remain above B_{ABC} levels through the end of the projection in 2023.

Status Determination from Modeling

Model projections of future catches of GOA arrowtooth flounder are below the overfishing levels in all years under FMP 1. The arrowtooth flounder female spawning biomass is above the MSST level in 2002.

Age and Size Composition

Under FMP 1, the mean age of the GOA arrowtooth flounder stock in 2008, as computed in model projections (Table H.4-29 of Appendix H), is 5.0 years. This compares with a mean age in the equilibrium unfished BSAI stock of 5.1 years. Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

Fishery-independent resource assessment surveys in the GOA have found that populations of arrowtooth flounder are comprised of a higher percentage of females than males. It is believed that this is a function of a higher natural mortality rate for males than for females. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

Table 4.5-14 summarizes the cumulative effects analysis for GOA arrowtooth flounder.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA arrowtooth flounder is rated as insignificant under FMP 1.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the GOA arrowtooth flounder stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are the same as those described for BSAI arrowtooth flounder under this FMP.

- **Cumulative Effects.** A cumulative effect is possible for mortality of GOA arrowtooth flounder, and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of the fisheries on the biomass level is insignificant.

- **Persistent Past Effects.** Past effects have not been identified for change in biomass in the GOA arrowtooth flounder stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are the same as those described for BSAI arowtooth flounder under this FMP.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of GOA arrowtooth flounder, and is rated as insignificant. The spawning biomass is above the B_{MSY} value for all years. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch
- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1 the effect of the spatial/temporal concentration of catch is considered insignificant for the stock.

- **Persistent Past Effects.** Past effects identified for the change in genetic structure and reproductive success of GOA arrowtooth flounder are the same as those described for BSAI arrowtooth flounder under this FMP.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success and genetic structure of arrowtooth flounder are the same as those described for BSAI arrowtooth flounder under this FMP.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the arrowtooth flounder catch and is ranked as insignificant. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under FMP 1, the change in prey availability for the GOA arrowtooth flounder is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified include climate changes and regime shifts. See Section 3.5.1.21 for more information.

- **Reasonably Foreseeable Future External Effects.** Future external effects on prey availability are the same as those discussed for BSAI arrowtooth flounder under this FMP.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability, and is considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, the change in habitat suitability for the GOA arrowtooth flounder is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified for GOA arrowtooth flounder include climate changes and regime shifts. Persistent past effects of the foreign, JV, and domestic fisheries are described in Section 3.5.1.21.

- **Reasonably Foreseeable Future External Effects.** Future external effects on habitat suitability are the same as those described for BSAI arrowtooth flounder under this FMP.

- **Cumulative Effects.** A cumulative effect is identified for GOA arrowtooth flounder habitat suitability, and is considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the arrowtooth flounder stock to sustain itself at or above the MSST is jeopardized.

4.5.1.9 Greenland Turbot and Deepwater Flatfish

The numerous fishery management actions that affect the Greenland turbot fisheries in the BSAI are described in more detail in Section 3.5.1.9 of this Programmatic SEIS. Greenland turbot is managed as its own stock under the BSAI groundfish FMP under the Tier 3 management category; thus MSSTs are defined for these species by the National Standard Guidelines. The reference F and ABC for the GOA deepwater flatfish management group are determined by the amount of population information available. ABCs for Dover sole were calculated using Tier 5. Greenland turbot and deepsea sole are in Tier 6 because no reliable biomass estimates exists. Section 3.5.1.22 discusses the past/present effects analysis for GOA deepwater flatfish.

BSAI Greenland Turbot – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on BSAI Greenland turbot. All of these impacts are expected to be insignificant. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The average annual fishing mortality imposed on the Greenland turbot stock in 2002 is 0.052. Model projections indicate that under this FMP the F will reach a maximum in 2004 of 0.19 and decrease thereafter to 0.162 by 2007. These values are well below the F_{MSY} proxy value of 0.48, the rate associated with the OFL. This impact is expected to be insignificant, because it is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

Total Biomass

The total biomass of Greenland turbot at the start of 2002 is estimated to be 106,000 mt. Model projections of future total BSAI biomass estimates are shown in Table H.4-5 of Appendix H. Under FMP 1, model projections indicate that the total BSAI biomass is expected to decline 19 percent of the 2002 value to 86,000 mt by 2007, with a 2003-2007 average value of 92,000 mt. Because total biomass would tend toward levels that would maintain the ability of the stock to sustain itself above the MSST, this effect would be insignificant under FMP 1.

Spawning Biomass

Spawning biomass of female Greenland turbot at the start of 2002 is estimated to be 67,800 mt. Model projections of future Greenland turbot spawning biomass estimates are shown in Table H.4-5 of Appendix H. Under FMP 1, model projections indicate that female spawning biomass is expected to decline to 31 percent of the 2002 value to 46,800 mt by 2007, with a 2003-2007 average value of 54,100 mt. Projected female spawning biomass is estimated to be above the B_{MSY} proxy value of 47,600 mt in the first four years of the projection, and would be below the B_{MSY} proxy rate in 2007. Because spawning biomass would tend toward levels that would maintain the ability of the stock to sustain itself above the MSST, this effect would be insignificant under FMP 1.

