- **Persistent Past Effects.** Persistent past effects on species within the other toothed whale group include incidental take and entanglement in foreign, JV, Federal domestic groundfish fisheries and State-managed fisheries, and subsistence hunting of beluga whales. The decline of the Cook Inlet beluga population is thought to have been the result of subsistence harvests, which ranged from 21 to 123 animals per year between 1993 and 1998. Only one beluga was harvested in 2001 by hunters from the Native Village of Tyonek and one beluga was harvested in 2002 by the Cook Inlet community hunters. Belugas are incidentally taken during the State-managed salmon gillnet fisheries in Bristol Bay and Cook Inlet with one beluga reported taken from the eastern Bering stock in 1996 and seven reported taken in Bristol Bay in 2000. In the BSAI and GOA groundfish fisheries, no mortality or serious injuries to belugas have been observed. Harbor porpoise have not been taken in the observed groundfish fisheries over a ten year period between 1990 to 1998 (Angliss *et al*. 2001). Salmon gillnet fisheries in southeast Alaska take approximately three individuals per year. Dall porpoise mean annual mortality was 6.0 for the Bering Sea groundfish trawl fishery, 1.2 for the GOA groundfish trawl fishery, and 1.6 for the Bering Sea groundfish longline fishery. The Alaska Peninsula/Aleutian Island salmon drift gillnet fishery has a higher take of Dall's Porpoise with an estimated 28 porpoises in one year (1990). Thousands of Pacific white-sided dolphins were killed annually between 1978 and 1991 in the high seas driftnet fisheries, which no long occur (Angliss *et al*. 2001). One Pacific white-sided dolphin was taken in the BSAI trawl fishery and one in the BSAI longline fishery during the same time span (Angliss *et al*. 2001). State-managed salmon gillnet fisheries take approximately two dolphins per year.

  Approximately 258,000 sperm whales in the North Pacific were harvested by commercial whalers between 1947 and 1987, with high counts in 1968 when 16,357 sperm whales were harvested, after which the population were severely depleted. Sperm whale interactions with longline fisheries operating in the GOA are known to occur and may be increasing in frequency. Sperm whales have been known to prey on sablefish caught on commercial longline gear in the GOA. Only three entanglements have been reported in the GOA longline fishery.

  For killer whales, the combined mortality from the observed groundfish fisheries was 1.4 whales per year (Angliss *et al*. 2001). While it is most likely that whales interacting with fisheries are from resident pods (since they eat fish), no genetic testing has been done on whales incidentally taken in the groundfish fisheries to ascertain whether they were from resident or transient stocks.

For beaked whales (Baird's, Cuvier's, or Stejneger's), no incidental takes or entanglements in BSAI and GOA groundfish trawl, longline, and pot fisheries have been documented (Hill and DeMaster 1999).

- **Reasonably Foreseeable Future External Effects.** Foreign fisheries outside the U.S. EEZ and State-managed fisheries were identified as potential effects in the futures. Several of these species range outside of BSAI and GOA during the winter months. Subsistence takes of some beluga whales would be expected to continue similar to the baseline conditions. Other species are not taken for subsistence purposes.

- **Cumulative Effects.** Cumulative effects of mortality resulting from internal and external factors are considered insignificant for all non-ESA listed species due to the low level of incidental take in the groundfish fisheries and limited external human-caused mortality.

  For the endangered sperm whale, the cumulative effect was also considered insignificant because the very low level of incidental take in the groundfish fisheries and very limited human-caused mortality from external sources is not expected to delay the recovery of sperm whale populations.

Prey Availability

- **Direct/Indirect Effects.** The groundfish fishery under FMP4.1 is not expected to increase the level of competitive interactions for toothed whale prey from the baseline condition and is therefore considered to have insignificant effects on toothed whale prey.

- **Persistent Past Effects.** Although this group preys on a wide variety of fish species, past effects on the availability of prey for this group are identified for fisheries in general and include the foreign, JV, and Federal domestic groundfish fisheries and the State-managed fisheries for salmon and herring. The diversity of diet in this whale group results in limited overlap for most species with the possible exception of sperm whales and resident killer whales.

- **Reasonably Foreseeable Future External Effects.** State-managed fisheries were identified as an external factor having a potential effect on prey for these species in the future. Climate and regime shift are also identified but the direction and magnitude of these effects are difficult to predict.

- **Cumulative Effects.** The ability of these whale species to forage over wide areas and on a variety of prey species moderates any potential impacts from fisheries competition. Cumulative effects on prey availability were identified for this group, including a very limited contribution from the groundfish fishery, but the degree of fishery harvest and bycatch of prey important to these whale species is not expected to have population-level effects on any species, including the endangered sperm whale, and is therefore considered insignificant.

Spatial/Temporal Concentrations of the Fisheries

- **Direct/Indirect Effects.** The groundfish fisheries have little competitive overlap with toothed whales; therefore, changes to the spatial/temporal concentration of the fisheries is expected to result in effects that are insignificant to sperm whales and other toothed whales at the population level.

- **Persistent Past Effects.** The spatial/temporal concentration of foreign, JV, and domestic groundfish fisheries and the State-managed fisheries are believed to have had minimal effects on the abundance and distribution of toothed whale prey.

- **Reasonably Foreseeable Future External Effects.** State-managed fisheries are expected to continue in a similar manner as the under the baseline conditions. Effects of future fishing activities on toothed whale prey are expected to be minimal.

- **Cumulative Effects.** The ability of toothed whales to forage over wide areas and on a variety of prey species moderates any potential impacts from localized depletion of prey from the spatial/temporal concentration of fisheries. Cumulative effects on prey abundance and distribution, including a very limited contribution from the groundfish fishery, are not expected to have population-level effects on any species, including the endangered sperm whale, and are therefore considered insignificant.

Disturbance

- **Direct/Indirect Effects.** Disturbance from the groundfish fishery under FMP 4.1 on sperm whale and other toothed whale populations is determined to be insignificant at the population level.

- **Persistent Past Effects.** Past potential disturbance effects on species in this group were identified for foreign, JV, and Federal domestic groundfish fisheries; however, there is little indication of an adverse effect from this level of disturbance. General vessel traffic likely also contributes to disturbance to these species.

- **Reasonably Foreseeable Future External Effects.** Increases in the general marine vessel traffic and continued fishing activity in the state-managed fisheries were identified as potential sources of disturbance.

- **Cumulative Effects.** The cumulative effect of disturbance from both internal and external factors is found to be insignificant for endangered sperm whales and other toothed whale species based on the lack of evidence that disturbance has a population-level effect for any of these species. For sperm whales, there is growing evidence that the whales are attracted to fishing vessels as reliable and easy sources of food.

Direct/Indirect Effects FMP 4.2 – Other Toothed Whales

Under FMP 4.2, the groundfish fisheries would be essentially closed until specific fisheries were certified to have no adverse effects on the environment. The potential impacts to marine mammals would therefore be even less than described under FMP 4.1 but the conclusions regarding direct/indirect effects for incidental

take and entanglement in marine debris, fisheries harvest of prey species, and spatial and temporal concentration of the fishery under FMP 4.2 are the same as described under FMP 4.1.

Cumulative Effects

Since the groundfish fisheries would be essentially closed under FMP 4.2, the cumulative effects for mortality, prey availability, spatial and temporal concentration of the fishery, and disturbance would all be dominated by the same persistent past and external factors discussed under FMP 4.1. Since the contribution of the groundfish fisheries to all of these effects is also greatly reduced relative to the baseline condition under FMP 4.1, the cumulative effects conclusions are the same as discussed under FMP 4.1.

4.8.8.8 Baleen Whales

Direct/Indirect Effects FMP 4.1

Incidental Take/Entanglement in Marine Debris

Since fishing effort is greatly reduced relative to the baseline under FMP 4.1, incidental takes of baleen whales would be expected to decrease under FMP 4.1. Under the baseline conditions, takes and entanglements associated with fishing activities are thought to be insignificant to baleen whales at the population level. Reducing these takes even further would also be considered to have insignificant effects on the population trajectory of baleen whales.

Fisheries Harvest of Prey Species

The effects of groundfish fisheries under FMP 4.1 are considered insignificant to baleen whales in regards to harvest of prey species due to the lack of competitive overlap in species targeted by each (see Section 4.5.8.8).

Spatial/Temporal Concentration of the Fishery

Groundfish fisheries have little competitive overlap with baleen whales forage species. Changes to the spatial/temporal concentration of the fisheries under FMP 4.1 are expected to result in effects that are insignificant to baleen whales at the population level.

Disturbance

FMP 4.1 is expected to result in decreased disturbance to baleen whales relative to the baseline. However, because the effects of disturbance are insignificant under the baseline conditions they would also be insignificant at the population level.

Cumulative Effects

The past/present effects on the baleen whale group are described in Section 3.8.11 through 3.8.18 (Tables 3.8-11 through 3.8-18). The effects considered in this analysis are listed in Table 4.5-69.

Representative direct effects used in this analysis include mortality and disturbance with the major indirect effects of availability of prey and spatial/temporal concentration of the fisheries (Table 4.1-6).

Mortality

- **Direct/Indirect Effects.** The reduced level of takes and entanglements of baleen whales projected to occur under the FMP 4.1 is considered insignificant at the population level for all species.

.

- **Persistent Past Effects.** Commercial whaling in the last century has had lingering effects on most of the baleen whales in this group with the possible exception of the minke whale. These include endangered blue whales, fin whales, sei whales, humpback whales, northern right whale and the non-ESA-listed gray whales and right whales. A full discussion of the effects of commercial whaling is presented in Section 3.8.

- **Reasonably Foreseeable Future External Effects.** Foreign fisheries outside the EEZ and State-managed fisheries are expected to continue to take small numbers of baleen whales in the coming years. Entanglements in fishing gear will continue to effect baleen whales throughout their ranges. Subsistence for gray whales and bowhead will continue to be the largest source of human-caused mortality.

- **Cumulative Effects.** Cumulative effects of mortality resulting from internal effects of the fishery and contributions from external factors are considered conditionally significant adverse for fin, humpback, and northern right whales due to past effects on their population, potential for interactions with fisheries, and their endangered status. Right whales are very rare so even one human-caused mortality could be considered significant. Given the overlap of their preferred habitat with the BSAI fisheries, the chances of future adverse interactions with fishing gear are more than negligible. The adverse rating for these three species is conditional on whether future take or entanglement substantially affects their rates of recovery. Cumulative effects are found to be insignificant for the endangered blue, bowhead, and sei whales. These species rarely interact with the fisheries so population-level effects are not anticipated. Mortality is also considered insignificant for non-ESA-listed minke and gray whales. Population-level effects are not expected for either of these species.

Prey Availability

- **Direct/Indirect Effects.** The effects of FMP 4.1 are determined to have an insignificant effect on baleen whale species in regards to harvest of prey species due to the lack of competitive overlap in species targeted by each.

- **Persistent Past Effects.** Past effects on availability of prey were not identified due to the lack of competitive overlap in prey species targeted.

- **Reasonably Foreseeable Future External Effects.** Future effects were identified as state-managed fisheries such as herring, which are preyed on by humpback whales and fin whales. Other species would not be directly affected through their prey.

- **Cumulative Effects.** Cumulative effects of prey availability on baleen whale species are not anticipated on a population level for any of the species in this group primarily due to the limited overlap of prey species with fisheries. The effects are considered insignificant for all species.

Temporal and Spatial Concentration of the Fishery

- **Direct/Indirect Effects.** Due to limited overlap of prey species taken, changes to the spatial/temporal concentration of the fisheries under FMP 4.1 are expected to have insignificant effects on baleen whales at the population level.

- **Persistent Past Effects.** Persistent past effects of temporal and spatial concentrations of the fisheries were not identified.

- **Reasonably Foreseeable Future External Effects.** State-managed fisheries would be expected to continue to contribute some degree of effect on several species in the baleen whales group.

- **Cumulative Effects.** Cumulative effects on the spatial and temporal concentration of harvest of baleen whale prey resulting from internal effects of the fishery and contributions from external factors are considered insignificant for endangered and non-ESA listed species in this group due to the limited overlap of prey species within the fisheries.

Disturbance

- **Direct/Indirect Effects.** FMP 4.1 is expected to result in decreased disturbance to endangered and non-ESA-listed baleen whales, but the effects are considered insignificant at the population level.

- **Persistent Past Effects.** Some level of disturbance has likely occurred from foreign, JV, and domestic groundfish fishing and State-managed fisheries along with general vessel traffic. For some species such as the gray and bowhead whales, subsistence activities have contributed to disturbance of these animals.

- **Reasonably Foreseeable Future External Effects.** State-managed fisheries and general vessel traffic from recreational boating and whale watching to commercial vessels would be expected to continue in future years as well as subsistence activities.

- **Cumulative Effects.** Cumulative effects of disturbance resulting from internal and external sources are determined to be similar to the baseline condition and not likely to result in a population-level effect for any of the species in this group. Therefore, the cumulative effect is considered to be insignificant for both endangered and non ESA-listed baleen whales.

Direct/Indirect Effects FMP 4.2

Under FMP 4.2, the groundfish fisheries would be essentially closed until specific fisheries were certified to have no adverse effects on the environment. The potential impacts to marine mammals would therefore be even less than described under FMP 4.1 but the conclusions regarding direct/indirect effects for incidental

take and entanglement in marine debris, fisheries harvest of prey species, and spatial and temporal concentration of the fishery under FMP 4.2 are the same as described under FMP 4.1.

Cumulative Effects

Since the groundfish fisheries would be essentially closed under FMP 4.2, the cumulative effects for mortality, prey availability, spatial and temporal concentration of the fishery, and disturbance would all be dominated by the same persistent past and external factors discussed under FMP 4.1. Since the contribution of the groundfish fisheries to all of these effects is also greatly reduced relative to the baseline condition under FMP 4.1, the cumulative effects conclusions are the same as discussed under FMP 4.1.

4.8.8.9 Sea Otters

Direct/Indirect Effects FMP 4.1

Incidental Take/Entanglement in Marine Debris

Since fishing effort is greatly reduced relative to the baseline under FMP 4.1, incidental takes of sea otters would be expected to decrease under FMP 4.1. Under the baseline conditions, takes and entanglements associated with fishing activities are thought to be insignificant to sea otters at the population level. Reducing these takes even further would also be considered to have insignificant effects on the population trajectory of sea otters.

Fisheries Harvest of Prey Species

Given the minor importance of groundfish in their diet (see Section 4.5.8.9), fisheries removals under FMP 4.1 are expected to be substantially reduced relative to the baseline condition but the effects on prey availability to otters are considered insignificant at the population level.

Spatial/Temporal Concentration of the Fishery

Because of the habitat preference of sea otters for shallow areas, they do not overlap spatially with groundfish fisheries. Therefore, the effects of the spatial/temporal concentrations of the fisheries under FMP 4.1 are insignificant for sea otters.

Disturbance

FMP 4.1 may result in decreased disturbance to sea otters relative to the baseline. However, because the effects of disturbance are insignificant under the baseline conditions they would also be insignificant at the population level under FMP 4.1.

Cumulative Effects

The past/present effects on the sea otter are described in Section 3.8.10 (Table 3.8-10). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case. This analysis seeks to provide an overall assessment of the species' population level response to its environment as it is influenced by the groundfish fishery. The effects considered in this analysis are listed in Table 4.5-70. Representative direct effects used in this analysis include mortality and disturbance with the major indirect effects of availability of prey and spatial/temporal concentration of the fisheries (Table 4.1-6).

Mortality

- **Direct/Indirect Effects**. The effects of incidental take and entanglement on sea otters under FMP 4.1 are considered insignificant.

- **Persistent Past Effects.** Commercial exploitation for pelts had a huge impact on sea otters dating from the mid-1700s to the late 1800s, causing them to become nearly extinct (Bancroft 1959, Lensink 1962). Alaska Natives have hunted sea otters for pelts and meat throughout history. Current harvest levels represent nine percent of PBR for the southwestern stock, 15 percent of PBR for the southcentral stock, and 35 percent of PBR for southeast stock (USFWS 2002a, 2002b and 2002c). Oils spills, such as the EVOS, can result in substantial mortality of sea otters. Sea otter numbers have declined dramatically from the Alaska Peninsula to the Bering Sea, and this stock is being considered for listing under the ESA.

- **Reasonably Foreseeable Future External Effects.** Low levels of incidental take in commercial and subsistence fisheries, subsistence hunting, and periodic mortalities from oil spills are likely to continue in the future. Population-level effects from transient killer whale predation may continue in the southwest Alaska stock, depending on the recovery of alternate prey and behavior of whales.

- **Cumulative Effects.** The cumulative effects of mortality from all sources are different for different stocks of sea otters. The populations of the southeast and southcentral stocks of sea otters appear to be stable or increasing and are not expected to have additional mortality pressures in the future. These stocks are considered to have insignificant cumulative effects from mortality. The rapid decline of the southwest Alaska stock does not appear to be the result of food shortages, disease, or toxic contamination and is likely the result of increased predation by killer whales following the collapse of their preferred sea lion prey population in the 1980s (Estes *et al*. 1998). Since the mechanism(s) of the population decline is still under investigation, the cumulative effect on the southwest stock is considered to be conditionally significant adverse through mortality.

Prey Availability

- **Direct/Indirect Effects.** The effects of harvest of key prey species in groundfish fisheries under FMP 4.1 are determined to be insignificant for sea otters.

- **Persistent Past Effects.** The groundfish fisheries have had little effect on the availability of prey in the past due to the limited overlap in prey species of the sea otter and the fish targeted by the groundfish fisheries. There is some minor overlap in State-managed crab fisheries and sea otter prey.

- **Reasonably Foreseeable Future External Effects.** State-managed crab fisheries that take crab from shallow waters were identified as external effects. The overlap primarily occurs in inshore areas or offshore areas with relatively shallow water.

- **Cumulative Effects.** Effects on prey availability were determined to be cumulative based on both internal effects of the groundfish fisheries and external factors as in the crab fisheries. These cumulative effects are determined to be insignificant due to the very limited overlap of these fisheries and the sea otter forage species and not likely to have population-level effects.

<u>Spatial/Temporal Concentration of the Fisheries</u>

- **Direct/Indirect Effects.** The effects of the spatial/temporal concentrations of the fisheries under FMP 4.1 are insignificant for sea otters.

- **Persistent Past Effects.** The limited spatial overlap of groundfish fisheries and other fisheries in the past have limited their interaction with sea otter prey. Past effects of spatial/temporal concentration have likely been in very specific areas and associated with State-managed crab fisheries.

- **Reasonably Foreseeable Future External Effects.** State-managed crab fisheries are likely to continue into the future at a level similar to the baseline conditions.

- **Cumulative Effects.** The cumulative effect of the spatial/temporal harvest of prey in the internal and external fisheries is considered to be insignificant due their limited spatial overlap with sea otter habitat. These fisheries are unlikely to have population-level effects.

<u>Disturbance</u>

- **Direct/Indirect Effects.** Levels of disturbance under FMP 4.1 are expected to be similar to the baseline and are therefore considered to be insignificant.

- **Persistent Past Effects.** Past effects of disturbance are primarily related to some minor disturbance by vessel traffic from fisheries and other vessels and disturbance associated with subsistence harvest of sea otters.

- **Reasonably Foreseeable Future External Effects.** State-managed fisheries are expected to continue at a level similar to the baseline. Commercial vessel traffic within sea otter habitat in future years would be expected to be similar the baseline.

- **Cumulative Effects.** Cumulative effects of disturbance on sea otters are considered insignificant and are unlikely to result in any population-level effects. The contribution of the groundfish fishery to the overall cumulative effect is minor.

Direct/Indirect Effects FMP 4.2

Under FMP 4.2, the groundfish fisheries would be essentially closed until specific fisheries were certified to have no adverse effects on the environment. The potential impacts to marine mammals would therefore be even less than described under FMP 4.1 but the conclusions regarding direct/indirect effects for incidental take and entanglement in marine debris, fisheries harvest of prey species, and spatial and temporal concentration of the fishery under FMP 4.2 are the same as described under FMP 4.1.

Cumulative Effects

Since the groundfish fisheries would be essentially closed under FMP 4.2, the cumulative effects for mortality, prey availability, spatial and temporal concentration of the fishery, and disturbance would all be dominated by the same persistent past and external factors discussed under FMP 4.1. Since the contribution of the groundfish fisheries to all of these effects is also greatly reduced relative to the baseline condition under FMP 4.1, the cumulative effects conclusions are the same as discussed under FMP 4.1.