Spatial/Temporal Concentration of Catch

The spatial/temporal characteristics of the annual BSAI Greenland turbot harvest, relative to the 2002 baseline, would not be affected under FMP 1. This impact is expected to be insignificant, because the concentration of harvest would not be sufficient to alter the genetic sub-population structure or reproductive success such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next five years under this FMP. Therefore, the effects of FMP 1 on habitat suitability are expected to be insignificant, because future levels of habitat disturbance would not lead to a detectable change in spawning or rearing success such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 on Greenland turbot would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next five years under FMP 1. Therefore, this impact is expected to be insignificant, because there is no evidence that future FMP 1 harvest levels or distribution of harvest would lead to a change in prey availability such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Summary of Direct and Indirect Effects of FMP 1 on BSAI Greenland Turbot

Under FMP 1, the spawning stock biomass of BSAI Greenland turbot is expected to be above the MSST. Since the F does not exceed F_{OFL} and the stock is expected to remain above the MSST, the expected changes under this FMP are not substantial enough to expect that the genetic diversity or the reproductive success of the spawning stocks would change under the new management regime. Thus, the indirect and direct effects under this FMP are considered insignificant.

Relative to the 2002 comparative baseline, the Greenland turbot stock is projected to continue not to be overfished under this FMP. The 20-year projection indicates that the female spawning stock is expected to decline until 2007 to below B_{MSY} levels and will increase thereafter through the end of the projection to be above B_{ABC} in 2023.

Status Determination from Modeling

Stock Size Relative to MSST

Model projections of future catches of BSAI Greenland turbot are below the OFLs in all years under FMP 1. The Greenland turbot stock is above the MSST level in 2002.

Age and Size Composition

Under FMP 1, the mean age of the BSAI Greenland turbot stock in 2008, as computed in model projections (Table H.4-5 of Appendix H), is 4.6 years. This compares with a mean age in the equilibrium unfished BSAI stock of 5.9 years. Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

The sex ratio of Greenland turbot in the BSAI is assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects Analysis of FMP 1

Table 4.5-15 summarizes the cumulative effects analysis for BSAI Greenland Turbot.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI Greenland turbot is rated as insignificant under FMP 1.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI Greenland turbot stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potential adverse effects of marine pollution; acute and/or chronic pollution events could cause Greenland turbot mortality. Climate changes and regime shifts are considered non-contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of Greenland turbot.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI Greenland turbot and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of the fisheries on the change in biomass is insignificant.

- **Persistent Past Effects.** Past effects have not been identified for the change in biomass in the BSAI Greenland turbot stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in biomass are indicated due to the potential adverse effects of marine pollution; acute and/or chronic pollution events could cause Greenland turbot mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the Greenland turbot biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. For more information on climate changes and regime shifts see Sections 3.5.1.9 and 3.10.

- **Cumulative Effects.** A cumulative effect is identified for the change in biomass level of BSAI Greenland turbot and is rated as insignificant. Fishing mortality at projected levels is well below the

OFL for this stock and the female spawning biomass is above the B_{MSY} value from 2003-2006. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch

- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1 the effect of the spatial/temporal concentration of catch is considered insignificant for the stock.

- **Persistent Past Effects.** Climate changes and regime shifts have been identified as persistent past effects for the spatial/temporal concentration of BSAI Greenland turbot catch. Climate changes and regime shifts are suspected of having an effect on the reproductive success of the Greenland turbot stock. See Section 3.5.1.9 for more information.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of Greenland turbot due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of BSAI Greenland turbot.

- **Cumulative Effects.** A cumulative effect is identified for the spatial/temporal concentration of the Greenland turbot catch and is rated as insignificant. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under FMP 1, the change in prey availability for the BSAI Greenland turbot is ranked as insignificant.

- **Persistent Past Effects.** Past effects are identified for the change in prey availability of the BSAI Greenland turbot stock. Past foreign, JV, and domestic fisheries have been identified as having influenced the availability of Greenland turbot prey, mainly pollock, which is their main prey item in the BSAI. Climate changes and regime shifts have also been identified as influencing Greenland turbot prey availability. See Section 3.5.1.9 for more information.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI Greenland turbot stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability and is considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, the change in habitat suitability for the BSAI Greenland turbot is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified for BSAI Greenland turbot include climate changes and regime shifts. The foreign, JV, and domestic fisheries have also influenced the habitat suitability of Greenland turbot, largely through the impacts of fishing gear on benthic habitats. See Section 3.5.1.9 for more information on the persistent past effects on Greenland turbot.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI Greenland turbot stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for BSAI Greenland turbot habitat suitability and is considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the Greenland turbot stock to sustain itself at or above the MSST is jeopardized.

GOA Deepwater Flatfish – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on the GOA deepwater flatfish complex. The potential effect of FMP 1 on this complex through fishing mortality is expected to be insignificant. The significance of all other potential direct and indirect effects on this group is unknown. Significance ratings are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The catch of GOA deepwater flatfish in 2002 was estimated to be 600 mt. Model projections of future catch are shown in Table H.4-25 of Appendix H. Under FMP 1, model projections indicate that the catch is expected to increase two and a half times the 2002 value to 1,600 mt by 2007, with a 2003-2007 average value of 1,600 mt. This impact is expected to be insignificant, because it is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

Reliable estimates of total and spawning biomass do not exist for these species. Consequently, the potential impact of FMP 1 on GOA deepwater flatfish biomass levels is unknown, because MSSTs have not been determined for the species in this group.

Spatial/Temporal Concentration of Catch

The spatial/temporal characteristics of the annual GOA deepwater flatfish harvest would not be affected under FMP 1, relative to the 2002 baseline. However, the effects of the temporal/spatial concentration of the catch on this stock under baseline conditions are unknown. Therefore, the potential effects of FMP 1 to affect genetic structure or reproductive success within the GOA deepwater flatfish populations must also be considered unknown.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 on the GOA deepwater flatfish complex would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat- mediated impacts would undergo significant qualitative change during the next five years under this FMP. Therefore, evidence is insufficient to conclude whether future levels of habitat disturbance would lead to a change in spawning or rearing success that would affect the ability of the stock to sustain itself at or above the MSST under FMP 1.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 on deepwater flatfish would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next five years under FMP 1. Therefore, evidence is insufficient to conclude whether future harvest levels and distribution of harvest under this FMP would lead to a change in prey availability that would affect the stock's ability to sustain itself at or above the MSST.

Summary of Direct and Indirect Effects of FMP 1 on GOA Deepwater Flatfish

The direct and indirect effects of FMP 1 on GOA deepwater flatfish cannot be determined from the MSST criteria used for stocks in Management Category Tiers 1-3. It is unknown what the estimate of female spawning biomass of these stocks would be over the five-year projection and what level of fishing mortality would correspond to the modeled catch estimated under this FMP.

Status Determination from Modeling

Stock Size Relative to MSST

The available information for flatfish species in the deepwater complex requires that they are classified into either the Tier 5 or Tier 6 management category. As a result, no MSSTs are defined for these species in the National Standard Guidelines. Therefore, it is not possible to determine the status of their stock size relative to MSST.

Age and Size Composition

Age and size composition estimates are not available for these species.

Sex Ratio

The sex ratio of deepwater flatfish in the GOA is assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

Table 4.5-16 summarizes the cumulative effects analysis for GOA deepwater flatfish.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA deepwater flatfish is rated as insignificant under FMP 1.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the GOA deepwater flatfish stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potential adverse effects of marine pollution; acute and/or chronic pollution events could cause deepwater flatfish mortality. Climate changes and regime shifts are considered non-contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of deepwater flatfish. The State of Alaska scallop fishery is identified as a non-contributing factor since bycatch of deepwater flatfish species is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is identified for mortality of GOA deepwater flatfish and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Total and spawning biomass estimates are unavailable for the deepwater flatfish species, therefore, the effects of FMP 1 on the change in biomass level are unknown.

- **Persistent Past Effects.** Past effects have not been identified for the change in biomass in the GOA deepwater flatfish stock complex.

- **Reasonably Foreseeable Future External Effects.** Future external effects. on the change in biomass are indicated due to the potential adverse effects of marine pollution; acute and/or chronic pollution events could cause deepwater flatfish mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the deepwater flatfish species biomass level. For more information on climate changes and regime shifts, see Sections 3.5.1.22 and 3.10. The State of Alaska scallop fishery has been identified as a non-contributing factor for change in biomass level since deepwater flatfish species bycatch is not expected to occur.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of GOA deepwater flatfish, but is unknown. It is unknown whether the combined effect of internal and external removals is likely to jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1 the effect of the spatial/temporal concentration of catch is unknown for the stock since the MSST is unable to be determined.

- **Persistent Past Effects.** Past effects include climate changes and regime shifts which are suspected of having an effect on the reproductive success of the deepwater flatfish stock complex. See Section 3.5.1.22 for more information on the effects of climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of GOA deepwater flatfish due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of GOA deepwater flatfish. The State of Alaska scallop fishery is identified as a non-contributing factor to change in genetic structure and reproductive success since bycatch of GOA deepwater flatfish species is not expected to occur.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the GOA deepwater flatfish catch; however, this effect unknown. It is unknown whether the combined effect of internal and external removals is likely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain current population levels is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under FMP 1, the change in prey availability for the GOA deepwater flatfish complex is unknown.

- **Persistent Past Effects.** Past effects are identified for the change in prey availability of the GOA deepwater flatfish stock complex and include climate changes and regime shifts. See Section 3.5.1.22 for more information.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA deepwater flatfish stock complex are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The State of Alaska scallop fishery has been identified as a potential adverse contributor to benthic prey availability. See Section 3.6.4 for information of the impacts of fishery gear on EFH.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability; however, this effect is unknown. It is unknown whether the combination of internal and external removals of prey is expected to jeopardize the ability of the stock to maintain current populations.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, the change in habitat suitability for the GOA deepwater flatfish complex is unknown.

- **Persistent Past Effects.** Past effects identified for GOA deepwater flatfish include climate changes and regime shifts. The foreign, JV, and domestic fisheries have also influenced the habitat suitability of deepwater flatfish, largely through the impacts of fishing gear on benthic habitats. See Section 3.5.1.22 for more information on the persistent past effects on deepwater flatfish.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA deepwater flatfish stock complex are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. The State of Alaska scallop fishery has been identified as a potential adverse contributor to habitat suitability. See Section 3.6.4 for more information on the impacts of fishery gear on EFH.

- **Cumulative Effects.** A cumulative effect is identified for GOA deepwater flatfish habitat suitability; however, this effect is unknown. It is unknown whether the combination of internal and external habitat disturbances is expected to lead to a detectable change in spawning or rearing success such that the ability of the deepwater flatfish stock complex to maintain current population levels is jeopardized.

4.5.1.10 Alaska Plaice and Other Flatfish and Rex Sole

The numerous fishery management actions that have affected the Alaska plaice, other flatfish, and rex sole fisheries in the BSAI and GOA are described in more detail in Sections 3.5.1.10 and 3.5.1.23 of this Programmatic SEIS.