4.8.9 Socioeconomic Alternative 4 Analysis

Alternative 4 represents a highly precautionary approach to managing fisheries under scientific uncertainty. This section contains both quantitative and qualitative assessments of select economic and social effects of FMP 4.1 and FMP 4.2.

4.8.9.1 Harvesting and Processing Sectors

The model and analytical framework used in the analysis of the effects of FMP 4.1 on the harvesting and processing sectors are described in Section 4.1.7.

Model projections of ex-vessel value and product value for this FMP are based on 2001 prices and product mixes. Because FMP 4.1 results in large reductions in catches of pollock and Pacific cod for both catcher vessels and catcher processors, actual prices might be expected to increase as a result of a reduction in the quantity of fish and the subsequent product supplied. The extent to which prices would increase depends on demand elasticities. Due to the presence of a large number of substitutes for Alaska groundfish products, the demand for these products is believed to be relatively elastic. In other words, prices for groundfish products are unlikely to be substantially influenced by changes in harvests. Also, ex-vessel prices are determined by negotiations between individual processors on one side and either bargaining associations for catcher vessels or individual fishermen on the other side. Ex-vessel prices may not behave as one might expect in a competitive market. Actual prices will ultimately depend on the relative bargaining power of harvesters and processors.

Historically, the product quality and prices for headed and gutted cod have often been higher for Pacific cod caught with fixed gear. Therefore, the elimination of the trawl fisheries and the expansion of the fixed-gear fisheries might be expected to increase the prices of headed and gutted Pacific cod. The use of product prices that are not gear-specific could underestimate the total product value for FMP 4.1 and would overstate the reduction in product value due to this FMP bookend. There is not a similar problem with ex-vessel value projections because gear-specific ex-vessel prices were used.

However, the assumption of constant prices and product mix may also result in bias in the opposite direction if a decline in catch quality puts downward pressure on average prices. This FMP would result in large shifts in catch both spatially and temporally relative to the comparative baseline. It is reasonable to assume that, subject to regulatory constraints, harvesters target catch in areas and time periods that maximize its value either by increasing the value (quality) of the fish or by decreasing the harvesting cost or both. If catch quality is lower, prices received are lower and total gross revenue is affected. The model projections for FMP 4.1 may understate the actual impact since 2001 ex-vessel prices are used to calculate ex-vessel value.

It is also possible that catch estimates from the model projections may be overstated. If catch rates are reduced substantially due to the spatial/temporal shift of harvests, it may not be possible or cost-effective for the fleet to take the full projected catch. Moreover, the concentration of fishing effort in the areas that remain open may lead to localized depletion of stocks and a decline in catch per unit of effort over the long-term. The model projections do not reflect these possibilities and therefore may overstate ex-vessel value and product value by overstating the quantity of catch.

It should also be noted that the model projections indicate that catches of Pacific cod do not decline significantly under this FMP. This projection is believed to be erroneous and an artifact of the way in which the model apportions catch between catcher vessels and catcher processors. The model redistributes a significant amount of catch from longline catcher processors to pot catcher vessels. In reality, such a reapportionment would not be expected to occur. Therefore, the model output overstates catcher vessel catches and understates catcher processor catches.

Finally, it is important to note that this analysis assumes that the no-take MPA established under this FMP bookend only apply to the groundfish fisheries. Non-groundfish fisheries would be allowed to be prosecuted within the borders of the marine protected areas subject to current regulations. However, it is possible that the no-take concept would be applied more broadly to include fisheries not managed under the groundfish FMPs. For example, the area closures could be applied in federal waters so as to prohibit crab fisheries in the BSAI, salmon fisheries in the southeast GOA, Bering Sea scallop fisheries, and halibut fisheries. It is also possible that the area closures could extend into State of Alaska waters if the state chose to implement complementary measures. The broader application of no-take marine protected areas would magnify the adverse economic impacts described in this analysis. In particular, small vessels that participate in non-groundfish fisheries may experience a larger decrease in revenues than what is projected in this analysis, as these vessels may be unable to travel beyond the boundaries of the area closures.

The net impact of upward and downward bias in projections of ex-vessel value and product value is difficult to determine; however, we expect that model projections of ex-vessel value and product value are likely to understate the adverse impact of FMP 4.1 on these variables. Whether the bias in projections is high or low, we expect large reductions in ex-vessel value and product value to occur under FMP 4.1 relative to the comparative baseline.

Table 4.8-6 summarizes projected impacts of FMP 4.1 on the harvesting and processing sectors. The numbers in the table reflect the 5-year average of outcomes projected for 2003 to 2007. Under FMP 4.1, there would be significant decreases in the harvest of groundfish species as a result of a large projected decrease in the TAC. The 5-year mean estimate of groundfish wholesale product value is about $0.5 billion, a 64 percent decrease when compared to the baseline.

The 5-year mean estimate of the pollock harvest is 1,035,000 mt (71 percent) lower than the comparative baseline. Pacific cod harvest are expected to decrease by 126,000 mt (58 percent), and harvest of species in the A-R-S-O species aggregation as a whole are predicted to decrease by 109,000 mt (74 percent). Only flatfish harvests do not change significantly in comparison to the comparative baseline. Total groundfish payments to labor are expected to decrease by 64 percent, and groundfish employment will decrease by about 6,000 FTE positions.

4.8.9.1.1 Catcher Vessels

Direct/Indirect Effects of FMP 4.1

Groundfish Landings By Species Group

A comparison of the 5-year average of outcomes projected for the 2003 to 2007 period to 2001 catcher vessel conditions reveals that the large decrease in groundfish TAC that occurs under FMP 4.1 will cause retained catches of all groundfish species to significantly decline (see the earlier discussion regarding the erroneous model projections of Pacific cod catches for this FMP).

Ex-Vessel Value

As a result of the overall decrease in retained catch, the total ex-vessel value of groundfish landed by catcher vessels is expected to decrease significantly relative to the comparative baseline. Fixed-gear catcher vessels are expected to experience a less dramatic decline in groundfish ex-vessel value in comparison to classes of trawl catcher vessels because of the measure in FMP 4.1 that prohibits trawling in all fisheries that can be prosecuted with other gear types. In effect, this measure represents an allocation of groundfish TAC to users of fixed gear. Nevertheless, the decrease in the TAC for Pacific cod is expected to cause the ex-vessel value of fixed-gear catcher vessels to decline significantly.

Employment and Payments to Labor

Groundfish employment and payments to labor by all classes of catcher vessels are expected to decrease significantly under FMP 4.1. Most of the decrease in employment and payments to labor is incurred by the three classes of AFA-eligible trawl catcher vessels and fixed-gear catcher vessels 33 to 59 ft in length.

Impacts on Excess Capacity

Because FMP 4.1 would result in a large decrease in the quantity of catch and products from the groundfish fisheries, it is expected to generally lead to significantly higher excess capacity in the harvesting sector. However, the impacts of FMP 4.1 on excess capacity will vary by vessel class. Vessels using trawl gear will see a significant increase in excess capacity because of the reapportionment of Pacific cod to fixed gear. For fixed-gear vessels, the FMP measures are expected to have both adverse and beneficial effects in terms of harvest capacity. The reapportionment of Pacific cod to fixed-gear vessels will reduce excess capacity. However, the decrease in the TAC will cause a decline in the overall catches of fixed-gear catcher vessels.

To control capacity in the groundfish fisheries, FMP 4.1 includes all current measures that address overcapacity, including the LLP, the sablefish longline fishery IFQ program; the cooperatives established in the BSAI pollock fishery under the AFA, and the western Alaska CDQ program. In addition, FMP 4.1 would implement effort-based measures (also referred to as input-based methods) to further control fishing capacity. These effort-based measures may include limits on trips, gear size, vessel size or vessel horsepower or seasonal exclusive area registration. All effort-based measures attempt to control capacity by directly regulating the character, amount or usage of various fishing inputs. Gear and vessel restrictions limit the type or quantity of those particular inputs. Seasonal exclusive area registration prohibits individual fishing units from operating outside a specified area each season, thereby restricting where inputs can be used. Trip limits restrict the extent to which inputs can be used by imposing a catch ceiling for an individual fishing trip. Trip limits are often accompanied by a limit on the frequency of landings, which restricts the duration of use of inputs.

Obviously such measures would have to be associated with a restriction on the number of fishermen, otherwise it is clear that no control is placed on total potential effort. The number of participants in the Alaska groundfish fisheries is currently capped by the LLP. The LLP also limits the number of vessels that can use fixed gear. Even if the number of fishermen is restricted, effort-based measures do little towards mitigating the race for fish, and fishermen will continue to have an incentive to fish harder in order to maintain or increase their share of the TAC. Moreover, while the measures considered here can severely restrict the type, amount or use of fishing inputs, experience in fisheries worldwide shows that, given time to adjust, fishermen will often find ways of increasing their fishing effort by substituting inputs that are not controlled.

Average Costs

FMP 4.1 is expected to a have a significantly adverse impact on the average costs of many fishing operations. The closure of sea lion critical habitat to trawling, establishment of no-take marine protected areas, and the TAC component of FMP 4.1 would lower harvest rates for most classes of catcher vessels. Consequently, average costs per unit of catch for catcher vessels can be expected to increase substantially under FMP 4.1 because of the reduction in the overall level of production resulting from lower catches. Many costs are fixed (e.g., loan repayments, general office and accounting expenses and insurance costs); and are not reduced with the level of production. These costs would be allocated to a smaller amount of product, raising the average cost per unit of product.

Additionally, the redistribution of fishing effort to fixed gear vessels may lead to grounds congestion, increased gear conflicts, increased fishing costs and reduced gross revenue for these vessels. For example, grounds crowding with pots and longline gear occurred in the halibut and sablefish fisheries prior to the implementation of the IFQ program.

The spatial displacement of fishing effort resulting from implementation of FMP 4.1 would be substantial for some catcher vessels. These changes can be expected to lead to increased operating costs since vessels will have to travel farther to reach open areas and will likely be required to fish in less productive areas in some cases. The greatest impact would be on smaller trawl and fixed-gear vessels because of their more limited fishing range.

It is reasonable to assume that, subject to regulatory constraints, harvesters target catch with the gear that maximizes its value either by increasing the quality of the fish or by decreasing the harvesting costs, or both. For example, bottom trawl gear and fixed gear are actively used in the BSAI and GOA Pacific cod fisheries. The fixed-gear cod fishery is an economically viable fishery; however, the feasibility and cost of having it completely replace the bottom trawl cod fishery is not known. The information required to compare harvesting costs by gear is unavailable. However, to the extent that the historical fishing gear was used because it has the lowest cost per unit of catch, the replacement of several bottom trawl fisheries with fixed-gear fisheries would increase cost per unit of catch.

The effort-based methods implemented under FMP 4.1 to control harvesting and processing capacity would impose additional costs on fishermen. In general, these methods are designed to increase the cost of producing effort for individual fishing units by prohibiting certain cost-effective ways of operating (Anderson 1989). To adjust to these imposed inefficiencies, fishermen will continue to increase their outlays on doing whatever is permitted to maintain or increase their share of the catch. These permitted adjustment costs may include expenditures not only on vessel and gear improvements or storing fish on board longer, but also on reequipping their vessels to make them usable in other fisheries (Scott 1979).

The expanded observer coverage, scale and VMS requirements would also impose additional operating costs on fishery participants. In addition to the cost of paying for additional observers (expected to be about $355 per deployment day, not including food costs), some smaller vessels may have difficulty in providing berths for observers.

Fishing Vessel Safety

FMP 4.1 is expected to result in a significant reduction in safety for the fishing vessels that remain active. While the large decrease in the groundfish TAC may reduce the number of active vessels and thereby decrease the number of persons at risk, it is likely that the decrease in catches will encourage vessel owners to reduce crew size in an effort to compensate for reduced earnings. Reductions in crew size, in turn, may increase the risk of vessel accidents. Both the closure of sea lion critical habitat to trawling and the establishment of no-take marine protected areas would result in vessels fishing farther from port and possibly in more hazardous areas. The adverse effects would be more extreme for smaller vessels. In addition, effort-based measures such as gear and vessel restrictions may require fishermen to employ smaller vessels, thereby decreasing fishing safety. Moreover, effort-based measures to control overcapacity require fishermen to use inefficient fishing methods and do little to reduce their impulse to intensify their fishing operations by, for example, operating farther from shore or in areas and seasons with more hazardous weather conditions.

Cumulative Effects of FMP 4.1

This section will assess the potential for the direct/indirect effects to interact with persistent past effects and other reasonably foreseeable future events, resulting in a cumulative effect. The persistent past effects on catcher vessels are presented in detail in Section 3.9 (Table 3.9-125) and the predicted direct/indirect effects are described above. Representative indicators for direct/indirect effects include groundfish landings by species group, groundfish ex-vessel value, employment, payments to labor, excess capacity, average costs, and fishing vessel safety. Table 4.8-6 summarizes this cumulative effects analysis.

Groundfish Landings By Species Group

- **Direct/Indirect Effects**. Significantly adverse effects are expected under FMP 4.1 due to the decrease in harvest.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities and other sources of municipal and state revenue. Details on these future external effects are listed in Section 4.5.9.1 under FMP 1.

- **Cumulative Effects**. Given the current downward trends in the commercial salmon and crab fisheries, the predicted change in retained harvests under FMP 4.1 is expected to result in significantly adverse cumulative effects. The significant reduction in harvest levels will further exacerbate the cumulative effects of reductions in other fisheries. Groundfish landings by species will be reduced resulting in significantly adverse cumulative effects.

Ex-Vessel Value

- **Direct/Indirect Effects.** The total ex-vessel value of groundfish landed by catcher vessels is expected to result in significantly adverse effects under FMP 4.1.

- **Persistent Past Effects.** The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects.** Overall reductions in groundfish catch is likely to dramatically decrease ex-vessel value for fixed-gear vessels while a less dramatic decline is likely for trawl vessels. Decreases in ex-vessel value in other fisheries such as salmon and crab may continue to occur, thereby exacerbating the cumulative effects of FMP 4.1. Changes in revenue streams that affect the ability of communities to provide municipal services, fund capital projects, borrow money, and retire or service debt have the greatest potential for cumulative effects on landing tax revenues from non-groundfish fisheries (such as salmon, crab, and halibut). During recent years, state municipal revenue sharing, power cost equalization and contributions to education programs have been decreasing. Given the potential of these conditions to contribute to decreased levels of harvest under FMP 4.1, cumulative effects ex-vessel value on are expected to be significantly adverse.

Employment and Payments to Labor

- **Direct/Indirect Effects**. Significantly adverse effects are projected for employment and payments to labor.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. Overall reductions in other fisheries such as salmon and crab, and the fact that many fishermen often rely on participation in multiple fisheries, significantly adverse cumulative effects are anticipated for FMP 4.1. The projected decrease in employment (60 percent) for the groundfish fisheries under this FMP will intensify the adverse effects experienced in other fisheries. While other economic activities and other sources of municipal and state revenue have the potential to mitigate these effects by providing other employment opportunities, many rural Alaska villages rely so heavily on fishing that other such options for earning income are not always available. This is particularly true if the economy and government spending are down. Thus, the reductions in harvesting under FMP 4.1 are expected to result in significantly adverse cumulative effects.

Impacts on Excess Capacity

- **Direct/Indirect Effects**. Changes in excess capacity are likely to be significantly adverse under FMP 4.1.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. Historical expansions in fishing capacity followed by reductions in harvest levels and product value have resulted in persistent adverse effects on excess capacity. Excess capacity has not only been a problem in the groundfish fishery but exists in other fisheries as well. The number of fishing permits would be greatly reduced under FMP 4.1 but the number of vessels would remain high, resulting in many vessels sitting idle, not permitted to fish. The dramatic reductions in harvest levels under FMP 4.1 combined with the persistent past effects of overcapacity are projected to result in significantly adverse cumulative effects on excess capacity. (For details refer to the Overcapacity Paper in Appendix F-8).

Average Costs

- **Direct/Indirect Effects**. Significantly adverse effects are expected to occur for average costs under FMP 4.1.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. Average costs in the groundfish fisheries are often associated or shared with other fisheries. Fixed costs are somewhat independent of the fisheries in that loan payments and general office and accounting expenses remain at a certain amount while ex-vessel value and product value are variable. Depending on area closures or the fixed or variable costs in other fisheries, when considered in combination with average costs in the groundfish fishery, cumulative effects may result. Should costs in other fisheries increase or decrease, vessels that are dependent on multiple fisheries are often sensitive to these changes. Although the overall reductions in TAC under FMP 4.1 may reduce costs, the increases in closure areas and the collective pressure of fixed costs are such that significantly adverse cumulative effects are anticipated.

Fishing Vessel Safety

- **Direct/Indirect Effects**. Significantly adverse effects are predicted under FMP 4.1.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. Vessel safety is primarily a function of the race for fish, and of distance to fishing areas and sea conditions relative to vessel size. The extent of closures proposed under FMP 4.1 are likely to increase the risk to the few vessels still permitted to harvest, as they may have to travel much greater distances to harvest fish. Significantly adverse cumulative effects are predicted under FMP 4.1.

4.8.9.1.2 Catcher Processors

Direct/Indirect Effects of FMP 4.1

Groundfish Landings By Species Group

A comparison of the 5-year average of outcomes projected for the 2003-2007 period to 2001 catcher processor conditions reveals that the large decrease in groundfish TAC that occurs under FMP 4.1 will cause catches of all groundfish species except flatfish to decline significantly.

Groundfish Gross Product Value

Groundfish employment and payments to labor by all classes of catcher processors are expected to decrease significantly under FMP 4.1.

Employment and Payments to Labor

As a result of the decrease in catch, the overall wholesale product value of groundfish processed by catcher processors is expected to decrease significantly relative to the comparative baseline. All classes of catcher processors would experience a significant decline in product value. Notwithstanding the model projection that flatfish catches will remain relatively stable compared to the baseline, the head-and-gut trawl catcher processors that focus on flatfish are expected to experience a significant decline in product value because of the reapportionment of Pacific cod to fixed-gear vessels. Moreover, fixed-gear catcher processors are expected to experience a significant decline in product value despite the reapportionment because of the overall reduction in the TAC.

Product Quality and Product Utilization Rate

A conditionally significant decrease in product quality is expected under this FMP relative to the comparative baseline. The additional area closures that are implemented under FMP 4.1 are expected to cause product quality to decline, but the intensity of this effect and the probability of its occurrence are uncertain. It is reasonable to assume that, subject to regulatory constraints, harvesters target catch in areas that maximizes its value either by increasing the quality of the fish or by decreasing the harvesting cost or both. Consequently, a measure that prohibits vessels from using historical fishing grounds may result in a decline in product quality (e.g., fish may be smaller or a less uniform size). In contrast, FMP 4.1 is expected to result in a conditionally significant increase in product utilization rates relative to the comparative baseline. The extension of improved retention and utilization regulations to all target fisheries is expected to result in an increase in product utilization. Moreover, the large decrease in catch that occurs under FMP 4.1 provides a strong incentive for processors to use the fish that are harvested to the fullest possible extent. However, the intensity of this effect and the probability of its occurrence are uncertain.

Excess Capacity

As with catcher vessels, FMP 4.1 is predicted to generally lead to significantly higher excess capacity.

Average Costs

As with catcher vessels, FMP 4.1 is predicted to generally lead to significantly higher average costs. The closure of sea lion critical habitat to trawling, establishment of no-take marine protected areas, and the TAC component of FMP 4.1 would lower harvest rates for catcher processors and consequently, average costs per unit of catch can be expected to increase substantially under FMP 4.1. Perhaps more importantly the overall reduction in TACs will reduce average costs. Many costs are fixed (e.g., loan repayments, general office and accounting expenses and insurance costs) and are not reduced with the level of production. These costs would be allocated to a smaller amount of product, raising the average cost per unit of product.

The extension of improved retention and utilization regulations to all target fisheries is expected to have a significantly adverse economic impact on all head-and-gut trawl catcher processors by decreasing gross revenues and/or increasing operating costs. The flatfish discard rates of these vessels are high in fisheries that target flatfish and in fisheries in which flatfish are caught incidentally. To the extent that the race for fish allows it, head-and-gut trawl catcher processors may offset the lost revenues or additional costs experienced under IR/IU regulations by taking additional fishing trips. However, the number of profitable trips vessels can make may be limited by seasonal decreases in fish quality and/or roe content that lower ex-vessel prices. Smaller head-and-gut trawl catcher processors may be disproportionately affected by IR/IU regulations, as they are more likely constrained by hold space during a fishing trip, their processing capacity is more limited, and their slower speed restricts their ability to increase revenue by taking additional trips.