Alaska plaice is evaluated under Tier 3a of Amendment 56 (Spencer *et al.* 2002b). Estimates of MSST are available for this stock. Although there are fifteen species considered as part of the "other flatfish" complex, only seven species comprise the majority of the catch. The other flatfish assemblage is managed under Tier 5, although it has been managed under Tier 4 and 3a in the past (Spencer *et al.* 2002a). Estimates of MSST are not available for this stock. The reference F and ABC for rex sole are determined by the amount of population information available. ABCs are calculated using F_{ABC} = 0.75 M and F_{OFL} = M (Tier 5), because maturity information is not available.

BSAI Alaska Plaice – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on BSAI Alaska plaice. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The projected fishing mortality imposed on the BSAI Alaska plaice stock in 2003 is 0.017. Model projections show this fishing mortality will remain at this level through 2005,then increase to 0.021 in 2006 and 2007, and lower to 0.019 in 2008 (Table H.4.9 of Appendix H). These values are below the $F_{35\%}$ level of 0.344 and the $F_{40\%}$ level of 0.279, which are taken as proxies for F_{ABC} and F_{OFL}, respectively. The proportion of SPR conserved under these mortality rates is 92 percent in 2003, decreases to 90 percent in 2006, and increases to 91 percent in 2008. The average implied SPR rate of fishing from 2003-2008 is 91 percent. The impact of fishing mortality on BSAI Alaska plaice is expected to be insignificant under FMP 1, because it is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

Total Biomass

Total biomass (ages 1 through 25+) of BSAI Alaska plaice at the start of 2003 is estimated to be 1,083,000 mt. Model projections of future total BSAI Alaska plaice biomass are shown in Table H.4.9 of Appendix H. Under FMP 1, model projections indicate that BSAI biomass is expected to increase to a value of 1,121,000 mt in 2008, with a 2003-2008 average value of 1,104,000 mt. Because total biomass would tend toward levels that would maintain the ability of the stock to sustain itself above the MSST, this effect would be insignificant under FMP 1.

Spawning Biomass

Spawning biomass of BSAI Alaska plaice at the start of 2003 is estimated to be 275,900 mt. Model projections of future total BSAI Alaska plaice biomass are shown in Table H.4.9 of Appendix H. Under FMP 1, model projections indicate that BSAI Alaska plaice biomass is expected to increase to a value of 283,300 mt in 2008, with a 2003-2008 average value of 278,800 mt. Because spawning biomass would tend toward levels that would maintain the ability of the stock to sustain itself above the MSST, this effect would be insignificant under FMP 1.

Spatial/Temporal Concentration of Catch

Alaska plaice is a relatively low-valued flatfish species that is taken as bycatch on the EBS shelf; little harvest occurs in the Aleutian Islands. Under FMP 1, an average of 10,500 mt is projected to be harvest annually from 2003-2008, coming nearly entirely from the EBS. The EBS yellowfin sole and rock sole fisheries account for most of the catch, contributing 7,450 mt (71 percent) and 1,440 mt (14 percent) of the average annual harvest. Recent observer data indicate that the harvest of Alaska plaice occurs year-round, and are determined largely from the seasonal allocations of the Pacific halibut prohibited species bycatch limits for flatfish trawl fisheries (Spencer *et al.* 2001). The impact of the spatial/temporal pattern of the harvest under FMP 1 is expected to be insignificant because the harvest concentration would not be sufficient to alter the genetic sub-population structure or reproductive success such that it would jeopardize the ability of the BSAI Alaska plaice stock to sustain itself at or above its MSST.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change under this FMP 1. There is no evidence that future levels of habitat disturbance would lead to a detectable change in spawning or rearing success such that it would jeopardize the ability of the BSAI Alaska plaice stock to sustain itself at or above the MSST. Therefore, this impact is expected to be insignificant under FMP 1.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that trophic interactions would undergo significant qualitative change under FMP 1. There is no evidence that future distribution of harvest would lead to a change in prey availability such that it would jeopardize the ability of the BSAI Alaska plaice stock to sustain itself at or above the MSST. Therefore, this impact is expected to be insignificant under FMP 1.

Summary of Direct and Indirect Effects of FMP 1 on BSAI Alaska Plaice

Because BSAI Alaska plaice are fished at less than the OFL and are above the MSST, the direct and indirect effects under FMP 1 are considered insignificant. Fishing rates are well within accepted scientific standards based on studies of population dynamics and estimates of natural variation of recruitment. Under these considerations, the spatial/temporal distribution of catch should have no significant direct impact on stock productivity.

Relative to the 2002 comparative baseline, the Alaska plaice stock is projected to continue not to be overfished under this FMP. The 20-year projection indicates that the female spawning stock is expected to remain at a high and stable level well above B_{ABC}.

Status Determination from Modeling

Stock Size Relative to MSST

Under FMP 1, the ABC is set at a lower level than the OFL, creating a buffer between these two harvest regulations. Model projections of future catches of BSAI Alaska plaice are below the ABC and OFL levels in all years. The BSAI Alaska plaice are above their respective MSST in the year 2002.

Age and Size Composition

Under FMP 1, the mean age of the BSAI Alaska plaice stock in 2008, as computed in model projections, is 4.40 years. This compares with a mean age in the equilibrium unfished stock of 4.51 years.

Sex Ratio

The sex ratio of BSAI Alaska plaice is assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

Table 4.5-17 summarizes the cumulative effects analysis for BSAI Alaska plaice.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI Alaska plaice is rated as insignificant under FMP 1.

- **Persistent Past Effects.** Past effects have not been identified for BSAI Alaska plaice mortality.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to the potential adverse effects of marine pollution; acute and/or chronic pollution events could cause other flatfish mortality. Climate changes and regime shifts are considered non-contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of Alaska plaice. For more information on climate changes and regime shifts, see Sections 3.5.1.10 and 3.10.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI Alaska plaice and is rated as insignificant. Fs for projected years are well below the other flatfish OFL. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under FMP 1, the effect of changes in biomass level is rated as insignificant.

- **Persistent Past Effects.** Past effects have not been identified for the change in biomass of BSAI Alaska plaice.

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are indicated due to potential adverse effects of marine pollution; acute and/or chronic pollution events could cause other flatfish mortality. Climate changes and regime shifts have also been identified as having an indirect potentially beneficial or adverse effect on the Alaska plaice biomass level. When the Aleutian Low is strong and water temperatures warm, flatfish recruitment is favored, whereas when the Aleutian Low is weak and the temperatures cooler, recruitment tends to be weak. For more information on climate changes and regime shifts, see Sections 3.5.1.10 and 3.10.

- **Cumulative Effects.** A cumulative effect is identified for the change in biomass level of BSAI Alaska plaice and is rated as insignificant. The combined effect of internal removals and removals due to reasonably foreseeable future external events is not expected to jeopardize the capacity of the stock to sustain itself above the MSST.

<u>Spatial/Temporal Concentration of Catch</u>

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1 the effect of the spatial/temporal concentration of catch is identified as insignificant.

- **Persistent Past Effects.** Past effects are not identified for genetic structure of the population. However, climate changes and regime shifts are identified as having persistent past effects on the reproductive success of the BSAI Alaska plaice stock. See Sections 3.5.1.10 and 3.10 for more information of climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the genetic structure of other flatfish include the potential adverse effects of marine pollution; acute and/or chronic pollution events could alter the genetic structure of the population by causing localized mortality. Climate changes and regime shifts have been identified as non-contributing factors to the change in genetic structure of the Alaska plaice stocks. These events are not expected to cause localized depletions that would significantly alter the genetic sub-population structure of the Alaska plaice stock. Change in reproductive success of Alaska plaice due to climate changes and regime shifts is identified as potentially beneficial or adverse. Marine pollution has been identified as a potential adverse effect since acute and/or chronic pollution events could also the reproductive success of BSAI Alaska plaice.

- **Cumulative Effects.** A cumulative effect is identified for the spatial/temporal concentration of the Alaska plaice catch and is rated as insignificant. The combined effect of internal removals and external removals are not expected to jeopardize the capacity of the stock to sustain itself above the MSST.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** Under FMP 1, the change in prey availability for the BSAI Alaska plaice is insignificant.

- **Persistent Past Effects.** Climate changes are identified as having effected prey availability of the BSAI Alaska plaice stock. The actual effect of climate changes and regime shifts on Alaska plaice prey availability is unknown, but could have had a potentially beneficial or adverse effect. See Sections 3.5.1.10 and 3.10 for more information on climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI Alaska plaice stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to maintain current population levels.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability and is rated as insignificant. The combined effect of internal removals and removals due to reasonably foreseeable future external events are not expected to jeopardize the capacity of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, the change in habitat suitability for the BSAI Alaska plaice is rated as insignificant.

- **Persistent Past Effects.** Past effects identified for BSAI Alaska plaice include climate changes and regime shifts. The actual effects of climate changes and regime shifts on habitat suitability are unknown, but could have a potentially beneficial or adverse effect. Habitat disturbances caused by the past foreign, JV, and domestic fisheries have also been identified as having persistent past effects on the BSAI Alaska plaice stock See Sections 3.5.1.10 and 3.10 for more information regarding the past fisheries and climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI Alaska plaice stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for BSAI Alaska plaice habitat suitability and is rated as insignificant. The combined effect of internal removals and removals due to reasonably foreseeable future external events is not expected to jeopardize the capacity of the stock to sustain itself above the MSST.

BSAI Other Flatfish – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on the BSAI other flatfish complex. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The catch of BSAI other flatfish in 2002 was estimated to be 2,600 mt. Model projections of future catch are shown in Table H.4.10 of Appendix H. Under FMP 1, model projections indicate that the catch is expected to decrease from the 2002 value to 2,200 mt in 2003 and then increase each year to 2,500 mt in 2007 (5 percent decrease from 2002). The 2003-2007 average catch is 2,300 mt. The impact of fishing mortality on BSAI other flatfish is expected to be insignificant under FMP 1, because it is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

Total and spawning biomass estimates are not available for these species. Therefore, the potential impact of FMP 1 on biomass level is unknown, because the MSST cannot be determined.

Spatial/Temporal Concentration of Catch

The spatial/temporal characteristics of the annual BSAI other flatfish harvest would not be affected under FMP 1, relative to the 2002 baseline year. Evidence is insufficient to conclude whether the harvest concentration under FMP 1 would lead to a detectable change in genetic diversity or reproductive success that would affect the stock's ability to sustain itself at or above the MSST. Therefore, the impact of the spatial/temporal pattern of the catch on BSAI other flatfish under FMP 1 is unknown.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next five years under this FMP. Because evidence is not available to determine whether, under FMP 1, future levels of habitat disturbance would lead to a change in spawning or rearing success that would affect the ability of the BSAI other flatfish stocks to sustain themselves at or above their MSSTs, this potential impact is unknown.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 on other flatfish would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next five years under FMP 1. Consequently, evidence is not available to determine whether future harvest levels and distribution of harvest under this FMP would lead to a change in prey availability that would affect the ability of the BSAI other flatfish stocks to sustain themselves at or above their MSSTs. Therefore, this potential impact is unknown.