The expanded observer coverage and scale and VMS requirements would also impose additional operating costs on fishery participants. In addition to the cost of paying for additional observers (expected to be about $355 per deployment day, not including food costs), some smaller vessels may have difficulty in providing berths for observers. A motion-compensated platform scale would cost between $6,000 and $12,000. In addition, smaller (less than 200 ft. LOA) at-sea processors may have insufficient space in which to install scales without considerable reconfiguration or removal of existing processing equipment (J. Gauvin, Groundfish Forum, pers. comm., December 2003.). The current list price of a VMS unit is about $2,000.

Fishing Vessel Safety

As with catcher vessels, FMP 4.1 is expected to result in a significant reduction in fishing vessel safety relative to the comparative baseline.

Cumulative Effects of FMP 4.1

This section will assess the potential for the direct/indirect effects to interact with persistent past effects and other reasonably foreseeable future events, resulting in a cumulative effect. The persistent past effects on catcher vessels are presented in detail in Section 3.9 (Table 3.9-125) and the predicted direct/indirect effects are described above. Representative indicators for direct/indirect effects include groundfish landings by species group, groundfish ex-vessel value, employment, payments to labor, excess capacity, average costs, and fishing vessel safety. For a summary of the cumulative effects analysis, please refer to Table 4.8-6.

Groundfish Landings By Species Group

- **Direct/Indirect Effects**. Significantly adverse effects are expected under FMP 4.1due to the decrease in harvest.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to an increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed in Section 4.5.9.1 under FMP 1.

- **Cumulative Effects**. As with catcher vessels, given the current downward trends in the commercial salmon and crab fisheries, the predicted change in retained harvests under FMP 4.1 is expected to result in significantly adverse cumulative effects. The significant reduction in harvest levels will further exacerbate the cumulative effects of reductions in other fisheries. Groundfish Landings by Species will be reduced resulting in significantly adverse cumulative effects.

Groundfish Gross Product Value

- **Direct/Indirect Effects**. The total gross product value of groundfish landed by catcher processors is expected to result in significantly adverse effects under FMP 4.1.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. As with catcher vessels, during recent years, state municipal revenue sharing, power cost equalization, and contributions to education programs have been decreasing. This often causes communities to rely on fish taxes for municipal revenue which may affect gross product value. The decreased level of harvest under FMP 4.1 is significant enough that reductions in harvest combined with increased municipal pressure will result in significantly adverse cumulative effects on gross product value, particularly for fixed-gear processors due to the reduction in TAC.

Employment and Payments to Labor

- **Direct/Indirect Effects**. Significantly adverse effects are projected for employment and payments to labor.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. Similar to catcher vessels, the overall reductions in other fisheries such as salmon and crab, contribute to the decrease in harvest levels under FMP 4.1. The projected decrease in employment (65 percent) for the groundfish fisheries under this FMP will exacerbate the adverse effects experienced in other fisheries. While other economic activities and other sources of municipal and state revenue have the potential to mitigate these effects by providing other employment opportunities, many rural Alaska villages rely so heavily on fishing that other such options for earning income are not always available. This is particularly true in smaller villages and if the economy and government spending are down. Thus, the reductions in harvesting under FMP 4.1 are expected to result in significantly adverse cumulative effects.

Product Quality and Product Utilization Rate

- **Direct/Indirect Effects**. Conditionally significant adverse effects are likely for product quality, but conditionally significant beneficial effects for product utilization rates are expected under FMP 4.1 relative to the baseline.

- **Persistent Past Effects**. For details on persistent past effects, please refer to the beginning of Section 4.5.9.1 Groundfish Landings By Species Group.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed under the Section 4.5.9.1.

- **Cumulative Effects**. Advances in technology have improved product quality and utilization for various fisheries throughout the world. The end of the race for fish has also made significant differences in product quality and utilization, however, any continuation of this harvest strategy in fisheries may hinder some of these improvements. Improvements in product quality might be expected in the future; however, the increased number of closure areas under FMP 4.1 may jeopardize some of the quality gained through better handling and techniques by the greater distances vessels may have to travel to harvest fish. Thus, conditionally significant adverse effects are predicted for product quality and significantly beneficial cumulative effects are projected for product utilization rate under FMP 4.1.

Impacts on Excess Capacity

- **Direct/Indirect Effects**. Changes in excess capacity are likely to be significantly adverse under FMP 4.1.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. Historical expansions in fishing capacity followed by reductions in harvest levels and product value have resulted in persistent adverse effects on excess capacity. Excess capacity has not only been a problem in the groundfish fishery but exists in other fisheries as well. The number of fishing permits would be greatly reduced under FMP 4.1 but the number of catcher processors would remain high, especially in the short-term. The dramatic reductions in harvest levels under FMP 4.1 combined with the persistent past effects of overcapacity are projected to result in significantly adverse cumulative effects on excess capacity. (For details please refer to the Overcapacity Paper in Appendix F-8).

Average Costs

- **Direct/Indirect Effects**. Significantly adverse effects are expected to occur for average costs under FMP 4.1.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. As with catcher vessels, average costs in for catcher processors are often associated or shared with other fisheries and include fixed and variable costs. Depending on area closures or the fixed or variable costs in other fisheries, when considered in combination with the increase in closure areas and reduced harvest rates under FMP 4.1 in the groundfish fishery, significantly adverse cumulative effects are likely. Should costs in other fisheries increase or decrease, catcher processors in the groundfish fishery may experience fewer or greater impacts to average costs.

Fishing Vessel Safety

- **Direct/Indirect Effects**. Significantly adverse effects are predicted under FMP 4.1.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. Vessel safety is primarily a function of the race for fish, and of distance to fishing areas and sea conditions relative to vessel size. The extent of closures proposed under FMP 4.1 are likely to increase the risk catcher processors, as they may have to travel much greater distances to harvest fish. Significantly adverse cumulative effects are predicted under FMP 4.1.

4.8.9.1.3 Inshore Processors and Motherships

Direct/Indirect Effects FMP 4.1

Groundfish Landings By Species Group

A comparison of the 5-year average of outcomes projected for the 2003 to 2007 period to 2001 inshore processor and mothership conditions reveals the large decrease in groundfish TAC that occurs under FMP 4.1 will cause catches of all groundfish species to decline significantly (see the earlier discussion regarding the erroneous model projections of Pacific cod catches for this FMP).

Groundfish Gross Product Value

As a result of the decrease in catch, the overall wholesale product value of groundfish processed by inshore processors and motherships is expected to decrease significantly relative to the comparative baseline. The economic impact of this decrease in groundfish product value would differ across processing facilities depending on the extent to which plants process other types of fish and shellfish resources, such as salmon, crab, halibut, and other finfish. For example, under FMP 4.1, the value of groundfish products produced by southcentral Alaska inshore plants would decline significantly but the decrease in total wholesale value of all fish and shellfish processed by these plants may not be significant. In contrast, groundfish represents a large portion of the wholesale production value of Bering Sea pollock shore plants. Under FMP 4.1, the decline in groundfish production value for these plants would result in a significant reduction in their total (groundfish and non-groundfish) wholesale value.

A significant decline in groundfish product value is also expected for southeast Alaska shore plants, Alaska Peninsula and Aleutian Islands shore plants, and Kodiak shore plants. This decline reflects the dependence of these processors on groundfish harvested in sea lion critical habitat or no-take marine protected areas.

Employment and Payments to Labor

Groundfish employment and payments to labor by all classes of inshore processors and motherships are expected to decrease significantly under FMP 4.1. Most of the decrease in employment and payments to labor is incurred by Bering Sea shore plants.

Product Quality and Product Utilization Rate

A significant decrease in product quality is expected under this FMP relative to the comparative baseline. The additional area closures that are implemented under FMP 4.1 may cause product quality to decline. It is reasonable to assume that, subject to regulatory constraints, harvesters target catch in areas that maximizes its value either by increasing the quality of the fish or by decreasing the harvesting cost or both.

Consequently, a measure that prohibits vessels from using historical fishing grounds may result in a decline in product quality (e.g., fish may be smaller or a less uniform size). In addition, Pacific cod and Alaska pollock are fragile fish whose quality deteriorates rapidly the longer the time between harvest and processing. Consequently, any factors that will increase the length of time to processing will lower the quality of the product produced. To the extent that FMP 4.1 results in catcher vessels traveling farther distances from (inshore) processors, and thereby lengthening the time between harvest and processing, the quality of surimi, fillets, and roe will be adversely affected.

In contrast, FMP 4.1 is expected to result in a conditionally significant increase in product utilization rates relative to the comparative baseline. The large decrease in catch that occurs under FMP 4.1 provides a strong incentive for processors to use the fish that are harvested to the fullest possible extent. However, both the intensity of this effect and the probability of its occurrence are uncertain.

Excess Capacity

As a result of the large decrease in groundfish catches, FMP 4.1 is predicted to generally lead to significantly higher excess capacity in both the harvesting and processing sectors, but some exceptions are expected. For example, those processing plants, such as southcentral Alaska inshore plants and floating inshore plants, that are only marginally dependent on groundfish may not experience a significantly higher excess capacity. This leads to direct/indirect effects ratings of insignificant/significantly adverse for excess capacity under FMP 4.1.

Average Costs

As a result of the large decrease in groundfish catches, FMP 4.1 is predicted to lead to significantly higher average costs. The overall amount of target species delivered to processors would decrease substantially. Average costs will increase because of the reduction in the overall level of production resulting from lower catches. Many costs are fixed (e.g., loan repayments, general office and accounting expenses and insurance costs) and will not change with the level of production. These costs would be allocated to a smaller amount of product, thereby raising the average cost per unit of product. The increase will be larger for those processors that are most dependent on groundfish. As average costs per unit of production rise, it is possible that they would exceed the value of production and lead to a shutdown or permanent closing of some processing plants and motherships.

Variable costs may also be increased under FMP 4.1. The reduction in supply of fish is likely to put upward pressure on ex-vessel prices. If spatial shifting of production raises average costs for catcher vessels, inshore plants and motherships may face increased pressure to pay higher prices for fish. The extent to which processors versus catcher vessels would absorb increased harvesting costs and be able to demand higher prices as total supply declines will depend on their relative bargaining power as well as price elasticities of the products made from the fish. However, increased ex-vessel prices are likely, and this could substantially raise variable costs of production for processors that have to purchase fish.

Cumulative Effects of FMP 4.1

This section will assess the potential for the direct/indirect effects to interact with persistent past effects and other reasonably foreseeable future events, resulting in a cumulative effect. The persistent past effects on catcher vessels are presented in detail in Section 3.9 (Table 3.9-125) and the predicted direct/indirect effects are described above. Representative indicators for direct/indirect effects include groundfish landings by species group, groundfish ex-vessel value, employment, payments to labor, excess capacity, average costs, and fishing vessel safety (see Table 4.8-6 for a summary of the cumulative effects).

Groundfish Landings By Species Group

- **Direct/Indirect Effects**. Significantly adverse effects are expected under FMP 4.1 due to the decrease in harvest.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed in Section 4.5.9.1 under FMP 1.

- **Cumulative Effects**. As with catcher processors, given the current downward trends in the commercial salmon and crab fisheries, the predicted change in retained harvests under FMP 4.1 is expected to result in significantly adverse cumulative effects. The significant reduction in harvest levels will further exacerbate the cumulative effects of reductions in other fisheries. Groundfish Landings by Species will be reduced resulting in significantly adverse cumulative effects.

Groundfish Gross Product Value

- **Direct/Indirect Effects**. The total gross product value of groundfish landed by inshore processors and motherships is expected to result in significantly adverse effects under FMP 4.1.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. As with catcher processors, during recent years, state municipal revenue sharing, power cost equalization, and contributions to education programs have been decreasing. This often causes communities to rely on fish taxes for municipal revenue which may affect gross product value. The decreased level of harvest under FMP 4.1 is significant enough that reductions in harvest combined with increased municipal pressure will result in significantly adverse cumulative effects on gross product value, particularly for fixed-gear processors due to the reduction in TAC.

Employment and Payments to Labor

- **Direct/Indirect Effects**. Significantly adverse effects are projected for employment and payments to labor.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. Similar to catcher processors, the overall reductions in other fisheries such as salmon and crab, contribute to the decrease in harvest levels under FMP 4.1. The projected decrease in employment (60 percent) for the groundfish fisheries under this FMP will exacerbate the adverse effects experienced in other fisheries. While other economic activities and other sources of municipal and state revenue have the potential to mitigate these effects by providing other employment opportunities, many rural Alaska villages rely so heavily on fishing that other such options for earning income are not always available. This is particularly true in smaller villages and if the economy and government spending are down. Thus, the reductions in harvesting under FMP 4.1 are expected to result in significantly adverse cumulative effects.

Product Quality and Product Utilization Rate

- **Direct/Indirect Effects**. Conditionally significant adverse effects are likely for product quality but conditionally significant beneficial effects for product utilization rates are expected under FMP 4.1 relative to the baseline.

- **Persistent Past Effects**. For details on persistent past effects, please refer to the beginning of Section 4.5.9.1 Groundfish Landings By Species Group.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed under the Section 4.5.9.1.

- **Cumulative Effects**. Advances in technology have improved product quality and utilization for various fisheries throughout the world. The end of the race for fish has also made significant differences in product quality and utilization, however, any continuation of this harvest strategy in fisheries may hinder some of these improvements. Improvements in product quality might be expected in the future; however, the increased number of closure areas under FMP 4.1 may jeopardize some of the quality gained through better handling and techniques due to the greater distances vessels may have to travel to harvest fish. The reduction in harvest levels under this FMP are likely to cause processors to maximize unit utilization rate as there may be much fewer fish to process. Thus, conditionally significant adverse effects are predicted for product quality but conditionally significant beneficial cumulative effects are projected for product utilization rate under FMP 4.1.

Impacts on Excess Capacity

- **Direct/Indirect Effects**. Changes in excess capacity are likely to be significantly adverse or insignificant under FMP 4.1.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. Historical expansions in fishing capacity followed by reductions in harvest levels and product value have resulted in persistent adverse effects on excess capacity. Excess capacity has not only been a problem in the groundfish fishery but exists in other fisheries as well. The number of fishing permits would be greatly reduced under FMP 4.1 but the number of catcher processors would remain high, especially in the short-term. The dramatic reductions in harvest levels under FMP 4.1 combined with the persistent past effects of overcapacity are projected to result in significantly adverse cumulative effects on excess capacity. (For details refer to the Overcapacity Paper in Appendix F-8).

Average Costs

- **Direct/Indirect Effects**. Significantly adverse effects are expected to occur for average costs under FMP 4.1.

- **Persistent Past Effects**. The persistent past effects include: foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of joint venture fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. The combination of these factors has contributed to increased demand for groundfish species. These effects are discussed in more detail under Groundfish Landings By Species Group at the beginning of Section 4.5.9.1.

- **Reasonably Foreseeable Future External Effects.** The future external effects include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.1.

- **Cumulative Effects**. As with catcher vessels, average costs in for catcher processors are often associated or shared with other fisheries and include fixed and variable costs. Depending on area closures or the fixed or variable costs in other fisheries, when considered in combination with the increase in closure areas and reduced harvest rates under FMP 4.1 in the groundfish fishery, significantly adverse cumulative effects are likely. Should costs in other fisheries increase or decrease, catcher processors in the groundfish fishery may experience fewer or greater impacts to average costs.

Direct/Indirect Effects of FMP 4.2

FMP 4.2 would suspend the harvest of groundfish until more information is known on the impacts of fishing on the environment. Only fisheries certified by NOAA Fisheries to have no significantly adverse effects on the environment would be authorized to operate in the EEZ off Alaska.

During the period in which groundfish fisheries are suspended, all revenue from the fisheries would be reduced by 100 percent from the baseline case under this FMP. Approximately $1.5 billion in product value is projected to be foregone if no fisheries are certified by 2004. About 11,300 FTE positions are projected to be lost if no fisheries are certified by that year.

Under this FMP, all 917 catcher vessels, 89 catcher processors, 3 motherships and 3 floating inshore plants that were active in the Alaska groundfish fisheries in 2001 would be displaced until fisheries are certified. This suspension is expected to have a significantly adverse effect on the catches of all groundfish species, groundfish ex-vessel value and product value, groundfish employment and payments to labor, excess capacity, product quality, product utilization rates, and average costs. In the absence of the groundfish fisheries, fishing vessel safety is expected to significantly improve.

While boats across and within various vessel classes differ in their dependence on groundfish fisheries, the suspension of the groundfish fisheries is expected to have an adverse economic effect on the average boat in all the vessel classes. AFA-eligible trawl catcher vessel classes generated more than 85 percent of their annual ex-vessel value (gross revenue) from groundfish in 2001, while pot catcher vessels generated only about 10 percent of their total gross revenue from groundfish. From this perspective, impacts of the suspension of the groundfish fisheries are likely to be much greater for vessels that are more dependent on groundfish. This effect is also true for processors (both catcher processors and inshore plants and motherships) who are heavily dependent on groundfish harvests. However, vessel classes that catch relatively small quantities of groundfish and processors who process small quantities of groundfish may still be significantly adversely affected. For instance, a study by Northern Economics, Inc. (1999) on the importance of salmon to the Aleutians East Borough showed that many fixed-gear catcher vessels 33-59 ft in length that use seine gear in salmon fisheries and fixed gear for groundfish are only marginally profitable. Loss of revenue from either groundfish or salmon is likely to push a number of these vessels and processors toward bankruptcy.

Cumulative Effects of FMP 4.2

Displaced fishermen could either shift to different fisheries or tie up their vessels. Those displaced fishermen who successfully shift to other fisheries are likely to recover some portion of the revenue previously generated from fishing for groundfish. However, it is probable that displaced vessel owners will have difficulty relocating their operations given the limited access programs that have been implemented in State of Alaska fisheries and other U.S. fisheries. Thus, the effect on processors will be similar due to the reduction in groundfish harvest overall. Moreover, while some vessels and processors are already outfitted to participate in non-groundfish fisheries, other boat owners or processors may not be capable of shifting into other fisheries without substantial additional capital outlays. It is also likely that some fishermen or processors may face increased costs and uncertain markets if they are forced to shift their operations away from the communities in which they live.

Given that opportunities for displaced fishermen and processors to recover their lost harvest and income would be limited, it is likely that some displaced fishermen would be forced to sell out or retire. It is uncertain how active the Alaska, nationwide or world market is for the types of vessels, gear and other investment capital used in the groundfish fisheries. However, it is possible that the Alaska market for these assets could quickly be flooded. Suspension of the groundfish fisheries would likely depress the immediate resale market for fishing equipment and vessels as well as diminish the long-term investment value of the vessels owned by displaced fishermen who opt to continue fishing. The same fate is possible for processors who rely heavily on groundfish harvests. This could create an economic hardship for those fishermen or processors who are relying on money earned from selling their fishing assets to supplement their retirement funds.

Transfer of effort from groundfish to non-groundfish fisheries could also indirectly create economic hardship in the form of reduced profitability for those already engaged in non-groundfish fisheries. The majority of fisheries in Alaska and other areas of the U.S. are fully utilized. If fishermen in Alaska groundfish fisheries were to shift their effort to other fisheries, catch per unit of effort and individual harvest for non-groundfish fishermen would likely decline due to the intensified fishing pressure on fish stocks. Lower individual catches would mean a decrease in the incomes of part-time and full-time commercial fishermen and possibly a reduction in the non-market value of the recreational fishing experience to the sport anglers who participate in non-groundfish fisheries.

See Table 4.8-6 for a summary of the cumulative effects on catcher vessels, catcher processors and inshore processors and motherships under FMP 4.2.

4.8.9.2 Regional Socioeconomic Effects

The predicted direct and indirect effects of the groundfish fishery under FMP 4.1 and FMP 4.2 are described below. The past/present effects on regions that participate in the groundfish fishery are described in Section 3.9 (and summarized in Table 3.9-126) and below; these regions (illustrated in Figures 3.9-9 through 3.9-13) include the Aleutian Islands/Alaska Peninsula (comprised of the Aleutians East Borough and the Aleutians West Census Area, which includes the communities of Unalaska, Nikolski, Atka, Adak and the Pribilof Islands), Kodiak Island (Kodiak Island Borough, which includes the City of Kodiak) southcentral Alaska (the Kenai Peninsula Borough, Matanuska-Susitna Borough, Municipality of Anchorage, and the Valdez-Cordova Census Area, which includes the PWS region), southeast Alaska (all of the southeastern part of the state, from Yakutat Borough to Dixon Entrance), Washington inland waters (all counties bordering Puget Sound and the Strait of Juan de Fuca), and Oregon coast (Lincoln, Tillamook, and Clatsop counties, the three northernmost Oregon coastal counties). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case (Table 4.8-6).

Due to the linkages of potential effects on regions that participate in the groundfish fishery to changes in harvest and processing levels under each of the policy alternatives and illustrative FMP bookends, the direct and indirect effects of each alternative are based on an economic model that distributes potential effects to each of the participating regions. The indicators used to assess potential regional effects include the following:

- In-Region Processing and Related Effects;
- Regionally Owned At-Sea Processors;
- Extra-regional Deliveries of Regionally Owned Catcher Vessels;
- In-region Deliveries of Regionally Owned Catcher Vessels; and
- Total Direct, Indirect, and Induced Labor Income and FTEs.

As discussed earlier, these indicators also reflect changes in other important regional characteristics such as secondary economic activity associated with the support of fishing, state and municipal revenue generated by fishing, and indirectly population, to the extent that it is related to employment opportunities. For more information on the economic model used to assess direct and indirect regional effects, see analysis for FMP 1 and Section 4.1.7 of the document.

Direct/Indirect Effects of FMP 4.1

Alternative 4 represents a highly precautionary approach, in which TAC is reduced, or in the case of FMP 4.2, eliminated until fishing activity is determined not to have significantly adverse effects. Additional management measures related to bycatch, protection of prohibited species, and habitat protection, including closures by gear types, are applied. Under FMP 4.1, in general there is a strong net overall decrease in fishery socioeconomic indicator values over baseline conditions for all regions. For example, total value of processing sales decreases by about 64 percent over baseline conditions, while total processing and harvesting related income and employment decrease by 64 and 61 percent, respectively, for all regions combined. The decreases are large (and significant) for each of the regions. The overall regional level (and individual community level) impacts will ultimately be based on the relative dependency of the locally operating (or owned) fishing sector components on the groundfish fishery, and, in turn, the dependency of local community and regional economies on the commercial fishing in overall. While there are a number of exceptions, in general the economies of Alaska Peninsula and Aleutian Islands communities (and the region as a whole) are less diversified into non-fishery related activity (and therefore more vulnerable at a higher level) than those seen in other Alaska regions, and particularly those of southcentral and southeast Alaska (with Kodiak in between). The following subsections provide a region-by-region summary of change under FMP 4.1 as compared to the baseline.

Alaska Peninsula and Aleutian Islands. Under FMP 4.1, total in-region groundfish processing value would decrease by 62 percent (with decreases in both the BSAI portion and GOA portion of the total). In region processing associated labor income and FTE jobs would also decrease by 62 percent. Regionally owned at-sea processing value (and associated payments to labor and FTEs) would decline sharply in percentage terms, but this is a very small sector in this region, with negligible impact on a regional basis. The value of extra-regional and in-region deliveries by regionally owned catcher vessels would decrease by 61 and 58 percent, respectively. Catcher vessel payments to labor and FTE jobs associated with extra-regional deliveries would decrease by about 61 and 65 percent respectively. For in-region deliveries, catcher vessel payments to labor and FTEs would decrease by about 58 and 59 percent, respectively, but for both extra-regional and in-region catcher vessel deliveries, the absolute values for this region are relatively small. With respect to the relative importance of the different sectors to net regional impacts, the in-region processing related activity accounts for the vast majority of fishery associated labor income and FTEs, so the decrease seen in processing values would be disproportionately important in relation to changes seen in the other sectors. (Further, in-region processing value may be taken as a proxy for regionally important municipal and borough revenues generated by local fish taxes.) The total regional direct, indirect, and induced labor income would decrease by about 62 percent and FTE employment would also decrease by about 62 percent under this FMP (from a base of $226 million in labor income and 4,796 FTEs). Under FMP 4.1, the Alaska Peninsula and Aleutian Islands region would experience significantly adverse impacts on the local sector level, the regional level, and the community level for all of the substantially engaged communities.

In addition to the profound adverse regional and community social impacts that would result from loss of revenues, economic opportunities and employment under from this FMP, the location of marine reserves may further disadvantage specific communities in this as well as other regions. Especially impacted would be communities with small vessel fleets with more limited options in terms of alternate areas to fish due to limited range (and a lack practical ability to switch between major gear types and fisheries).

Kodiak Island. Total in-region groundfish processing value would decrease by 64 percent (with a lower value for GOA; BSAI values are not a significant portion of the regional total). Associated labor income and FTE jobs would also decrease by 64 percent. Regionally owned at-sea processing value would decline by 77 percent (with the vast majority of the decline attributable to changes in BSAI values), and associated labor income and FTEs would decline by 79 and 75 percent, respectively. (In this region under baseline conditions, in-region processing accounts for about three-quarters of the combined processing total value of sales and regionally owned at-sea processing accounts for about one-quarter of the total; labor income and FTEs distribution between these processing sectors follow a similar pattern.) The value of extra-regional deliveries by regionally owned catcher vessels would decrease by 19 percent and the value of in-region deliveries by regionally owned catcher vessels would decrease 55 percent. Catcher vessel payments to labor and FTE jobs associated with extra-regional deliveries would decrease by about 19 and 20 percent respectively. For in-region deliveries, catcher vessel payments to labor and FTEs would decrease by about 55 and 57 percent, respectively, but over a smaller base than seen for extra-regional deliveries. On a regional basis, catcher vessel activity is a relatively more important component of fishery associated labor income and FTEs than was seen in the Alaska Peninsula/Aleutian Islands region, but processing activity still dominates these categories in the regional totals. The total regional direct, indirect, and induced labor income would decrease by about 62 percent and FTE employment would decrease by about 57 percent under this FMP (from a base of $66 million in labor income and 1,600 FTEs). In the Kodiak Island region under FMP 4.1, significantly adverse impacts would occur at the local sector level. The city and region of Kodiak is somewhat less vulnerable to community and regional level impacts than is the case in the Alaska Peninsula and Aleutian Islands region and communities, due to greater size and economic diversity along with a lesser degree of dependence on groundfish per se, but there would be adverse impacts felt at the community and regional level (and within the commercial fishing sector of the economy, groundfish dependency is as important in Kodiak as it is in the Alaska Peninsula and Aleutian Islands region).

Southcentral Alaska. Total in-region groundfish processing value would decrease by 29 percent (all attributable to GOA decreases). Associated labor income and FTE jobs would also decrease by 29 percent. Regionally owned at-sea processing value would decrease by 62 percent (with relatively large decreases in BSAI values and smaller declines in GOA values), and associated labor income and FTEs both decreasing by 62 percent. (In this region under baseline conditions, in-region processing accounts for about four-fifths of the combined processing total value of sales and regionally owned at-sea processing accounts for about one-fifth of the total; labor income follows a similar pattern, but FTE employment is somewhat more heavily weighted toward the at-sea sector.) The value of extra-regional and in-region deliveries by regionally owned catcher vessels would decrease by 49 and 36 percent, respectively. Catcher vessel payments to labor and FTE jobs associated with extra regional deliveries would decrease by about 49 and 54 percent, respectively. For in-region deliveries, catcher vessel payments to labor and FTEs would decrease by about 36 and 40 percent, respectively. In this region, catcher vessel associated FTE jobs far surpass processing FTEs in the regional totals, but payments to labor for processing still surpass those for catcher vessels. Processing labor income figures for this region should be treated with caution, however, as the model tends to overstate actual payments due to the relative proportion of high value species processed. The total regional direct, indirect, and induced labor income would decrease by about 39 percent and FTE employment would decrease about 44 percent (from a base of $23 million in labor income and 567 FTEs). Under FMP 4.1, significantly adverse impacts would accrue to local sectors within the southcentral Alaska region. No significant impacts would be felt at the regional level, and community level impacts would tend to be attenuated by the relative size and economic diversity of the engaged communities. Overall, groundfish dependency is substantially lower for southcentral entities than for those in the Alaska Peninsula and Aleutian Islands region as well as the Kodiak Island region.

Southeast Alaska. Total in-region groundfish processing value would decrease by 88 percent (all attributable to GOA decreases). Associated labor income and FTE jobs would also decrease by 88 percent (but both are relatively low values). Regionally owned at-sea processing value would decrease by 94 percent (with decreases in both BSAI and GOA values), and associated labor income and FTEs both decreasing by 94 percent. (In this region under baseline conditions, in-region processing accounts for about seven-tenths of the combined processing total value of sales and regionally owned at-sea processing accounts for about three-tenths of the total; labor income follows a similar pattern, but FTE employment is somewhat more heavily weighted toward the at-sea sector.) The value of extra-regional and in-region deliveries by regionally owned catcher vessels would decrease by 25 and 88 percent, respectively. Catcher vessel payments to labor associated with extra regional deliveries would decrease by about 25 percent and FTE jobs would decrease by 23 percent. For in-region deliveries, catcher vessel payments to labor and FTEs would both decrease by about 88 percent. For this region, catcher vessel FTE employment far outpaces processing related employment, but payments to labor for processing still outpace those for catcher vessels. Processing labor income figures for this region should be treated with caution, however, as the model tends to overstate actual payments due to the relative proportion of high value species processed. The total regional direct, indirect, and induced labor income would decrease by about 77 percent and FTE employment would decrease by about 70 percent (from a base of $34 million in labor income and 879 FTEs). FMP 4.1 would have significantly adverse impacts on local sectors in the southeast Alaska region. In general, regional and community level impacts would be less pronounced than the output data might otherwise suggest, given the lower degree of dependency on groundfish than seen in some of the other Alaska regions, but impacts would still be felt at the community level for some of the smaller communities in the region that are relatively heavily engaged in the fishery.

Washington Inland Waters. Total in-region groundfish processing value changes are negligible on a regional basis due to low baseline values and small changes from the baseline. Associated labor income and FTE jobs would decrease by 29 percent, but their overall low value render these changes not significant. Regionally owned at-sea processing value would decrease by 67 percent (with decreases in both BSAI and GOA values, although GOA values are comparatively very small), and associated labor income and FTEs would decrease by 67 and 64 percent, respectively. The value of extra-regional and in-region deliveries by regionally owned catcher vessels would both decrease by 64 percent. Catcher vessel payments to labor and FTE jobs associated with extra regional deliveries would decrease by about 64 and 40 percent, respectively. For in-region deliveries, catcher vessel payments to labor and FTEs would decrease by about 64 and 22 percent, respectively. In this region, processing dominates the regional labor income and FTE employment totals when compared to analogous catcher vessel figures, but it is important to note that catcher vessel totals are still far higher for this region than for any other. The total regional direct, indirect, and induced labor income would decrease by about 66 percent and FTE employment would decrease by about 64 percent (from a base of $557 million in labor income and 10,316 FTEs). Under FMP 4.1, impacts to local sectors would be adverse and significant. Community level impacts would not be significant, given the nature of the concentration of the sectors in the greater Seattle metropolitan area.

Oregon Coast. Total in-region groundfish processing value changes are zero, along with associated labor income and FTE jobs, as there is no activity under baseline conditions or under this FMP. Similarly, there are no regionally owned at-sea processors under baseline conditions or foreseen under this FMP, so all processing values, labor income, and FTE job values are zero. The value of extra-regional deliveries by regionally owned catcher vessels would decrease by 64 percent, and associated labor income and FTE jobs would decrease 64 and 40 percent, respectively. There is no in-region activity by catcher vessels owned in this region, so all values for product, labor income, and FTE jobs are zero under both baseline conditions and this FMP. The total regional direct, indirect, and induced labor income would decrease by about 64 percent and FTE employment would decrease by about 54 percent (from a base of $15 million in labor income and 318 FTEs). Under FMP 4.1, Oregon coast catcher vessels would experience significantly adverse impacts, but regional and community level impacts would be less than significant, given the scale and diversity of the local economies and communities.

Cumulative Effects of FMP 4.1

For a summary of the direct/indirect and cumulative ratings see Table 4.8-6.

In-Region Processing and Related Effects

- **Direct/Indirect Effects**. For FMP 4.1, direct/indirect effects are considered significantly adverse for the Alaska Peninsula/Aleutian Islands and Kodiak Island regions, conditionally significant adverse for the southcentral Alaska and southeast Alaska regions and insignificant for the Washington inland waters and Oregon coast regions.

- **Persistent Past Effects.** The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. For more detail, refer to the analysis for in-region processing, FMP 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future External Effects.** Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities. Other sources of municipal and state revenue, and effects of long-term climate change and regime shifts. For more detail, refer to the analysis for in-region processing, FMP 1, Section 4.5.9.2.

- **Cumulative Effects**. Under FMP 4.1, cumulative effects on in-region processing and related characteristics, such as municipal revenue and secondary economic development, are conditionally significant adverse for the four Alaska regions (Alaska Peninsula/Aleutian Islands, Kodiak Island, southcentral Alaska, and southeast Alaska). The influence of external factors is adverse for many of the in-region processors based in Alaska and their associated regions. Trends in multi-species fisheries and other sources of municipal and state revenue, primarily due to the continued crab closures, downturn in salmon and reductions in state and municipal revenue, result in adverse effects on in-region processing and municipal revenue. For the Washington inland waters and Oregon coast regions, direct/indirect effects are insignificant, and there are no reasonably foreseeable events that would have a significant contribution, resulting in a finding of insignificant cumulative effect.

Regionally Owned At-Sea Processors

- **Direct/Indirect Effects**. Under FMP 4.1, direct/indirect effects are considered insignificant for the Alaska Peninsula/Aleutian Islands (negligible regional ownership) and Oregon coast (no regional ownership, and significantly adverse for the Kodiak Island, southcentral Alaska, southeast Alaska, and Washington inland waters regions.

- **Persistent Past Effects** The persistent past effects include trends and developments in fisheries, and to a lesser extent, trends in state and municipal revenue. For more detail see the analysis for in-region processing, FMP 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future External Effects** Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate change and regime shifts. For more detail, see the analysis for in-region processing, FMP 1, Section 4.5.9.2.

- **Cumulative Effects**. Under FMP 4.1, direct/indirect effects are insignificant or significantly adverse. Within southcentral Alaska, Washington inland waters, and Oregon coast regions, fisheries are a small part of the regional economies and effects are dwarfed by other trends. Cumulative effects for these regions are insignificant. Adverse trends in other fisheries (particularly salmon) and reductions on municipal revenue, decrease regional labor income and employment benefits, particularly in the Alaska Peninsula/Aleutian Islands, Kodiak Island, and southeast Alaska regions. Cumulative effects for these regions are conditionally significant adverse.

<u>Extra-Regional Deliveries of Regionally Owned Catcher Vessels</u>

- **Direct/Indirect Effects**. Under FMP 4.1, direct and indirect effects are significantly adverse for all regions.

- **Persistent Past Effects.** The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. Catcher vessels are affected by changes that have occurred in the groundfish industry related to allocation and AFA sideboards, and by their participation in multi-species fisheries, particularly salmon, crab, and halibut. For more detail, see the discussion of persistent past effects under In-region processing in FMP 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future External Effects.** Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities. Other sources of municipal and state revenue, and effects of long-term climate change and regime shifts. These effects are the same for all indicators of effect for all alternatives; for more detail see the discussion of persistent past effects under In-region processing in FMP 1, Section 4.5.9.2.

- **Cumulative Effects**. Under FMP 4.1, direct/indirect effects significantly adverse for all six regions. Within southcentral Alaska, Washington inland waters, and Oregon coast regions, fisheries are a small part of the regional economies and effects are dwarfed by other trends. Cumulative effects for these regions are insignificant. Adverse trends in other fisheries (particularly salmon) and reductions on municipal revenue, decrease regional labor income and employment benefits, particularly in the Alaska Peninsula/Aleutian Islands, Kodiak Island, and southeast Alaska regions. Cumulative effects for these regions are conditionally significant adverse.

In-Region Deliveries of Regionally Owned Catcher Vessels

- **Direct/Indirect Effects**. Under FMP 4.1, direct/indirect effects are considered significantly adverse for all regions except the Oregon coast (no in-region deliveries), which is insignificant.

- **Persistent Past Effects.** The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. For more detail, see the discussion of persistent past effects under In-region processing in FMP 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future External Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate change and regime shifts. These effects are the same for all indicators of effect for all alternatives; for more detail see the discussion of persistent past effects under In-region processing in FMP 1, Section 4.5.9.2.

- **Cumulative Effects**. Under FMP 4.1, the direct/indirect effects conditionally significant adverse for five of the six regions, and insignificant for one. Given the size and diversity of regional economies, in southcentral Alaska, Washington inland waters, and the Oregon coast, adverse external effects are offset and cumulative effects are insignificant. The significant decrease in extra-regional deliveries to the Alaska Peninsula/Aleutian Islands, Kodiak Island, and southeast Alaska, in conjunction with adverse external effects related to other fisheries and revenue sharing results in a conditionally significant adverse cumulative effect for these three regions.

Total Direct, Indirect, and Induced Labor Income and FTEs

- **Direct/Indirect Effects**. Under FMP 4.1, direct/indirect effects on labor income and employment are significantly adverse for all six regions.

- **Persistent Past Effects.** The persistent past effects include trends and developments in fisheries, trends in state and municipal revenue, and public infrastructure and facility projects. Fishing is a major component of income and employment in many small Alaskan coastal communities. Federal, state, and local revenue has funded public infrastructure and facility projects that generate income and employment in many regions and communities. For more detail, see the discussion of persistent past effects under in-region processing in FMP 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future External Effects.** Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities. other sources of municipal and state revenue, and effects of long-term climate change and regime shifts. These effects are the same for all indicators of effect for all alternatives. For more detail, see the discussion of persistent past effects under in-region processing in FMP 1, Section 4.5.9.2.

- **Cumulative Effects**. Under FMP 4.1 direct/indirect effects on labor income and employment are significantly adverse for all regions. Within southcentral Alaska, Washington inland waters, and

Oregon coast regions, fisheries are a small part of the regional economies and effects are dwarfed by other trends. Cumulative effects for these regions are insignificant. Adverse trends in other fisheries (salmon and crab) and reductions on municipal revenue, decrease regional labor income and employment benefits, particularly in the Alaska Peninsula/Aleutian Islands, Kodiak Islands, and southeast Alaska regions. Cumulative effects for the Alaska Peninsula/Aleutian Islands, Kodiak Island, and southeast Alaska regions are conditionally significant adverse.

Direct/Indirect Effects of FMP 4.2

Under this FMP, the commercial harvest of groundfish would be suspended for an indeterminate period of time until it can be determined that fishing activities are not having a significantly adverse effect on sustainable fisheries, habitat, and the ecosystem. The regional impacts of the discontinuation of the fishery would be immediate, adverse, and significant for all regions in all categories of effects.

Cumulative Effects of FMP 4.2

For a summary of the direct/indirect and cumulative ratings see Table 4.8-6.

<u>In-Region Processing and Related Effects</u>

- **Direct/Indirect Effects**. For FMP 4.2, the indeterminate cessation in fishing would result in significantly adverse direct/indirect effects for all regions, except for the Oregon coast region, which has no in-region processing and is insignificant. Refer to the previous section for a more detailed discussion of direct/indirect effects.

- **Persistent Past Effects.** The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. For more detail, refer to the analysis for in-region processing, FMP 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future External Effects.** Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities. Other sources of municipal and state revenue, and effects of long-term climate change and regime shifts. For more detail, refer to the analysis for in-region processing, FMP 1, Section 4.5.9.2.

- **Cumulative Effects**. Under FMP 4.2, significantly adverse direct/indirect effects would combine with adverse trends in multi-species fisheries (crab closures, downturn in salmon fishery) and other sources of municipal and state revenue, resulting in significantly adverse cumulative effects for the Alaska Peninsula/Aleutian Islands, Kodiak Island, and southeast Alaska regions. Although the direct/indirect effects would be significantly adverse for the participants in the fishery in southcentral Alaska and Washington inland waters regions, because of the diversity of regional economies, the cumulative effects would be insignificant. For the Oregon coast region, direct/indirect effects are insignificant, and there are no reasonably foreseeable future events that would have a significant contribution, resulting in a finding of insignificant cumulative effect.