Summary of Direct and Indirect Effects of FMP 1 on BSAI Other Flatfish

The direct and indirect effects of FMP 1 on BSAI other flatfish cannot be determined from the MSST criteria used for stocks in Management Category Tiers 1-3. It is unknown what the estimate of female spawning biomass of these stocks is over the five-year projection and what level of fishing mortality corresponds to the modeled catch estimated under this FMP.

Status Determination from Modeling

Stock Size Relative to MSST

The available information for flatfish species in the other flatfish complex requires that they are classified into either the Tier 4 or Tier 5 management category. As a result, no MSSTs are defined for these species in the National Standard Guidelines. Therefore, it is not possible to determine the status of their stock sizes relative to their MSSTs.

Age and Size Composition

Age and size composition estimates are not available for these species.

Sex Ratio

The sex ratios of the species in the other flatfish category in the BSAI are assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

Table 4.5-18 summarizes the cumulative effects analysis for BSAI other flatfish.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI other flatfish is rated as insignificant under FMP 1.

- **Persistent Past Effects.** Past effects have not been identified for BSAI other flatfish mortality.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are the same as those described for BSAI Alaska plaice under this FMP.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI other flatfish and is rated as insignificant. Fs for projected years are well below the other flatfish OFL. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under FMP 1, the effect of changes in biomass level is rated as unknown since the MSST for this stock is not possible to be determined.

- **Persistent Past Effects.** Past effects have not been identified for the BSAI other flatfish change in biomass level effect indicator.

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are the same as those described for BSAI Alaska plaice under this FMP.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI other flatfish, but this effect is unknown. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch

- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1 the effect of the spatial/temporal concentration of catch is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects identified for the spatial/temporal concentration of catch are the same as those described for BSAI Alaska plaice under this FMP.

- **Reasonably Foreseeable Future External Effects.** Future external effects identified for the spatial/temporal concentration of catch are the same as those described for BSAI Alaska plaice under this FMP.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the other flatfish catch, but this effect is unknown since the MSST is not possible to be determined. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

Change in Prey Availability

- **Direct/Indirect Effects.** Under FMP 1, the change in prey availability for the BSAI other flatfish is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects identified for the change in prey availability are the same as those described for BSAI Alaska plaice under this FMP.

- **Reasonably Foreseeable Future External Effects.** Future external effects identified for the change in prey availability are the same as those described for BSAI Alaska plaice under this FMP.

- **Cumulative Effects.** A cumulative effect is possible for the change in prey availability. However, this effect is unknown since it is not possible to determine the MSST. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, the change in habitat suitability for the BSAI other flatfish is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects identified for habitat suitability of BSAI other flatfish are the same as those described for BSAI Alaska plaice under this FMP.

- **Reasonably Foreseeable Future External Effects.** Future external effects identified for habitat suitability are the same as those described for BSAI Alaska plaice under this FMP.

- **Cumulative Effects.** A cumulative effect is possible for BSAI other flatfish habitat suitability; however, this effect is unknown. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

GOA Rex Sole – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on GOA rex sole. The significance ratings for these potential effects are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The catch of GOA rex sole in 2002 was estimated to be 3,000 mt. Model projections of future catch are shown in Table H.4.26 of Appendix H. Under FMP 1, model projections indicate that the catch is expected to increase from the 2002 value to 3,300 mt in 2003and then decrease thereafter to 2,500 mt in 2007. The 2003-2007 average catch is 3,000 mt. The impact of fishing mortality on GOA rex sole is expected to be insignificant under FMP 1, because it is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

Total and spawning biomass estimates are not available for this species, and the MSST cannot be determined. Therefore, the potential effect of FMP 1 on GOA rex sole biomass levels is unknown.

Spatial/Temporal Concentration of Catch

The spatial/temporal characteristics of the annual GOA rex sole harvest would not be affected under FMP 1, relative to the 2002 baseline year. Evidence is insufficient to conclude whether the harvest concentration under FMP 1 would lead to a detectable change in genetic diversity or reproductive success that would affect the stock's ability to sustain itself at or above the MSST. Therefore, the impact of the spatial/temporal pattern of the catch on GOA rex sole under FMP 1 is unknown.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next five years under this FMP. The potential impact of FMP 1 is unknown because evidence is not available to determine whether future levels of habitat disturbance would lead to a change in spawning or rearing success that would affect the ability of the GOA rex sole stock to sustain itself at or above the MSST.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 on rex sole would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next five years under FMP 1. Therefore, it is unknown whether future harvest levels and distribution of harvest would lead to a change in prey availability that would affect the GOA rex sole stock's ability to sustain itself at or above the MSST.

Summary of Direct and Indirect Effects of FMP 1 on GOA Rex Sole

The direct and indirect effects of FMP 1 on GOA rex sole cannot be determined from the MSST criteria used for stocks in Management Category Tiers 1-3. Potential changes in the F would be too small to affect MSY and are therefore considered insignificant. It is unknown what the estimate of female spawning biomass of this stock would be over the five-year projection and what level of fishing mortality would correspond to the modeled catch estimated under this FMP.

Status Determination from Modeling

Stock Size Relative to MSST

The available information for rex sole requires that they are classified in the Tier 5 management category. As a result, no MSSTs are defined for these species in the National Standard Guidelines. Therefore, it is not possible to determine the status of their stock size relative to MSST.

Age and Size Composition

Age and size composition estimates are not available for this species.