Regionally Owned At-Sea Processors

- **Direct/Indirect Effects**. For FMP 4.2, the indeterminate cessation in fishing would result in significantly adverse direct/ indirect effects for all regions, except for the Oregon coast, which has no at-sea processing and is insignificant. Refer to the previous section for a more detailed discussion of direct/indirect effects.

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, and to a lesser extent, trends in state and municipal revenue. For more detail see the analysis for in-region processing, FMP 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future External Effects.** Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate change and regime shifts. For more detail, see the analysis for in-region processing, FMP 1, Section 4.5.9.2.

- **Cumulative Effects**. Under FMP 4.2, significantly adverse direct/indirect effects would combine with adverse trends in multi-species fisheries (crab closures, downturn in salmon fishery) and other sources of municipal and state revenue, resulting in significantly adverse cumulative effects for the Alaska Peninsula/Aleutian Islands, Kodiak Island, and southeast Alaska regions. Although the direct/indirect effects would be significantly adverse for the participants in the fishery in southcentral Alaska and Washington inland waters regions, because of the diversity of regional economies, the cumulative effects would be insignificant. For the Oregon coast region, direct/indirect effects are insignificant, and there are no reasonably foreseeable future events that would have a significant contribution, resulting in a finding of insignificant cumulative effect.

Extra-Regional Deliveries of Regionally Owned Catcher Vessels

- **Direct/Indirect Effects**. For FMP 4.2, the indeterminate cessation in fishing would result in significantly adverse direct/indirect effects for all regions. See the previous section for a more detailed discussion of direct/indirect effects.

- **Persistent Past Effects.** The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. Catcher vessels are affected by changes that have occurred in the groundfish industry related to allocation and AFA sideboards, and by their participation in multi-species fisheries, particularly salmon, crab, and halibut. For more detail, see the discussion of persistent past effects under In-region processing in FMP 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future External Effects.** Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities. Other sources of municipal and state revenue, and effects of long-term climate change and regime shifts. These effects are the same for all indicators of effect for all alternatives; for more detail see the discussion of persistent past effects under In-region processing in FMP 1, Section 4.5.9.2.

- **Cumulative Effects**. Under FMP 4.2, significantly adverse direct/indirect effects would combine with adverse trends in multi-species fisheries (crab closures, downturn in salmon fishery) and other sources of municipal and state revenue, resulting in significantly adverse cumulative effects for the Alaska Peninsula/Aleutian Islands, Kodiak Island, and southeast Alaska regions. Although the direct/indirect effects would be significantly adverse for the participants in the fishery in southcentral Alaska, Washington inland waters, and Oregon coast regions, because of the diversity of regional economies, the cumulative effects would be insignificant.

In-Region Deliveries of Regionally Owned Catcher Vessels

- **Direct/Indirect Effects**. For FMP 4.2, the indeterminate cessation in fishing would result in significantly adverse direct/ indirect effects for all regions, except for the Oregon coast, which has no in-region deliveries and is insignificant. See the previous section for a more detailed discussion of direct/ indirect effects.

- **Persistent Past Effects.** The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. For more detail, see the discussion of persistent past effects under In-region processing in FMP 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future External Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate change and regime shifts. These effects are the same for all indicators of effect for all alternatives; for more detail see the discussion of persistent past effects under In-region processing in FMP 1, Section 4.5.9.2.

- **Cumulative Effects**. Under FMP 4.2, significantly adverse direct/indirect effects would combine with adverse trends in multi-species fisheries (crab closures, downturn in salmon fishery) and other sources of municipal and state revenue, resulting in significantly adverse cumulative effects for the Alaska Peninsula/Aleutian Islands, Kodiak Island, and southeast Alaska regions. Although the direct/indirect effects would be significantly adverse for the participants in the fishery in southcentral Alaska and, Washington inland waters regions, because of the diversity of regional economies, the cumulative effects would be insignificant. For the Oregon coast region, direct/indirect effects are insignificant, and there are no reasonably foreseeable future events that would have a significant contribution, resulting in a finding of insignificant cumulative effect.

Total Direct, Indirect, and Induced Labor Income and FTEs

- **Direct/Indirect Effects.** For FMP 4.2, the indeterminate cessation in fishing would result in significantly adverse direct/ indirect effects for all regions. See previous section for a more detailed discussion of direct/ indirect effects.

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, trends in state and municipal revenue, and public infrastructure and facility projects. Fishing is a major component of income and employment in many small Alaskan coastal communities. Federal, state, and local revenue has funded public infrastructure and facility projects that generate income and employment in many regions and communities. For more detail, see the discussion of persistent past effects under in-region processing in FMP 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future External Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities. other sources of municipal and state revenue, and effects of long-term climate change and regime shifts. These effects are the same for all indicators of effect for all alternatives. For more detail, see the discussion of persistent past effects under in-region processing in FMP 1, Section 4.5.9.2.

- **Cumulative Effects**. Under FMP 4.2, significantly adverse direct/indirect effects would combine with adverse trends in multi-species fisheries (crab closures, downturn in salmon fishery) and other sources of municipal and state revenue, resulting in significantly adverse cumulative effects for the Alaska Peninsula/Aleutian Islands, Kodiak Island, and southeast Alaska regions. Although the direct/indirect effects would be significantly adverse for the participants in the fishery in southcentral Alaska, Washington inland waters, and Oregon coast regions, because of the diversity of regional economies, the cumulative effects would be insignificant.

4.8.9.3 Community Development Quota Program

The predicted direct and indirect effects of the groundfish fishery under FMP 4.1 and FMP 4.2 are described below. The past/present effects on CDQ are described in Section 3.9 and below (Table 3.9-126). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case. The representative indicator used in this analysis is allocation of catch to CDQ groups. It should be noted that allocation reflects potential revenue to CDQ groups, and indirectly the potential funds that are available for approved economic development activities in CDQ communities (Table 4.8-6).

Direct/Indirect Effects of FMP 4.1 and FMP 4.2

The CDQ program would continue in its present structure under FMP 4.1, but the steep declines in the overall fishery would be mirrored by similarly steep declines in CDQ royalties, employment, and income. As with the rest of the regions participating in the fishery, impacts to the CDQ region would be significantly adverse.

The CDQ region would also experience significantly adverse social impacts under FMP 4.2. While the multi-species CDQ program would continue, this would allow royalties, income, and employment levels to continue at only a fraction of the level seen under baseline conditions.

Cumulative Effects of FMP 4.1 and FMP 4.2

For a summary of the direct/indirect and cumulative ratings see Table 4.8-6.

- **Direct/Indirect Effects**. The direct/indirect effects on the CDQ program under FMP 4.1 and FMP 4.2 are significantly adverse.

- **Persistent Past Effects**. The past/present effects on the CDQ program for groundfish fisheries include establishment of CDQ program; FMP amendments that further added or defined CDQ in 1992,1995,1996, and 1998; establishment of multi-species CDQ programs, and persistent limitations on economic development and associated employment activities. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Reasonably Foreseeable Future External Effects**. Other fisheries, other economic development activities, other sources of municipal and state revenue all have the potential to affect the CDQ program adversely or beneficially. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Cumulative Effects**. Under FMP 4.1 and FMP 4.2, a cumulative effect is identified for the CDQ Program, and the effect is judged to be significantly adverse. Impacts to the CDQ region would be significantly adverse due to declines in CDQ royalties, employment and income.

4.8.9.4 Subsistence

The predicted direct and indirect effects of the groundfish fishery under FMP 4.1 and FMP 4.2 are described below. The past/present effects on subsistence are described in Section 3.9 and below (Table 3.9-126). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case. The representative indicators used in this analysis are other fisheries such as foreign JV, domestic, and state-managed fisheries, other economic development activities, sport and personal use, and long-term climate change and regime shift (Table 4.8-6).

Direct/Indirect Effects of FMP 4.1 and FMP 4.2

Potential impacts to subsistence fall into four main categories: subsistence use of groundfish, subsistence use of Steller sea lions, subsistence use of salmon in western Alaska and bycatch in the groundfish fisheries, and indirect impacts on other subsistence activities, including loss of income that would be otherwise directed toward subsistence pursuits and the loss of access to commercial fishing vessels and gear that would be otherwise be available for joint production opportunities. Under this FMP, commercial fishery activity is sharply reduced, but it is not clear that this would have direct beneficial or adverse impacts on the subsistence groundfish fishing conditions in relation to the subsistence fishery that is occurring under baseline conditions, but it is assumed that any change would not be large enough to reach significant levels. Steller sea lion populations are expected to benefit under this FMP due to a beneficial effect on pelagic forage availability. This would be a conditionally significant beneficial benefit for Steller sea lion subsistence activities, with the condition being that Steller populations would need to increase to point where subsistence activities substantially benefit through a reduction in effort needed for hunting success and/or the perceived recovery of the Steller population fostered a substantial increase in subsistence activity. Salmon bycatch would be reduced under this FMP, however, current information does not allow a determination that the level of bycatch reduction would result in significant increases in salmon returns to subsistence fishery areas. Therefore, while reduction in salmon bycatch would be generally beneficial for subsistence salmon fisheries, current data do not suggest that these benefits would rise to the level of significance. Catcher vessel activity and labor income are anticipated to decline sharply under this FMP, therefore it is expected that adverse indirect impacts to subsistence through a decline in income or joint production opportunities will occur.

It is not clear whether subsistence related groundfish fishing would experience direct impacts under FMP 4.2. Local groundfish availability may increase with the elimination of the commercial groundfish fishery, but the magnitude of this increase is unknown and the effect of this increase on subsistence activity is unknown. Given the relatively low level of groundfish subsistence use, it is assumed that any direct increase groundfish subsistence likely under this FMP would be insignificant. Steller sea lion populations are expected to benefit under this FMP due to a beneficial effect on pelagic forage availability. This would be a conditionally significant beneficial benefit for Steller sea lion subsistence activities, with the condition being that Steller populations would need to increase to point where subsistence activities substantially benefit through a reduction in effort needed for hunting success and/or the perceived recovery of the Steller population fostered a substantial increase in subsistence activity. Salmon bycatch would be eliminated under this FMP. This would result in a conditionally significant beneficial benefit for salmon subsistence fisheries, with the condition being that as a result of bycatch elimination salmon returns increased significantly to subsistence salmon fishery areas. Indirect impacts to subsistence in the form of loss of income and the loss of joint production opportunities would occur, and are considered significantly adverse.

Cumulative Effects of FMP 4.1 and FMP 4.2

The predicted direct and indirect effects of the groundfish fishery under FMP 4.1 and FMP 4.2 are described above. The past/present effects on subsistence are described in Section 3.9. This section will assess the potential for these effects to interact with other reasonably foreseeable future events and activities in the cumulative case. Representative indicators used in this analysis are the same as those used in the direct/indirect analysis and include subsistence use of groundfish, subsistence use of Steller sea lions, subsistence use of salmon, and indirect impacts on other subsistence activities such as income and joint production opportunities. For a summary of the direct/indirect and cumulative ratings see Table 4.8-6.

<u>Subsistence Use of Groundfish</u>

- **Direct/Indirect Effects**. Under FMP 4.1, commercial fishery activity is sharply reduced, but it is not clear that this would have direct beneficial or adverse impacts on the subsistence groundfish fishing conditions in relation to the subsistence fishery that is occurring under baseline conditions, but it is assumed that any change would not be large enough to reach significant levels. Under FMP 4.2 it is not clear whether subsistence related groundfish fishing would experience direct impacts under this FMP. Local groundfish availability may increase with the elimination of the commercial groundfish fishery, but the magnitude of this increase is unknown and the effect of this increase on subsistence activity is unknown. Given the relatively low level of groundfish subsistence use, it is assumed that any direct increase groundfish subsistence likely under this FMP would be insignificant.

- **Persistent Past Effects**. Foreign JV, domestic, and state-managed fisheries have decreased populations of some species of groundfish used for subsistence. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Reasonably Foreseeable Future External Effects**. Other fisheries and long-term climate change have a potential to adversely contribute to subsistence use of the groundfish fisheries. Economic development and sport and personal use are not likely to adversely contribute to subsistence use of the groundfish fisheries. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Cumulative Effects**. Under FMP 4.1 and FMP 4.2, a cumulative effect is identified for subsistence use of groundfish, and the effect is judged to be insignificant. Under FMP 4.1 commercial fishery activities are sharply reduced and under FMP 4.2 subsistence groundfish harvest in federal waters fishing is suspended. The cumulative effects could be adverse, but not enough to have significant indirect impacts to subsistence. The external impacts of economic development activities and sport and personal use of groundfish are not likely to contribute adversely to the groundfish fisheries. However, other state-managed fisheries could have adverse impacts to the subsistence use of groundfish due to the direct competition for the same species, but those impacts are not considered to be significant. The long-term climate change could adversely effect groundfish stocks.

<u>Subsistence Use of Steller Sea Lions</u>

- **Direct/Indirect Effects**. Under FMP 4.1 Steller sea lion populations are expected to benefit due to a beneficial effect on pelagic forage availability. This would be a conditionally significant beneficial benefit for Steller sea lion subsistence activities, with the condition being that Steller populations would need to increase to point where subsistence activities substantially benefit through a reduction in effort needed for hunting success and/or the perceived recovery of the Steller population fostered a substantial increase in subsistence activity. Under FMP 4.2 Steller sea lion populations are expected to benefit due to a beneficial effect on pelagic forage availability. This would be a conditionally significant beneficial benefit for Steller sea lion subsistence activities, with the condition being that Steller populations would need to increase to point where subsistence activities substantially benefit through a reduction in effort needed for hunting success and/or the perceived recovery of the Steller population fostered a substantial increase in subsistence activity.

- **Persistent Past Effects**. The past/present effects on subsistence use of Steller sea lions include the following: a long-term decline in population of Steller sea lions due to a number of factors; a long-term decline in relative importance of marine mammals in local diets; commercial groundfish fishing taking prey species utilized by Steller sea lions; and Steller sea lion protection measures designed to assist in population recovery instituted in 2000. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Reasonably Foreseeable Future External Effects**. Other fisheries, economic development, and long-term climate change have a potential to adversely contribute to Steller sea lions subsistence activities. Sport and personal use is not likely to adversely contribute to subsistence use of Steller sea lions. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Cumulative Effects**. Under FMP 4.1 and FMP 4.2, a cumulative effect is identified for subsistence use of Steller sea lions and the effect is judged to be conditionally significant beneficial. The reduction of open fisheries under FMP 4.1 and the closure of fisheries under FMP 4.2 could have a beneficial impact on Steller population levels.

Subsistence Use of Western Alaskan Salmon and Bycatch in the Groundfish Fishery

- **Direct/Indirect Effects**. Under FMP 4.1, salmon bycatch would be reduced, however, current information does not allow a determination that the level of bycatch reduction would result in significant increases in salmon returns to subsistence fishery areas. Therefore, while reduction in salmon bycatch would be generally beneficial for subsistence salmon fisheries, current data do not suggest that these benefits would rise to the level of significance. Under FMP 4.2 salmon bycatch would be eliminated under this FMP. This would result in a conditionally significant beneficial benefit for salmon subsistence fisheries, with the condition being that as a result of bycatch elimination salmon returns increased significantly to subsistence salmon fishery areas.

- **Persistent Past Effects**. The past/present effects on subsistence use of salmon include the following: utilization for subsistence since pre-contact times; and Area M closures implemented to decrease intercept of salmon. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Reasonably Foreseeable Future External Effects**. Other fisheries, other economic development activities and long-term climate change and regime shift could all adversely contribute to salmon subsistence activities. Sport and personal use is not likely to adversely contribute to salmon subsistence activities. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Cumulative Effects**. Under FMP 4.1, a cumulative effect is identified for subsistence use of salmon, and is judged to be insignificant. The reduction in salmon bycatch is offset by external effects that adversely affect subsistence use of salmon. Under FMP 4.2 a cumulative effect is identified for subsistence use of salmon and the effect is judged to be conditionally significant beneficial. Given the poor stock status of salmon runs in western Alaska, decreasing bycatch in BSAI and GOA could help to restore stock and improve recovery.

Indirect Impacts on Other Subsistence Activities

- **Direct/Indirect Effects**. Under FMP 4.1, catcher vessel activity and labor income are anticipated to decline sharply, therefore it is expected that significantly adverse indirect impacts to subsistence through a decline in income or joint production opportunities will occur. Under FMP 4.2 indirect impacts to subsistence in the form of loss of income and the loss of joint production opportunities would occur.

- **Persistent Past Effects**. The past/present effects on the indirect impacts on other subsistence activities include joint production as a part of local groundfish and other commercial fishery development from the outset; and income from fishing used for investment in subsistence is similar to use of income from other activities. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Reasonably Foreseeable Future External Effects**. Other fisheries, other economic development activities, and long-term climate change and regime shift could all adversely or beneficially contribute to indirect subsistence activities. Sport and personal use is not likely to adversely contribute to indirect impacts on other subsistence activities. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Cumulative Effects**. Under FMP 4.1 and FMP 4.2 a cumulative effect is identified for subsistence use of salmon and the effect is judged to be significantly adverse. Under FMP 4.1 income, catcher vessel activity, and joint production opportunities are adversely affected by reduced fishing activities. Under FMP 4.2 income, catcher vessel activity, and joint production opportunities are eliminated.

4.8.9.5 Environmental Justice

The predicted direct and indirect effects of the groundfish fishery under FMP 4.1 and FMP 4.2 are described below. The past/present effects on Environmental Justice are described in Section 3.9 (Table 3.9-126) and below. This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case. The external factors used in this analysis are other fisheries such as foreign, domestic, and state-managed fisheries; other economic development activities; other sources of municipal/state revenue; and long-term climate change and regime shift (Table 4.8-6).

Direct/Indirect Effects of FMP 4.1

Potential impacts that drive Environmental Justice issues include employment/municipal revenue and taxes in communities with significant percentages of special populations (Alaska Native and minority processing workforce); revenue to Native-owned catcher vessels; revenue to Native-owned catcher processors; subsistence activities associated with groundfish, Steller sea lion, and salmon; and the loss of income from fishing that would be otherwise directed toward subsistence pursuits and the loss of access to commercial fishing vessels and gear that would otherwise be available for joint production opportunities. The regions that could experience potential impacts include the Alaska Peninsula and Aleutian Islands, Kodiak Island, southcentral Alaska, southeast Alaska, Washington inland waters, Oregon coast, the CDQ regions, and western Alaska communities that harvest salmon for subsistence purposes.

Alaska Peninsula and Aleutian Islands. As described in existing conditions, this region encompasses a number of groundfish fishing communities, of which several have predominantly Alaska Native populations. Also as described under existing conditions, the in-region processing workforce is predominantly a minority population. in-region processing employment would decrease below baseline conditions by about 2,131 jobs; therefore, this loss of jobs in a region with predominantly minority populations engaged in the processing industry would result in a marked Environmental Justice impact. Total in-region groundfish processing value would decrease from $464 million to $178 million. Decreased in-region processing value would correspond to reduced municipal revenue and taxes to the local communities and would therefore result in associated Environmental Justice impacts for those communities with substantial minority populations. In this region the ownership and crews of the catcher vessels are assumed to tend to mirror the demographic composition of populations of the home port communities, so local fleets from at least a few communities in this region are likely to be owned and crewed by Alaska Native residents. Under this FMP bookend, the total value of catcher vessel operations would decrease as would corresponding labor income and employment; therefore, an Environmental Justice impact would likely result.

Kodiak Island. As described in existing conditions, groundfish processing and catcher vessel activity in this region is highly concentrated in the City of Kodiak. Although the city is ethnically diverse, it does not have a predominantly Alaska Native population as do some of the groundfish fishing communities in the Alaska Peninsula/Aleutian Islands region. However, as described under existing conditions, the in-region processing workforce is predominantly a minority population. in-region processing employment would decrease over baseline conditions by about 367 jobs; therefore, an Environmental Justice impact would result. Total in-region groundfish processing value would decrease from $81 million to $29 million. Decreased in-region processing value would correspond to reduced municipal revenue and taxes to the City and the Kodiak Island Borough, but given local and regional demographics, this is not likely to be an Environmental Justice issue. Ownership and crews of the catcher vessels are assumed to mirror the demographic composition of populations of the City of Kodiak itself, and therefore the local fleet associated population is not likely to be predominantly Alaska Native (or comprised of other identified minority populations). Under this FMP bookend, the total value of catcher vessel operations would decrease as would corresponding labor income and employment, but given demographic assumptions, this is unlikely to be an Environmental Justice issue.

Southcentral Alaska. As described in existing conditions, Environmental Justice concerns are much less salient in this region than in the Alaska Peninsula/Aleutian Islands or Kodiak Island regions. The communities most directly engaged in the groundfish fishery, particularly with respect to the processing sector, are largely non-Native communities, and have relatively large populations and diversified economic opportunities. Further, there is a relatively low level of groundfish related processing employment overall. Catcher vessel related employment is assumed to mirror community demographics, and thus it is unlikely that Environmental Justice issues will be associated with any employment change. In general, under this FMP overall combined direct, indirect, and induced labor income and FTEs decrease, but this change is not linked to Environmental Justice concerns. Similarly, processing value decreases, as do catcher vessel associated values, but these changes are not tied to Environmental Justice concerns.

Southeast Alaska. The situation in this region is similar to that seen in southcentral Alaska, with the possible exception of the community of Yakutat, which is more predominantly Alaska Native than the other regionally important groundfish communities. Data confidentiality constraints preclude a discussion of Yakutat alone, but otherwise overall Environmental Justice concerns appear not to apply in this region. In general, under this FMP overall combined direct, indirect, and induced labor income and FTEs decrease, but this change is not linked to Environmental Justice concerns. Similarly, processing value decreases as do analogous catcher vessel associated values, but this change is not associated with Environmental Justice concerns. See

Washington Inland Waters. The greater Seattle area is the regional community most engaged in the groundfish fishery, and it is a demographically and economically diverse major metropolitan area. in-region processing does not occur, and while a number of other communities in the region outside of Seattle are home to groundfish catcher vessels, there is no indication that these communities or the associated vessel owners and crew are comprised of minority populations. As described in existing conditions, Environmental Justice concerns for this region are concentrated in the at-sea processing sector, due to the predominance of minority representation within this workforce. Under this FMP , at-sea processing labor income and FTEs decrease by 67 and 64 percent, respectively, which would result in Environmental Justice impacts. See

Oregon Coast. This region is engaged in the commercial groundfish fishery through its regionally owned catcher vessel fleet. This fleet is concentrated in a limited number of communities in the region, and there is no indication that these are minority communities, nor is there any indication that the population directly associated with fleet ownership and/or crew is either a minority population or a low-income population. In general, under this FMP overall combined direct, indirect, and induced labor income and FTEs decrease, as do catcher vessel related values, but these changes are not linked to Environmental Justice concerns. See

CDQ Region. The CDQ region is predominantly comprised of Alaska Native communities that have relatively limited commercial economic opportunities, so any adverse impacts to this program and region are likely to involve Environmental Justice concerns. Under this FMP, the structure of the CDQ program would not change from baseline conditions. However, the precipitous decline of the fishery due to reductions in TAC and area closures associated with specific gear types would result in adverse impacts to the CDQ program (income and employment opportunities for Alaska Natives, economic development revenue available to CDQ communities), and these would be considered Environmental Justice impacts.

Subsistence. Subsistence activities typically disproportionately involve Alaska Native communities and populations, and in a few cases (such as Steller sea lion subsistence) exclusively involve Alaska Native individuals and groups. As a result, adverse impacts to subsistence pursuits are likely to involve Environmental Justice concerns. Subsistence activities where there are potential Environmental Justice issues include the following:

- Harvest of groundfish (which occurs to some extent in all four Alaska regions), Steller sea lion (primarily and activity in the Alaska Peninsula/Aleutian Islands region), and salmon (primarily an issue in western Alaska, where poor runs have adversely affected subsistence harvests).

- The loss of income from fishing that would otherwise be directed toward subsistence pursuits and the loss of access to commercial fishing vessels and gear that would otherwise be available for joint production (which occurs to some extent in all four Alaska regions).

Management measures associated with reductions in TAC and salmon bycatch, and increases in area closures to protect habitat will benefit subsistence harvest of Salmon and Steller sea lions. As a result there would be insignificant Environmental Justice effects on subsistence harvests. However, this FMP would result in significant loss of income and joint production opportunities, primarily in the Alaska Peninsula/Aleutian Island region, resulting in an adverse Environmental Justice effect.

Cumulative Effects of FMP 4.1

The predicted direct and indirect effects of the groundfish fishery under the Alternative 4 are described above. The past/present effects on Environmental Justice Issues are described in Section 3.9. This section will assess the potential for these effects to interact with other reasonably foreseeable future events and activities in the cumulative case. The representative indicator used in this analysis is the same as that used in the direct/indirect analysis (Table 4.8-6).

Environmental Justice

- **Direct/Indirect Effects**. Under FMP 4.1, significantly adverse Environmental Justice effects would result from reductions in minority processing income employment (Alaska Peninsula/Aleutian

Islands, Kodiak Island, Washington inland waters); Alaskan Native harvesting income and employment (Alaska Peninsula/Aleutian Islands); tax revenues to communities with significant Alaskan Native populations (Alaska Peninsula/Aleutian Islands); CDQ region income, employment and economic development funds; and income and joint production opportunities that support subsistence harvests (Alaska Peninsula/Aleutian Islands).

- **Persistent Past Effects**. Persistent past effects include trends and developments in other fisheries, and trends in state and municipal revenue. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Reasonably Foreseeable Future External Effects**. Other fisheries, other economic development activities, other sources of municipal state revenue and long-term climate change and regime shift have the potential to adversely or beneficially affect Environmental Justice issues. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Cumulative Effects**. Under FMP 4.1, the reductions in TAC and large closure areas would create significantly adverse cumulative Environmental Justice effects for the Alaska Peninsula/Aleutian Islands, Kodiak and Washington inland waters. The adverse direct/indirect effects on special population income and employment activities, CDQ region income/employment/ development funds, and income and joint production for subsistence pursuits combined with adverse external effects and trends (salmon and crab downturns, reductions in municipal revenue) to result in significantly adverse cumulative Environmental Justice issues in the Alaska Peninsula/ Aleutian Islands, Kodiak Island, Washington inland waters, and CDQ regions. Cumulative effects on subsistence harvest of salmon and Steller sea lion are beneficial but insignificant, and do not raise Environmental Justice concerns.

Direct/Indirect Effects of FMP 4.2

FMP 4.2 suspends the fishery for an indeterminate amount time, and significantly adverse impacts to Alaska Native fishing communities would result in Environmental Justice impacts. Processing worker job losses in the in-region processing sectors in the Alaska Peninsula/Aleutian Islands and Kodiak regions would result in Environmental Justice impacts, as would losses of jobs to at-sea processing workers operating out of the Washington inland waters region. Catcher vessel income and job losses in Alaska Native communities (primarily in the Alaska Peninsula/Aleutian Islands region) would also involve Environmental Justice concerns, as would the loss of tax revenue to communities with predominant Alaska Native populations. Further, impacts to the CDQ program, due to the loss of revenue, employment opportunities, and economic development funds, would be significantly adverse; given the demography of the CDQ region, these constitute Environmental Justice impacts. While subsistence harvest of salmon and Steller sea lions would benefit, the loss of income and joint production opportunities, primarily in the Alaska Peninsula/Aleutian Islands region, would also qualify as an Environmental Justice issue.

Cumulative Effects of FMP 4.2

The predicted direct and indirect effects of the groundfish fishery under the Alternative 4 are described above. The past/present effects on Environmental Justice Issues are described in Section 3.9. This section will assess the potential for these effects to interact with other reasonably foreseeable future events and activities in the cumulative case. The representative indicator used in this analysis is the same as that used in the direct/indirect analysis (Table 4.8-6).

Environmental Justice

- **Direct/Indirect Effects**. Under FMP 4.2, significantly adverse Environmental Justice effects would result from reductions in minority processing income employment (Alaska Peninsula/Aleutian Islands, Kodiak Island, Washington inland waters); Alaskan Native harvesting income and employment (Alaska Peninsula/Aleutian Islands); tax revenues to communities with significant Alaskan Native populations (Alaska Peninsula/Aleutian Islands); CDQ region income, employment and economic development funds; and income and joint production opportunities that support subsistence harvests (Alaska Peninsula/Aleutian Islands).

- **Persistent Past Effects**. Persistent past effects include trends and developments in other fisheries, and trends in state and municipal revenue. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Reasonably Foreseeable Future External Effects**. Other fisheries, other economic development activities, other sources of municipal state revenue and long-term climate change and regime shift have the potential to adversely or beneficially affect Environmental Justice issues. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Cumulative Effects.** Under FMP 4.2, the suspension of fisheries would create significantly adverse cumulative Environmental Justice effects similar to FMP 4.1, only more severe. The adverse direct/indirect effects on special population income and employment activities, CDQ region income/employment/ development funds, and income and joint production for subsistence pursuits combine with adverse external effects and trends (salmon and crab downturns, reductions in municipal revenue) to result in conditionally significant cumulative Environmental Justice issues in the Alaska Peninsula/ Aleutian Islands, Kodiak Island, Washington inland waters, and CDQ regions. Cumulative effects on subsistence harvest of salmon and Steller sea lion are beneficial but insignificant, and do not raise Environmental Justice concerns.

4.8.9.6 Market Channels and Benefits to United States Consumers

The predicted direct and indirect effects of the groundfish fishery under FMP 4.1 and FMP 4.2 are described below. The past/present effects on Market Channels and Benefits to U.S. Consumers are described in Section 3.9 and below (Table 3.9-127). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case. Representative indicators used in this analysis include product quantity, product year-round availability, product quality, and product diversity on Market Channels and Benefits to U.S. Consumers activities (Table 4.8-6).

Direct/Indirect Effects of FMP 4.1 and FMP 4.2

FMP 4.1 is not expected to have a significant effect on benefits to U.S. consumers of groundfish products relative to the comparative baseline. FMP 4.1 will result in large reductions in the domestic production of several different groundfish products. The projected 5-year mean of the wholesale product value of BSAI and GOA groundfish after primary processing is $0.5 billion. This product value mean is approximately one-third of the comparative baseline. The most likely result of the decrease in the production would be an adverse effect on the U.S. seafood trade balance, as more groundfish products are imported to offset the reduced domestic supply. The imported groundfish products, such as the twice-frozen fillets and blocks imported from China, may be generally lower in quality than domestic products. The price elasticity of demand for groundfish products is fairly high in the U.S. market, but assuming that demand is not perfectly elastic, the decreased production could result in higher prices and a loss of consumer surplus (i.e., net benefits) to the American public. The magnitude of that loss will depend on price elasticities that are not quantifiable at this time and on the degree to which production is shifted toward or away from the export markets. However, it is unlikely that the decrease in consumer surplus will be significant relative to the comparative baseline using the 20 percent standard as the significance criterion.

FMP 4.2 is expected to have a conditionally significant adverse effect on benefits to U.S. consumers of groundfish products relative to the comparative baseline. Both the intensity of this effect and the probability of its occurrence are uncertain. Under FMP 4.2, the production of groundfish products in fisheries occurring in the EEZ off Alaska will be suspended until more information is known on the impacts of fishing on the environment. An estimate of the final market value of BSAI and GOA seafood products that will be foregone under this FMP is not available; however, it would be substantially greater than $1.5 billion, the estimated product value of BSAI and GOA groundfish after primary processing that will be foregone under FMP 4.2. The most likely result of the decrease in the production would be a adverse effect on the U.S. seafood trade balance, as more groundfish products are imported to offset the reduced domestic supply. The imported products, such as the "twice-frozen" fillets and blocks imported from China, may be generally lower in quality than domestic products. Even if more foreign groundfish products are imported, the increase may be unable to compensate for the effects of a suspension of U.S. harvests of groundfish in the EEZ off Alaska. The result could be a significant decrease in the supply of pollock and Pacific cod fillets to the U.S. market. The supply of surimi for the domestic seafood analog market and other products may also be reduced. In turn, these decreases in supply could have adverse effects on American seafood consumers. The price elasticity of demand for groundfish products is fairly high in the U.S. market, but assuming that demand is not perfectly elastic, the suspension of the Alaska groundfish fisheries could result in higher prices for groundfish products and a loss of consumer surplus (i.e., net benefits) to the American public.

Cumulative Effects of FMP 4.1 and FMP 4.2

For a summary of the direct/indirect and cumulative ratings see Table 4.8-6.

Market Channels and Benefits to U.S. Consumers

- **Direct/Indirect Effects of FMP 4.1 and FMP 4.2**. Under FMP 4.1, increases in benefits to U.S. consumers of groundfish products are expected to occur but are insignificant. Under FMP 4.2 the production of groundfish products in fisheries occurring in the EEZ off Alaska will be suspended and the supply of seafood products to the U.S. market will decrease. This is expected to have a conditionally significant adverse effect on benefits to U.S. consumers of groundfish products.

- **Persistent Past Effects**. These effects on benefits to U.S. consumers of groundfish products include: Alaska Seafood Marketing Institute product promotion activities, research and public awareness regarding the health benefits of seafood consumption, aquaculture development increasing overall availability and demand for seafood products, and changes in processing technology increasing seafood quality.

- **Reasonably Foreseeable Future External Effects**. Reasonably foreseeable effects include other fisheries (supply of product) and long-term climate change and regime shift. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Cumulative Effects**. Under FMP 4.1, a cumulative effect is identified for benefits to U.S. consumers of groundfish products, and the effect is judged to be insignificant. The external impacts of other fisheries have the potential to contribute adversely or beneficially to the U.S. consumers of groundfish products and the groundfish market channels. However, the wholesale groundfish product value in conjunction with products from other fisheries is not expected to change benefits to U.S. consumers. The long-term climate change and regime shift could adversely effect availability for market channels due to the natural fluctuations in groundfish stocks. Under FMP 4.2 a cumulative effect is identified for benefits to U.S. consumers of groundfish products, and the effect is judged to be significantly adverse. The suspension of production of groundfish products in fisheries occurring in the EEZ off Alaska could decrease product quality, supply, and production of pollock and Pacific cod fillets, offset the seafood trade balance as more groundfish products are imported, increase prices for groundfish products, and have an adverse effect on seafood consumers.

4.8.9.7 The Value of the Bering Sea and Gulf of Alaska Marine Ecosystems (including Non-Consumptive and Non-Use Benefits)

The predicted direct and indirect effects of the groundfish fishery under FMP 4.1 and FMP 4.2 are described below. Benefits derived from marine ecosystems and associated species are used as a surrogate to evaluate non-consumptive and non-use benefits. The past/present effects on non-consumptive and non-use benefits to U.S. general public are described in Section 3.9 (Table 3.9-127) and below. This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case. The representative indicator used in this analysis is benefits the public derives from marine ecosystems and associated species (including non-consumptive and non-use benefits) (Table 4.8-6).

Direct/Indirect Effects of FMP 4.1 and FMP 4.2

FMP 4.1 is predicted to significantly increase the level of benefits the Bering Sea and GOA marine ecosystems and associated species provide relative to the comparative baseline. These findings are based on the assessment of the direct and indirect effects of FMP 4.1 on the environment with respect to the ecosystem issues of predator-prey relationships, energy flow and balance, and diversity. This assessment of ecosystem effects is presented in Section 4.8.10 of the draft Programmatic SEIS.

As described in Section 3.9.7, the Bering Sea and GOA marine ecosystems and species associated with them provide a broad range of benefits to the American public. Some of the goods and services these ecosystems produce are not exchanged in normal market transactions but have value nonetheless. While there are difficulties in estimating the value the public places on protecting ecological conditions, Section 3.9.7 provides a qualitative discussion of possible benefits provided by the Bering Sea and GOA marine ecosystems. In addition to supporting commercial fisheries, these ecosystems support an array of recreational fishing and subsistence activities as well as non-consumptive activities such as wildlife viewing. Furthermore, some people may not directly interact with the Bering Sea and GOA marine ecosystems and the various species associated with them but derive satisfaction from knowing that the structure and function of these ecosystems are protected.

The focus in this analysis is on the direct and indirect effects of the alternatives on ecosystem benefits other than those that accrue to members of society who make a living harvesting, processing and distributing BSAI and GOA groundfish products or who purchase and consume these products. The direct and indirect effects of the alternatives on firms and communities that derive value from the commercial harvest and processing of groundfish are described elsewhere in the draft Programmatic SEIS. Similarly, the effects of the alternatives on consumers of groundfish products are discussed in a separate section of the draft Programmatic SEIS.

The value people assign to those marine ecosystem benefits that are unrelated to commercial groundfish fisheries are thought to be considerable. For example, the value of protecting the Steller sea lion alone may be substantial. As discussed in Section 3.9.7, a contingent valuation study suggests that there is a significant willingness to pay on the part of the American public for an expanded federal Steller sea lion recovery program. At this time, however, there is insufficient information to provide a comprehensive measure of the benefits derived from these ecosystems and the various species associated with them.

FMP 4.1 assumes that the current groundfish fisheries are producing large-scale adverse effects on the Bering Sea and GOA marine ecosystems. A primary purpose of this FMP bookend is to provide increased protection for habitat and the overall ecosystem. To mitigate the possibility of detrimental biological and environmental impacts from fishing, for example, this bookend would designate 20-50 percent of the management area as no-take marine reserves covering the full range of marine habitats within the 1,000-m bathymetric line (Figure 4.2-6). As part of this area in the Aleutian Islands, a Special Management Area would be established to protect coral and other live bottom habitats. This area would also include spawning reserve areas for intensively fished species. Comprehensive trawl exclusion zones would be set aside to protect all Steller sea lion critical habitat, and trawling itself would be restricted to only those fisheries that cannot be prosecuted with other gear types.

As discussed in Section 4.8.10, the measures implemented under FMP 4.1 are expected to have significantly or conditionally significant beneficial consequences for predator-prey relationships, energy flow and balance, and diversity. In turn, these beneficial effects on the Bering Sea and GOA marine ecosystems and associated species are expected to lead to a significant increase in the levels of some of the benefits these ecosystems and species provide.

FMP 4.2 is predicted to significantly increase the level of benefits the Bering Sea and GOA marine ecosystems and associated species provide relative to the comparative baseline. These findings are based on the assessment of the direct and indirect effects of FMP 4.2 on the environment with respect to the ecosystem issues of predator-prey relationships, energy flow and balance, and diversity. This assessment of ecosystem effects is presented in Section 4.8.10 of the draft Programmatic SEIS.

By suspending all fishing, FMP 4.2 would remove all risk that groundfish fisheries have an adverse effects on the Bering Sea and GOA marine ecosystems and species associated with them. A groundfish fishery may be reopened under this FMP bookend, but only if it can be shown to pose no significant threat of adverse environmental impacts or if adverse effects can be successfully mitigated through use of fishery-specific regulations. As discussed in Section 4.8.10, these measures are expected to have significantly or conditionally significant beneficial consequences for predator-prey relationships, energy flow and balance, and diversity. In turn, these beneficial effects on the Bering Sea and GOA marine ecosystems and associated species are expected to lead to a significant increase in the levels of some of the benefits these ecosystems and species provide.

Cumulative Effects of FMP 4.1 and FMP 4.2

For a summary of the direct/indirect and cumulative ratings, refer to Table 4.8-6.

<u>Benefits Derived from Marine Ecosystems and Associated Species</u>

- **Direct/Indirect Effects**. FMP 4.1 is predicted to have a significantly beneficial impact on the levels of benefits these ecosystems and associated species generate. Under FMP 4.2 fishing is suspended this is assumed to contribute to healthier ecosystems and significantly increase the benefits these ecosystems and species provide relative to the comparative baseline.

- **Persistent Past Effects**. Persistent past effects on non-consumptive and non-use benefits) include: an increase in public awareness of marine ecosystems; increased participation in recreational fishing and eco-tourism activities; and public perceptions with regard to fisheries management. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Reasonably Foreseeable Future External Effects**. Reasonably foreseeable future effects include other fisheries, and long-term climate change and regime shifts. These factors do not vary among alternatives; for more detail refer to the analysis in FMP 1.

- **Cumulative Effects**. Under FMP 4.1, a cumulative effect is identified for benefits the public derives from marine ecosystems and associated species (including non-consumptive and non-use benefits), and the effect is judged to be conditionally significant beneficial. The external impacts of other fisheries have the potential to contribute adversely to benefits the public derives from marine ecosystems and associated species. FMP 4.1 management measures could have adverse effects on the introduction of non-native species. However, the bookend could have beneficial effects on the change in pelagic forage availability, spacial and temporal concentration of fishery impact on forage, removal of top predators (potential for seabird bycatch and subsistence harvests of marine mammals), energy removal and energy redirection, changes in species, functional, and structural habitat diversity for the ecosystem. The long-term climate change and regime shift could adversely effect ecosystems and associated species due to the natural fluctuations in groundfish stocks.