Sex Ratio

The sex ratio of rex sole in the GOA is assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

Table 4.5-19 summarizes the cumulative effects analysis for GOA rex sole.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA rex sole is rated as insignificant under FMP 1.

- **Persistent Past Effects.** Large removals of rex sole by the past foreign, JV, and domestic fisheries have been identified as having had an adverse persistent past effect on GOA rex sole stocks. See Section 3.5.1.23 for details regarding these effects.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to the potential adverse effects of marine pollution; acute and/or chronic pollution events could cause rex sole mortality. Climate changes and regime shifts are considered non-contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of rex sole. The State of Alaska scallop fishery has also been identified as a non-contributing factor since it is not expected to contribute to direct mortality of rex sole.

- **Cumulative Effects.** A cumulative effect is identified for mortality of GOA rex sole and is rated as insignificant. Fs for projected years are well below the rex sole OFL. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under FMP 1, the effect of changes in biomass level is rated as unknown since the MSST for this stock is not possible to be determined.

- **Persistent Past Effects.** Large removals of rex sole by past foreign, JV, and domestic fisheries have been identified as having had a adverse persistent past effect on GOA rex sole stocks. See Section 3.5.1.23 for details regarding these effects.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in biomass are indicated due to potential adverse effects of marine pollution; acute and/or chronic pollution events could cause rex sole mortality. Climate changes and regime shifts have also been identified as having an indirect potentially beneficial or adverse effect on the rex sole biomass level. The State of Alaska Scallop Fishery is identified as a non-contributing factor since it is not expected to contribute to direct mortality of rex sole. For more information on climate changes and regime shifts, see Sections 3.5.1.23 and 3.10.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of GOA rex sole, but is the effect is unknown. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch
- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under FMP 1 the effect of the spatial/temporal concentration of catch is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects are not identified for genetic structure of the population; however, climate changes and regime shifts are identified as having persistent past effects on the reproductive success of the GOA rex sole stock. See Sections 3.5.1.23 and 3.10 for more information on climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the genetic structure of rex sole include the potential adverse effects of marine pollution; an acute and/or chronic pollution event could alter the genetic structure of the population by causing localized mortality. The State of Alaska scallop fishery and climate changes and regime shifts have both been identified as non-contributing factors to the change in genetic structure of rex sole stocks. These events are not expected to cause localized depletions that would alter the genetic sub-population structure of rex sole stock. Change in reproductive success of rex sole due to climate changes and regime shifts is identified as having a potentially beneficial or adverse effect. Marine pollution has been identified as a potential adverse effect since acute and/or chronic pollution events could also the reproductive success of GOA rex sole. Again, the State of Alaska scallop fishery has been identified as a non-contributing factor since the scallop fishery is not expected to contribute to rex sole removals.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the rex sole catch; however, these effects are unknown since the MSST is not possible to be determined. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

Change in Prey Availability

- **Direct/Indirect Effects.** Under FMP 1, the change in prey availability for the GOA rex sole is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Climate change and regime shifts have been identified as having effected the change in prey availability of the GOA rex sole stock. The actual effect of climate changes and regime shifts on rex sole prey availability is unknown, but could have had a potentially beneficial or adverse effect. See Sections 3.5.1.23 and 3.10 for more information on climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA rex sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to maintain current population levels. The State of Alaska scallop fishery has been identified as having a potential adverse effect on rex sole prey availability since the habitat disturbances caused by dredging could influence the benthic prey availability.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability; however, this effect is unknown since it is not possible to determine the MSST. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under FMP 1, the change in habitat suitability for the GOA rex sole is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects identified for GOA rex sole include climate changes and regime shifts. The actual effects of climate changes and regime shifts on habitat suitability are unknown, but could have a potentially beneficial or adverse effect. Habitat disturbances caused by the past foreign, JV, and domestic fisheries have also been identified as having persistent past effects on the GOA rex sole stock. See Sections 3.5.1.23 and 3.10 for more information regarding the past fisheries and climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA rex sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. The State of Alaska scallop fishery is identified as having potential adverse effects on rex sole habitat suitability that may cause changes in the spawning or rearing success of the stock.

- **Cumulative Effects.** A cumulative effect is identified for GOA rex sole habitat suitability; however, this effect is unknown. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

4.5.1.11 Pacific Ocean Perch

Pacific ocean perch (*Sebastes alutus*) are managed as a single stock in the EBS, Aleutian Islands, and GOA, and separate assessments are made for each region. Within the GOA, ABC limits are apportioned within four management areas in an effort to reduce the risk of localized depletion. Trawl fishing is not permitted in the southeast/east Yakutat area and the ABC (approximately 12 percent of the total GOA ABC) normally allocated to that area is not likely to be caught. Pacific ocean perch are managed under Tier 3 in both the BSAI and GOA.

BSAI Pacific Ocean Perch – Direct/Indirect Effects of FMP 1

The following discussions briefly describe the direct and indirect impact analyses of FMP 1 on BSAI and GOA Pacific ocean perch. All of these potential effects are expected to be insignificant. The significance ratings are summarized in Appendix A, Table 4.5-83. For significance criteria, see Appendix A, Table 4.1-1.