Under FMP 4.2, a cumulative effect is identified for benefits the public derives from marine ecosystems and associated species (including non-consumptive and non-use benefits), and the effect is judged to be conditionally significant beneficial. The external impacts of other fisheries have the potential to contribute adversely to benefits the public derives from marine ecosystems and associated species. The elimination of fishing under FMP 4.2 will provide increased protection for the habitat and overall ecosystem. FMP 4.2 could have beneficial effects on the change in pelagic forage availability, spacial and temporal concentration of fishery impact on forage, removal of top predators (potential for seabird bycatch and subsistence harvests of marine mammals), energy removal and energy redirection, changes in species, functional, and structural habitat diversity for the ecosystem. Future climatic conditions, in combination with fisheries-related pressures, could also affect species diversity.

4.8.10 Ecosystem Alternative 4 Analysis

Ecosystems are populations (consisting of single species) and communities (consisting of two or more species) of interacting organisms and their physical environment that form a functional unit with a characteristic trophic structure (food web) and material cycles (movement of mass and energy among the groups). The following analyses of potential direct/indirect and cumulative effects of Alternative 4 apply to the BSAI and GOA ecosystems. Where available information allows, each ecosystem is addressed separately. In most cases, however, information is insufficient to allow individual consideration, and the two ecosystems are treated as a single entity.

As explained in Section 4.5.10, the analyses include numerous indicators representing potential direct, indirect, and cumulative effects of the alternative and specific bookends where applicable. Significance thresholds for the effect categories are presented in Table 4.1-7.

Direct/Indirect Effects – FMP 4.1

The following discussions assess the potential direct/indirect effects of FMP 4.1 on the BSAI and GOA ecosystems.

<u>Change in Pelagic Forage Availability</u>

Pelagic forage availability is assessed by evaluating population trends in pelagic forage biomass for species with age-structured population models. These include walleye pollock in the GOA (Figure H.4-17 of Appendix H) and Bering Sea walleye pollock and Aleutian Islands Atka mackerel (Figure H.4-18 of Appendix H). Trends in bycatch of other forage species (herring, squid, and forage species group) in the groundfish fisheries are a measure of the potential impact on those groups in the BSAI and GOA (Figure H.4-19 and Figure H.4-20 of Appendix H). Table 4.5-81 summarizes the average values from 2003-2008 for these measures and the percent change in these values from the baseline. In FMP 4.1, pelagic forage biomass in the BSAI (Bering Sea walleye pollock + Aleutian Islands Atka mackerel) would increase slightly by about 2 percent. In the GOA, pelagic forage biomass (specifically, walleye pollock) would increase by 63 percent relative to the baseline. These increases would result from setting F75 percent for prey species in this FMP. Average biomass remains within the bounds of historically estimated biomass that occurred before a target fishery emerged. Bycatch of other forage species would decline by about 45 percent in the BSAI and 79 percent in the GOA. The extensive fishing closure areas in this alternative may change bycatch estimates. The absolute amount of pelagic forage bycatch in each region would be relatively small (900 mt and 60 mt, respectively). Estimates of forage biomass from food web models of the EBS indicate that this bycatch would be a small proportion of the total forage biomass (Aydin *et al*. 2002). However, the lack of population-level assessments for some of the species in the forage species group means that species-level effects are unknown.

On the basis of the above considerations, FMP 4.1 is determined to have an insignificant effect on the BSAI and GOA ecosystems with respect to pelagic forage availability to target species. The increases in target species forage in this alternative have the potential to provide beneficial benefits to marine mammals such as Steller sea lions, harbor seals, and northern fur seals. Therefore, FMP 4.1 is determined to have significantly beneficial (Steller sea lions) and conditionally significant beneficial (northern fur seals) effects on prey availability to marine mammals. Sections 4.8.1 through 4.8.8 discuss the effects of pelagic forage abundance on these groups.

Spatial and Temporal Concentration of Fishery Impact on Forage

The impact of the spatial/temporal concentration of fisheries on forage species is assessed qualitatively by looking at the potential for the alternatives to concentrate fishing on forage species (walleye pollock, Atka mackerel, herring, squid, and other groups) in regions used by predators that are tied to land, such as pinnipeds and breeding seabirds. Additionally, concentration levels high enough to lead to ESA listing or prevention of recovery in an ESA-listed species are also considered. FMP 4.1 has comprehensive trawl exclusion zones to protect all designated SSL critical habitat, continues the ban on forage fish, sets precautionary harvest levels for target species that are prey (pollock and Atka mackerel, in particular), and has finer spatial allocations of TAC. These controls on spatial/temporal allocations of catch are more stringent than those included in the baseline and are judged to have significantly beneficial effects on spatial/temporal forage availability to Steller sea lions and harbor seals. FMP 4.1 is also considered conditionally significant beneficial on the prey availability of northern fur seals. For seabirds, these measures would have an insignificant effect on the spatial/temporal concentration of the fishery on forage species.

Removal of Top Predators

Removal of top predators, either through directed fishing or bycatch, is assessed by evaluating the trophic level of the catch relative to trophic level of the groundfish biomass (Figures H.4-21 through H.4-24 of Appendix H), bycatch levels of sensitive top predator species such as birds and sharks (Figures H.4-25 and H.4-26), and a qualitative evaluation of the potential for catch levels to cause one or more top-level predator species to fall below biologically acceptable limits (minimum stock size threshold for groundfish, ESA listing or prevention of recovery for an ESA-listed species). Trophic level of the catch in both the BSAI and GOA is a very stable property, changing less than 3 percent on average from the baseline, and the trophic level of the groundfish species for which we have age-structured models and which dominate the catch changes less than 1 percent on average. Under FMP 4.1, top-predator bycatch amounts would decrease relative to the baseline by an average of about 13 percent in the BSAI and about 86 percent in the GOA. The absolute values of average catch for these species are estimated to be 585 mt and 180 mt in the respective regions under this FMP (Table 4.5-81). These are large decreases relative to the baseline and would be considered an improvement over existing conditions.

The baseline determination is that historical whaling has resulted in low present-day abundance of whale species in the North Pacific. FMP 4.1 would not further impair the recovery of whale species through direct takes. Although this FMP could increase the amount of longline fishing, which tends to have higher levels of seabird bycatch relative to other fisheries, it proposes to set protection measures for all seabird species and to develop fishing methods that reduce incidental take. Consequently, levels of seabird and pinniped bycatch under FMP 4.1 would not lead to an ESA listing for any of those populations or prevent any of these species from recovery under the ESA. Sections 4.8.7 and 4.8.8 discuss the effects of groundfish fishery direct takes on specific seabird and marine mammal populations. The effect of shark bycatch on shark populations is unknown at present, and research directed at better assessing population levels of these sensitive (late maturing, low fecundity, low natural mortality) species is needed to better assess the potential for groundfish fisheries to affect these populations. By breaking sharks out of the other species group for TAC setting and setting the TAC level on the basis of the least abundant member of the group, FMP 4.1 may provide increased protection for sharks. Thus, it could have a significantly beneficial effect on this top predator group. Stability in trophic level of the catch is indicative of little effect of the fishery on target and PSC species top predators (Greenland turbot, arrowtooth flounder, sablefish, Pacific cod, and Pacific halibut). Overall, FMP 4.1 would have a significantly beneficial effect on top predators.

Introduction of Non-Native Species

The introduction of non-native species through ballast water exchange and hull-fouling organism release from fishing vessels could potentially disrupt the Alaskan marine food web structure (Fay 2002). There have been 24 species of non-indigenous species of plants and animals documented primarily in shallow-water marine and estuarine ecosystems of Alaska, with 15 species recorded in PWS. It is possible that most of these introductions were from tankers or other large commercial vessels that have large amounts of ballast exchange. However, exchange via fishery vessels that take on ballast from areas where invasive species have already been established and then transit through Alaskan inshore waters has been identified as a threat in a recently developed State of Alaska Aquatic Nuisance Species Management Plan (Fay 2002). Consequently, this effect is evaluated as conditionally significant adverse in the baseline.

Total groundfish catch levels are used as indicators for potential changes in the amount of these releases via groundfish fishery vessels (Figures H.4-27 and H.4-28 of Appendix H). Total catch would decrease by about 64 percent in the BSAI and 63 percent in the GOA under FMP 4.1, relative to the baseline. Therefore, FMP 4.1 would substantially reduce the potential for fishing vessel introduction of non-native species through ballast water exchange or release of hull-fouling organisms. However, there is insufficient information regarding fishing effort levels that would result in a successful introduction and this potential effect is evaluated as conditionally significant beneficial with respect to predator-prey relationships.

Energy Flow and Balance

As discussed in Section 3.10, fishing may alter the amount and flow of energy in an ecosystem by removing energy and altering energetic pathways through the return of discards and fish processing offal back into the sea. The recipients, locations, and forms of this returned biomass may differ from those in an unfished system. Baseline energy removals, in the form of total catch, were less than one percent of the total system energy determined by mass-balance modeling of the system and were determined to have an insignificant effect on the ecosystem. FMP 4.1 catch removals (Table 4.5-81), which decrease by about 64 percent and

63 percent from the baseline in the BSAI and GOA, respectively, show the potential for large improvements relative to the baseline with respect to producing changes in system biomass, respiration, production, or energy cycling outside the range of natural variability (Table 4.1-7). Because of existing uncertainty regarding these potential effects, FMP 4.1 is rated conditionally significant beneficial with respect to energy removal.

Energy re-direction, in the form of discards, fishery offal production, or unobserved gear-related mortality, can potentially change the natural pathways of energy flow in the system. Animals damaged when passing through the meshes of trawls may later die and be consumed by scavengers. Bottom trawls can expose benthic organisms and make them more vulnerable to predation. Discards and offal production can cause local enrichment and changes in species composition or water quality if discards or offal returns are concentrated there. These effects were determined to be insignificant at the ecosystem level in the baseline. Estimates of total discards (Figures H.4-29 and H.4-30 of Appendix H) under FMP 4.1 show a 46 percent decrease in the BSAI and a 64 percent decrease in the GOA relative to the baseline. Because these amounts of change would be large improvements over baseline conditions, they would create the potential for a conditionally significant beneficial effect on ecosystem-level energy cycling characteristics. The conditional rating, however, reflects uncertainty regarding the degree to which fishery-related discards, offal release, and gear-related mortality actually affect energy re-direction at the ecosystem level.

Change in Species Diversity

Fishing can alter different measures of diversity. Species-level diversity, or the number of species, can be altered if fishing essentially removes a species from the system. Fishing can alter functional diversity from a trophic standpoint if it selectively removes or depletes a trophic guild member and thus changes the way biomass is distributed within a trophic guild. Functional diversity can be altered if fishing methods, such as bottom trawling, remove or deplete organisms such as corals, sea anemones, or sponges that provide structural habitat for other species. Fishing can alter genetic diversity by selectively removing faster-growing fish or removing spawning aggregations that might have genetic characteristics that are different from other spawning aggregations. Larger, older fishes may be more heterozygous (i.e., have more genetic differences or diversity) and some stock structures may have a genetic component (see review in Jennings and Kaiser 1998). Consequently, one would expect a decline in genetic diversity to result from heavy exploitation of a fishery.

Significance thresholds for effects of fishing on species diversity have catch removals high enough to cause the biomass of one or more species (target or non-target) to fall below, or to be kept from recovering from levels already below minimum biologically acceptable limits (MSST for target species, ESA listing for non-target species) (Table 4.1-7). Bycatch amounts of sensitive (low population turnover rates) groups that lack population estimates (skates, sharks, grenadiers, and sessile invertebrates, such as corals, inhabiting Habitat Areas of Particular Concern, or HAPC) may also indicate potential for fishing impact on these species (Figures H.4-31 and H.4-32 of Appendix H). Closed areas also provide protection, particularly to less-mobile species like HAPC biota, so the amount of area closures across habitat types can indicate the degree of species-level diversity protection. Baseline determinations were made of insignificance for some species and unknown for skates and sharks.

Under FMP 4.1, bycatch of HAPC biota would decrease by about 44 percent in the BSAI and 60 percent in the GOA (Table 4.5-81). This FMP would also provide substantial increases in closed areas in the form of no-take reserves. These closures would produce even greater decreases in HAPC biota bycatches that are not modeled here and would likely be sufficient to prevent species extinction for these sessile animals. Catch amounts of target species, prohibited species, seabirds, and marine mammals would be insufficient to bring these species below minimum population thresholds. The practice of setting TAC for a group based on the least abundance species in the complex, and breaking species out of complexes when possible, would prevent skates, sharks, and grenadiers from reaching minimum population thresholds. Although forage species population levels are not known, their relatively high turnover rates, the ban on forage fish fisheries in this FMP, and the practice of breaking species out of a complex when possible, are considered sufficient to protect them from falling below minimum biologically acceptable limits. Therefore, this alternative is determined to be significantly beneficial since it provides substantial improvements to species diversity relative to the baseline. Sections 4.8.1 through 4.8.8 discuss more detailed analyses of the potential for fishery removals to affect minimum population thresholds for each of these groups and thus ultimately to affect species diversity.

Change in Functional Diversity

Functional (either trophic or structural habitat) diversity can be altered through fishing if fishing selectively removes one member of a functional guild, which may result in increases in other guild members. Indicators of the possible magnitude of effects include qualitative evaluation of guild or size diversity changes relative to fishery removals, bottom gear effort changes that would provide a measure of benthic guild disturbance, and bycatch amounts of HAPC biota, a structural habitat guild. Members of the HAPC biota guild serve important functional roles in providing fish and invertebrates with structural habitat and refuge from predation. The long-lived nature of corals, in particular, makes them susceptible to permanent eradication in fished areas. Some of the area closures in FMP 4.1 have been designed with corals in mind and would ensure that there is a broad spatial distribution of corals in the Aleutian Islands, in particular. Therefore, FMP 4.1 is determined to have potential for significant improvements relative to the baseline condition for structural habitat diversity. Thus, FMP 4.1 may provide significantly beneficial improvements relative to the baseline with respect to both trophic and structural habitat diversity.

Change in Genetic Diversity

Genetic diversity can be affected by fishing through heavy exploitation of certain spawning aggregations or systematic targeting of older age classes that tend to have greater genetic diversity. Under FMP 4.1, no target species would fall below MSST, there would be finer areas for spatial management of TAC, and spawning area reserves would be established to protect exploited species that are fished intensively at spawning time. Consequently, the groundfish fisheries would have an insignificant effect on genetic diversity as managed under FMP 4.1. However, baseline genetic diversity remains unknown for most species and the actual direct/indirect effects of fishing on genetic diversity are also largely unknown.

Cumulative Effects Analysis – FMP 4.1

The following sections discuss the potential cumulative effects on the ecosystem of FMP 4.1, acting additively or interactively with the effects of external human actions and natural processes persisting from the past, ongoing in the present, and predicted for the reasonably foreseeable future. These potential cumulative effects are summarized in Table 4.8-7. Data and calculations supporting the cumulative energy removal analyses for all of the alternatives are presented in Table 4.5-81.

Change in Pelagic Forage Availability

- **Direct/Indirect Effects.** The effects of FMP 4.1 are expected to be significantly beneficial for prey species utilized by the Steller sea lion, and conditionally significant beneficial for northern fur seal forage availability. FMP 4.1 would have an insignificant effect on BSAI and GOA groundfish target species with respect to pelagic forage availability.

- **Persistent Past Effects.** Past effects of forage fish bycatch by the BSAI pollock and GOA rockfish domestic fisheries, and targeted domestic catches of pollock and Atka mackerel, are likely to have affected forage fish populations in ways that may persist into the present and future (Section 3.10.1.4). From about 1925 to 1941, Alaska herring harvests for oil and meal ranged from about 50,000 to 150,000 mt per year, and a large foreign herring fishery removed from about 30,000 to 150,000 mt per year during the 1960s and 1970s (ADF&G 2003a). Past climatic changes, including inter-decadal oscillations and ENSO events, have been shown to affect forage fish populations (Section 3.10.1.5), and these effects may persist.

- **Reasonably Foreseeable Future External Effects.** The State of Alaska manages herring fisheries on a sustainable basis and has established a maximum exploitation rate (fraction of the spawning population removed by the fishery) of 20 percent. Fisheries are closed if stock size falls below MSST. Lower exploitation rates are applied when herring stocks decline to near-threshold levels (ADF&G 2003a). This management approach is expected to continue for the indefinite future. Subsistence harvests will continue to remove an increment of pelagic forage biomass each year. Relative to the BSAI and GOA groundfish fisheries, however, the additional contribution of subsistence fisheries to the annual removal of pelagic forage biomass is likely to be very small. The EVOS suggests that a large oil or fuel spill that coincides in space and time with herring or capelin spawning would most likely produce population declines, and other pelagic forage species (such as eulachon, which spawn on beaches) might also be adversely affected. Finally, future climate changes, especially a regime shift, would likely affect the productivity, and thereby the population sizes, of pelagic forage species (Section 3.10.1.5).

- **Cumulative Effects.** Based on the direct/indirect effects conclusions for FMP 4.1, the groundfish fisheries would contribute a beneficial increment to any broader cumulative effect. A potentially adverse contribution by one or more external factors, including State of Alaska directed fishery removals and subsistence harvests of forage fishes such as herring, capelin, or eulachon, could offset the beneficial contribution of the groundfish fisheries by some increment of forage fish removal. In addition, a large marine oil or fuel spill would have the potential to deplete forage fish populations to a significant extent. Therefore, the potential cumulative effect associated with FMP 4.1 is considered to be conditionally significant beneficial because the beneficial contribution of this FMP could be offset by external factors under the conditions described.

Spatial/Temporal Concentration of Fishery Impact on Forage

- **Direct/Indirect Effects.** The effects of implementing FMP 4.1 are expected to be significantly beneficial for prey species utilized by the Steller sea lion, and conditionally significant beneficial for northern fur seal forage availability. FMP 4.1 would have an insignificant effect on seabirds with respect to pelagic forage availability.

- **Persistent Past Effects.** Geographic and seasonal concentrations of past forage fish bycatch from the BSAI pollock and GOA rockfish fisheries, herring bycatch, and targeted catches of pollock and Atka mackerel have affected forage fish populations in ways that may have persisted into the present and future (Section 3.10.1.4). Past herring fisheries have followed a stable pattern of timing and location dictated by the spawning behavior of the fish (ADF&G 2003a). Past climatic changes, including inter-decadal oscillations and ENSO events, have shown effects on recruitment rates and distribution patterns of forage fish populations (Section 3.10.1.5). Such effects may be exerting a persistent effect on forage fish populations, although evidence is not sufficient to allow quantification.

- **Reasonably Foreseeable Future External Effects.** The State of Alaska directed herring fishery will exert fishing pressures on herring and other forage fish populations at particular times and places that could overlap with fishing pressures from the groundfish fisheries. Because the herring fishery is mainly inshore, overlapping with the groundfish fishery is more likely temporal than spatial. Subsistence harvest patterns are not coordinated with commercial fishing effort and will sometimes overlap with spatial/temporal patterns of the groundfish fishery, but the incremental contribution of subsistence to this cumulative effect will continue to be negligible. The EVOS of 1989 suggests that a large oil or fuel spill that coincides in space and time with herring or capelin spawning would most likely produce population declines and adversely impact other pelagic forage species (such as eulachon, which spawn on beaches). Finally, future climate change, especially a regime shift, could alter the spatial/temporal distributions of pelagic forage species in ways that are synergistic with spatial/temporal concentrations of fishing effort in the BSAI and GOA groundfish fisheries.

- **Cumulative Effects.** The potential effects of the spatial/temporal concentration of fisheries on forage species availability as modeled under FMP 4.1 are rated as significantly beneficial for Steller sea lion prey species, conditionally significant beneficial for northern fur seal prey species, and insignificant for seabird forage availability. A potentially adverse contribution by one or more external factors could offset this beneficial contribution by some increment of forage fish removal in the future. For example, if the fishing efforts of State of Alaska directed fisheries, principally for herring, and subsistence fish harvests converge in space and time with a fuel or oil spill, forage fish populations could be depressed sufficiently to impair the long-term viability of ecologically important top predators such as seabirds and marine mammals (Table 4.1-7). Future climate change, consistent with effects observed in the recent past (Section 3.10.1.5), could alter the spatial/temporal distributions of pelagic forage species and offset the beneficial contribution of groundfish fishery management. The potential cumulative effect associated with FMP 4.1 is considered conditionally significant beneficial because the beneficial contribution of these FMPs could be offset by external factors under the conditions described.