Fishing Mortality

The projected fishing mortality imposed on the BSAI Pacific ocean perch stock in 2003 is 0.033. Model projections show this fishing mortality will decrease to 0.027 in 2005 and then increase to 0.033 in 2008 (Table H.4-12 of Appendix H). These values are below the $F_{35\%}$ level of 0.057 and the $F_{40\%}$ level of 0.048, which are taken as proxies for F_{ABC} and F_{OFL}, respectively. The implied SPR fishing rates under FMP 1 is 51 percent in 2003, increasing to 56 percent in 2005, and decreasing to 51 percent in 2008. The average implied SPR rate of fishing from 2003-2008 is 51 percent. The impact of fishing mortality on BSAI Pacific ocean perch is expected to be insignificant under FMP 1, because it is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

Total Biomass

Total biomass (ages 3 through 21+) of BSAI Pacific ocean perch at the start of 2003 is estimated to be 374,000 mt. Model projections of future total BSAI Pacific ocean perch biomass are shown in Table H.4-12 of Appendix H. Under FMP 1, model projections indicate that BSAI Pacific ocean perch biomass is expected to increase to a value of 396,000 mt in 2008, with a 2003-2008 average value of 385,000 mt. Because total biomass would tend toward levels that would maintain the ability of the stock to sustain itself above the MSST, this effect would be insignificant under FMP 1.

Spawning Biomass

Spawning biomass of BSAI Pacific ocean perch at the start of 2003 is estimated to be 135,500 mt. Model projections of future total BSAI Pacific ocean perch biomass are shown in Table H.4-12 of Appendix H. Under FMP 1, model projections indicate that BSAI Pacific ocean perch biomass is expected to decrease to a value of 135,300 mt in 2004, then increase to a value of 138,800 mt in 2008, with a 2003-2008 average value of 136,800 mt. Because spawning biomass would tend toward levels that would maintain the ability of the stock to sustain itself above the MSST, this effect would be insignificant under FMP 1.

Spatial/Temporal Concentration of Catch

In recent years, the Pacific ocean perch directed fishery in the Aleutian Islands typically occurs in the month of July. Fishery observer data from 2000-2002 indicates that approximately 80 percent of the Pacific ocean perch in the BSAI are harvested during this month; there is no directed fishing for Pacific ocean perch in the EBS management area. Projected harvest under FMP 1 indicates that an average of 10,600 mt is harvested in the BSAI area, with 49 percent from the eastern Aleutians, 23 percent from the western Aleutians, 22 percent from the central Aleutians, and 6 percent from the EBS. This impact is expected to be insignificant, because the concentration of harvest under FMP 1 would not be sufficient to alter the genetic sub-population structure or reproductive success such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Habitat Suitability

Any habitat-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change under this FMP 1.Therefore, the effects of FMP 1 on habitat suitability are expected to be insignificant, because future levels of habitat disturbance would not lead to a detectable change in spawning or rearing success such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Prey Availability

As with habitat-mediated impacts, any predation-mediated impacts of FMP 1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that trophic interactions would undergo significant qualitative change under FMP 1. Therefore, this impact is expected to be insignificant, because there is no evidence that future FMP 1 harvest levels or distribution of harvest would lead to a change in prey availability such that it would jeopardize the ability of the stock to sustain itself at or above the MSST.

Summary of Direct and Indirect Effects of FMP 1 on BSAI Pacific Ocean Perch

Because BSAI Pacific ocean perch are fished at less than the OFL and are above the minimum stock size threshold, the direct and indirect effects under FMP 1 are considered insignificant. Fishing rates are well within accepted scientific standards based on studies of population dynamics and estimates of natural variation of recruitment. Under these considerations, the spatial/temporal distribution of catch should have no significant direct impact on stock productivity.

Status Determination from Modeling

Stock Size Relative to MSST

Under FMP 1, the ABC is set at a lower level than the OFL, creating a buffer between these two harvest regulations. Model projections of future catches of BSAI Pacific ocean perch are below the ABC and OFL levels in all years, and projected spawning stock biomass is above B_{MSY} ($B_{35\%}$) level of 120,200 mt; thus, BSAI Pacific ocean perch are determined to be above the MSST level under FMP 1 (Table H.4-12 of Appendix H).

Age and Size Composition

Under FMP 1, the mean age of the BSAI Pacific ocean perch stock in 2008, as computed in model projections, is 10.38 years. This compares with a mean age in the equilibrium unfished stock of 14.01 years.

Sex Ratio

The sex ratio of BSAI Pacific ocean perch is assumed to be 50:50. No information is available to suggest that this would change under FMP 1.

Cumulative Effects of FMP 1

Table 4.5-20 summarizes the cumulative effects analysis for BSAI Pacific ocean perch.

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI Pacific ocean perch stock is insignificant under FMP 1.

- **Persistent Past Effects.** The past foreign, JV, and domestic fisheries are identified as having had adverse effects on the BSAI Pacific ocean perch stock. Large removals of Pacific ocean perch occurred in the past and there appears to be a lingering effect on the BSAI populations (see Section 3.5.1.11).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fishery is not expected to contribute to BSAI Pacific ocean perch mortality since bycatch in this fishery is not expected. Marine pollution is identified as making a potential adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not identified as being contributors to Pacific ocean perch mortality.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI Pacific ocean perch and is rated as insignificant. Pacific ocean perch are fished at less than the OFL. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

<u>Change in Biomass</u>

- **Direct/Indirect Effects.** Change in biomass of the BSAI Pacific ocean perch stock is expected to be insignificant under FMP 1.

- **Persistent Past Effects.** The past foreign, JV, and domestic fisheries are identified as having had adverse effects on the BSAI Pacific ocean perch stock. Large removals of Pacific ocean perch occurred in the past and there appears to be a lingering effect on the BSAI populations (see Section 3.5.1.11).