Removal of Top Predators

- **Direct/Indirect Effects.** FMP 4.1 would have a significantly beneficial effect on top predators. Under FMP 4.1, the predicted decreases in catch are large relative to the baseline and would be an improvement over existing conditions. Protection measures would be put in place for all seabird species, and fishing methods developed to reduce incidental take. Therefore, levels of seabird and pinniped bycatch in the groundfish fisheries under FMP 4.1 would not lead to an ESA listing for any of those populations or prevent any of these species from recovery under the ESA.

  FMP 4.1 would have a conditionally significant adverse effect on seabirds; an insignificant effect on whales, pinnipeds, top-predator target, and PSC species; and an unknown effect on sharks. The greatest concern regarding the effects of FMP 4.1 on top predators is the increased potential for bycatch of seabirds. Increased fishing effort and the maintenance of former, rather than improved seabird protection measures, under FMP 4.1 are considered conditionally significant adverse measures for ESA-listed seabirds such as short-tailed albatross. Also, removal of area closures around the Pribilof Islands may lead to disproportionate take of fulmars from that colony. The conditionally significant rating reflects uncertainty of future bycatch levels and existing population-level effects of bycatch removals on seabird species (Section 3.7).

- **Persistent Past Effects**. Before passage of the MSA in 1976, groundfish fisheries in the BSAI and GOA produced much higher than present bycatch levels of sharks, seabirds, and marine mammals. Historical whaling, resulting in high mortality levels in the 1960s (Section 3.10.1.3), produced a sustained effect on these slowly reproducing populations that is reflected in the low present-day abundance of whale species in the North Pacific. State of Alaska directed groundfish fisheries, which are small and sustainably regulated, have annually removed top predators such as sablefish and Pacific cod at levels safely above MSST (ADF&G 2003b). These fisheries also produced shark, seabird, and marine mammal bycatch in the past, although quantitative data are lacking on past and current bycatch levels in these fisheries. Past and present groundfish fisheries operating outside of U.S. jurisdiction in the western Bering Sea have also contributed to the bycatch of top predators, in some cases at high levels (Sections 3.7.1 and 3.10.1). Marine mammals continue to be removed for subsistence, although at much lower levels than in the past, and past harvests may have had a sustained effect on some populations that persist today. Finally, there is evidence that past climatic variability may have affected the recruitment and distribution of some top predator fish species (Section 3.10.1.5; Hollowed *et al.* 1998).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fishery will continue to remove a sustainable portion of the Pacific halibut population, a top predator. The current management plan is likely to continue in the reasonably foreseeable future, although a modified approach has been proposed to produce a yield similar to the present policy while reducing variations in annual yield due to changes in stock abundance, assessment methods, and estimated removals by other fisheries (Clark and Hare 2003). High levels of seabird bycatch and resulting direct mortality are expected to continue annually from North Pacific Ocean longline fisheries operating outside of the EEZ. Available data and estimates for the annual incidental take of individual bird species by these external fisheries are provided and discussed in Sections 3.7.1-19. The State of Alaska directed groundfish fisheries, operating in state waters of the eastern GOA and southeast Alaska, Cook Inlet, PWS, Kodiak, and the Alaska Peninsula, and in all state waters for lingcod, sablefish, and Pacific cod, will continue to remove targeted top predatory fish species in small numbers relative to the domestic groundfish fisheries in federal waters (ADF&G 2003b). Subsistence harvests of marine mammals will continue in the future with an increasing trend toward co-management by NOAA Fisheries and Alaska Native organizations. The Protected Resources Division of NOAA Fisheries will continue to develop management and conservation programs to ensure that annual subsistence harvests are sustainable (NOAA Fisheries 2003). A large fuel or oil spill at sea would result in direct mortality of marine mammals, with mortality levels depending on the location, size, and timing of the spill. Finally, a future climatic regime shift could alter total numbers of top predators in the BSAI and GOA ecosystems by increasing or limiting recruitment.

- **Cumulative Effects.** Based on the potential effects of FMP 4.1 on top predator populations, the groundfish fisheries could contribute a beneficial increment to any broader cumulative effect on top predators. A potentially adverse contribution by one or more external factors, particularly a continuation of high levels of seabird bycatch by North Pacific Ocean longline fisheries operating outside the EEZ, would incrementally offset the beneficial contribution of FMP 4.1. Because these external fisheries are generally not managed in conjunction with the BSAI and GOA domestic groundfish fisheries, there is a likelihood that the present high levels of seabird bycatch outside the EEZ will continue in the future. The conditions under which the beneficial contribution could be offset are the continuation of high external seabird bycatch rates in conjunction with a large fuel or oil spill, along with incremental removals of top predators by the IPHC longline fishery, State of Alaska directed groundfish fisheries, and subsistence harvests of marine mammals. As determined from recent climatic studies (Section 3.3), a climatic regime shift is probable in the future and could influence the potential cumulative effect by affecting biological recruitment. For these reasons, the effects of FMP 4.1 are determined to be conditionally significant beneficial.

Introduction of Non-Native Species

- **Direct/Indirect Effects.** FMP 4.1 may reduce the potential for adverse effects on predator-prey relationships through the introduction of non-native species through limiting fishing vessels in Alaskan waters annually. This potential effect is considered conditionally significant beneficial due to lack of information regarding fishing effort levels and the probability that an introduced exotic species will establish a viable population.

- **Persistent Past Effects.** For decades, the annual arrival of groundfish fishing vessels from ports outside of Alaska has made it possible for non-native species to enter Alaskan waters through the release of ballast water and hull-fouling organisms. Commercial shipping has provided a similar means for the introduction of non-native species (Fay 2002). There have been 24 non-indigenous species of plants and animals documented in Alaskan waters, with 15 of these recorded in PWS, where most of the research has been conducted. Although oil tankers, through the release of ballast water, have been speculated to be the primary source for these introductions, cruise ships and fishing vessels coming from areas where invasive species have already been established have also been identified as a threat in the State of Alaska Aquatic Nuisance Species Management Plan (Fay 2002). From 1991 to 2001, 396,522 accidental escapes of Atlantic salmon were reported from British Columbia fish farms (ADF&G 2002a). Concerns have been expressed regarding the potential effects of introduced Atlantic salmon on native Pacific salmon populations, including diseases and parasites, colonization, interbreeding and hybridization, predation, habitat destruction, and competition, particularly in locations where depressed stocks of Pacific salmon species provide a potential niche for the Atlantic species (Brodeur and Busby 1998, ADF&G 2002a). In the past, Alaska's northern climate, geographic isolation, and small human population, among other factors, may have prevented the establishment of viable populations by non-native species introduced from more temperate regions (Fay 2002).

- **Reasonably Foreseeable Future External Effects.** IPHC longline fishery vessels, international longline and groundfish fleets operating outside the EEZ, and vessels participating in State of Alaska directed fisheries will continue to be potential sources of exotic introductions in the reasonably foreseeable future. In addition, commercial shipping, including cruise ships, barges and tankers with high-volume ballast water releases, will continue to bring non-native species into Alaskan waters on a recurring basis, maintaining a continuing pressure on indigenous populations (Fay 2002). Escapes and releases of farmed Atlantic salmon from Washington State and British Columbia net-pens might eventually establish runs in GOA coastal streams and rivers. Introduced pathogens and parasites associated with farmed Atlantic or Pacific salmon could infect wild stocks. A future regime shift or long-term warming trend could remove the protection that colder conditions may currently provide against exotic species, allowing viable non-native populations to become established.

- **Cumulative Effects.** The potential effect of FMP 4.1 on the introduction of non-native species is rated conditionally significant beneficial. However, when sources of exotic species external to the domestic groundfish industry are considered in combination with FMP 4.1, it is conceivable that viable populations could eventually become established in the BSAI and/or GOA (Table 4.1-7). If these external factors remain similar to baseline conditions in the future, the cumulative outcome would be beneficially influenced under FMP 4.1. One possible, but unproven, condition for this outcome would be a future climatic regime shift or long-term warming trend that might allow exotic species currently limited by low seawater temperatures to establish viable populations in the BSAI and/or GOA. In considering these conditions, the potential cumulative effects of FMP 4.1 are rated conditionally significant beneficial for the introduction of non-native species.

Energy Removal

- **Direct/Indirect Effects.** The effects of FMP 4.1 on energy removal would be conditionally significant beneficial. Total catch under FMP 4.1 and FMP 4.2 decreases by about 64 and 63 percent from the baseline in the BSAI and GOA, respectively (Table 4.5-81). These are large improvements relative to the baseline in producing changes in system biomass, respiration, production, or energy cycling outside the range of natural variability (Table 4.1-7).

- **Persistent Past Effects.** The domestic groundfish fisheries, State of Alaska commercial fisheries, IPHC longline fisheries, commercial harvests of marine mammals, and subsistence harvests have all removed biomass from the BSAI and GOA ecosystems, either as targeted species or as bycatch, and these removals, in a regulated and mitigated form, continue today (Section 3.10). Aggregate biomass levels removed by unregulated past human activities would have been influenced by climatic effects on overall system productivity, with biomass removals increasing as productivity increased and decreasing with climate-related productivity declines**.**

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fisheries, State of Alaska commercial fisheries, subsistence fish harvests, and subsistence marine mammal harvests will continue to remove biomass from the BSAI and GOA ecosystems in the future. The incremental contribution of the combined State of Alaska herring and crab and IPHC halibut fisheries is estimated at about 4 percent of the cumulative biomass that would be removed annually under this FMP (Table 4.5-81). The State of Alaska directed groundfish and subsistence fisheries will remove an additional small increment annually (ADF&G 2003b, 2001). It should be noted that Russian and other fisheries operating in the western Bering Sea and in international waters of the central Bering Sea (doughnut hole) will also remove biomass in the future, but these regions show sufficient differences from the EBS with respect to production regimes and topographic and hydrographic features that are viewed as only partly comparable systems, and their interactive components with the EBS, where present, have not yet been characterized (Aydin *et al.* 2002).

- **Cumulative Effects.** The implementation of FMP 4.1 is predicted to have a conditionally significant beneficial cumulative effect on energy removal. If the annual total catches of the State of Alaska herring and crab and IPHC halibut fisheries in the future are similar to the 1997-2001 averages, the combined total catch of these external fisheries will represent a 17.3 percent addition to the estimated total catch for the groundfish fisheries alone under this FMP (Table 4.5-81). Thus, under FMP 4.1, the groundfish fisheries would remove a much smaller portion of the cumulative total energy (as biomass) than under Alternatives 1, 2, or 3, where the relative contributions of the external fisheries would be smaller. Whether this improvement in biomass removal would actually produce a measurable increase in energy within the BSAI and GOA ecosystems, and how that increase would be biologically manifested, cannot be predicted.

Energy Redirection

- **Direct/Indirect Effects.** The effects of FMP 4.1 on energy redirection are evaluated as conditionally significant beneficial. Projections of total discard biomass modeled for FMP 4.1 show about a 46 percent decrease in the BSAI and a 64 percent decrease in the GOA from baseline conditions (Table 4.5-81). These are large changes from baseline conditions, and create the potential for a conditionally significant beneficial effect on ecosystem-level energy cycling characteristics (Table 4.1-7).

- **Persistent Past Effects.** Ecosystem energetics is a dynamic process and it is difficult to know whether past changes in energy cycling and pathways of energy flow in the BSAI and GOA produced effects that still persist. The most far-reaching changes in quantities and geographic patterns of bycatch discards and offal production from both fish and marine mammal harvests came with international agreements, legislation, and regulatory actions in the 1950s through the 1970s, culminating in passage of the MSA in 1976 (Section 3.10.1.3). These corrective actions greatly curtailed the destabilizing levels of energy redirection that reached their peak in the mid-twentieth century from commercial whaling, fur seal harvests, high-seas driftnet fisheries, and the international commercial groundfish and salmon fisheries that existed. It seems likely, therefore, that under current management practices, quantities and patterns of energy redirection in the BSAI and GOA are much more limited than 50 years ago.

- **Reasonably Foreseeable Future External Effects.** Quantities and geographic patterns of bycatch discards and fish processing wastes released into the sea from the IPHC and State of Alaska commercial fisheries and subsistence harvests are not expected to change substantially in the future. External energy will also enter the system as graywater and refuse released into the sea from commercial freighters, tankers, and cruise ships. Finally, future climatic trends have the potential to affect energy cycling in the ecosystem; in particular, a warming trend would be expected to accelerate rates of energy conversion, whereas cooler conditions would tend to have a retarding effect.

- **Cumulative Effects.** The implementation of FMP 4.1 is predicted to have a conditionally significant beneficial cumulative effect on the ecosystem through energy redirection. The BSAI and GOA groundfish fisheries would remove and return much smaller quantities of energy (as biomass) relative to external sources such as the IPHC halibut fishery, State of Alaska commercial fisheries, annual subsistence harvests of fish and marine mammals. At the local level, water quality degradation will still result from the release of fish processing offal into low-energy environments, such as coves and bays, where nutrients from these wastes can concentrate in sheltered waters and alter local patterns of energy cycling. However, it is expected that the lower quantities of fish processing waste released under FMP 4.1would moderate this effect.

Change in Species Diversity

- **Direct/Indirect Effects.** Potential effects of FMP 4.1 on species diversity are rated as significantly beneficial for all groups. Targeted catch reductions and greater discrimination in TAC setting, substantial bycatch reductions, increases in closed areas in the form of no-take reserves, the ban on forage fish fisheries, and other protective measures under this FMP would all be significant influences in keeping most species above minimum biologically acceptable limits (Table 4.1-7).

- **Persistent Past Effects**. Although the pre-MSA international groundfish fisheries, the domestic groundfish fisheries after passage of the MSA in 1976, and the IPHC, State of Alaska, and subsistence fisheries have cumulatively removed large quantities of fish from the BSAI and GOA ecosystems in the past, the timing of various increases and decreases in species abundance of fish, seabirds, and marine mammals has not shown a consistent correlation with groundfish fishing intensity (Sections 3.10.1). With the notable exception of the Steller's sea cow extinction in the 1760s (Section 3.10.1.1), changes in species diversity have not characterized the BSAI and GOA ecosystems. Although no fishing-related species removals have been documented under fisheries management policies in effect during the past 30 years, elasmobranchs (sharks, skates, and rays) are particularly susceptible to removal, and benthic invertebrate (including HAPC) species are susceptible to bottom trawling (Section 3.10.3). Seabirds have been particularly vulnerable to bycatch mortality, leading to reduced populations of some bird species below minimum biologically acceptable limits. Lack of data on seabird population trends prevents analysis of past effects of fisheries management or environmental change on most seabird species (Section 3.7), but commercial fisheries have been implicated in some declines through bycatch potential. Livingston *et al*. (1999) found that long-term increases and decreases in the abundance of selected BSAI invertebrate, fish, bird, and marine mammal species did not show beneficial correlations with prey abundance, and that cyclic fluctuations in species abundance occurred in both fished and unfished species. As emphasized in Section 3.10.1.5, evidence is accumulating that physical oceanographic factors, particularly climate, have a controlling influence on biological community composition in the BSAI and GOA.

- **Reasonably Foreseeable Future External Effects.** Although past levels of seabird bycatch by the IPHC, western Bering Sea, and State of Alaska fisheries have not been thoroughly or consistently quantified, they are considered substantial and can be expected to continue in the future (Section 3.7). In addition, subsistence harvests of some marine mammal species (Section 3.8), particularly those with relatively small and geographically distinct subpopulations (e.g, belugas, harbor seals), may deplete numbers to levels near or below biologically acceptable limits in the future. The potential for introduced exotic species to establish viable populations in the BSAI and GOA will also continue. Such exotics may include Atlantic salmon escapes from net-pen farms, invertebrates and plants introduced through ballast water and from ship hulls, and pathogens introduced by Pacific salmon species that have escaped from fish farms (Fay 2002, ADF&G 2002a, Brodeur and Busby 1998). Future climate changes could alter the productivity and distribution of individual species and make it easier for introduced exotics to establish viable populations.

- **Cumulative Effects.** FMP 4.1 would produce a conditionally significant beneficial cumulative effect on species diversity, relative to the baseline, by reducing adverse contributions from the BSAI and GOA groundfish fisheries, particularly with respect to seabird bycatch. The beneficial incremental contribution of FMP 4.1, however, could be offset by any of several possible conditions in the future. Seabird bycatch from the IPHC longline fishery, western Bering Sea fisheries, and State of Alaska commercial fisheries could increase. Also, one or more introduced exotic species might establish a viable population that would change species diversity in a adverse way by competing with native species for food and habitat (Fay 2002). The consistent, sustained concentration of harvest effort on particularly accessible subpopulations of marine mammals from year to year could intensify the external adverse contribution. Finally, climate change has the potential to alter species productivity and distribution, and a long-term warming trend might facilitate the establishment of viable populations by one or more exotic species.

Change in Functional (Trophic) Diversity

- **Direct/Indirect Effects.** The effects of the groundfish fisheries on trophic diversity under FMP 4.1 are predicted to be significantly beneficial. This rating reflects the potential of the reduced fishing effort and increased protective measures under this FMP to sustain natural levels of species, size, age, and other measures of diversity within trophic guilds and to maintain functional diversity within the range of natural variability observed for the system (Table 4.1-7).

- **Persistent Past Effects**. It is considered unlikely that past removals of fish by the pre-MSA international groundfish fisheries, the domestic groundfish fisheries after passage of the MSA in 1976, and the IPHC, State of Alaska, and subsistence fisheries significantly affected the variety of species within trophic guilds. Livingston *et al*. (1999) found no evidence that groundfish fisheries had caused declines in trophic guild diversity for the groups studied. They also found that past changes in species diversity within guilds related to increases in a dominant guild member (e.g., pollock, rock sole) rather than to decreases in abundance caused by fishing pressure (Section 3.10.3). Past variations in climate, such as ENSO events, interdecadal oscillations, and regime shifts, may have affected trophic diversity by influencing the productivity and distribution of different species in different ways, thereby altering the relative proportions of species within guilds. However, little research on this type of effect was conducted in the BSAI and GOA in past decades.

- **Reasonably Foreseeable Future External Effects.** NOAA Fisheries and ADF&G biologists have recently brought attention to the potential for escaped farmed Atlantic salmon to establish viable Alaskan populations in competition with one or more of the five Pacific salmon species and steelhead (Brodeur and Busby 1998, ADF&G 2002a, Fay 2002). In addition, the concentrated take of marine mammals from the same local subpopulations over a period of years could affect species diversity within piscivore guilds, that is, guilds consisting of fish-eating species. Releases of ballast water and hull-fouling organisms introduced to BSAI and GOA waters from fishing vessels and commercial shipping could also lead to the establishment of viable populations in competition with native species at similar trophic levels (Fay 2002). A climatic regime shift in the future could affect trophic diversity by forcing trends that expand some trophic levels and contract others, and a long-term warming trend could facilitate the establishment of relatively cold-intolerant exotic populations.

- **Cumulative Effects.** The implementation of FMP 4.1 would produce a conditionally significant beneficial cumulative effect by reducing fishing pressures and increasing protective measures that would help to sustain diversity within trophic guilds. Incremental contributions from several external sources could offset the beneficial contribution of FMP 4.1. However, none of these potential external conditions is likely to be interactive or synergistic with the direct/indirect effects of FMP 4.1 because different trophic guilds may be affected and an offsetting effect on trophic diversity overall is possible in the future.

Change in Functional (Structural Habitat) Diversity

- **Direct/Indirect Effects.** The issue of concern with respect to functional diversity in terms of structural habitat is the removal, by bottom gear, of HAPC biota such as corals, sea anemones and other sessile invertebrates that provide physical structures used as habitat by other species, including economically important groundfish species and their prey. Present trawl closures to protect the Steller's sea lion are spread throughout the Aleutian chain, but these closures are further inshore than areas where corals can be found. Some of the area closures in FMP 4.1 have been designed with corals in mind and would ensure that there is a broad spatial distribution of corals, particularly in the Aleutians. Also, bottom trawl effort would likely decline in this FMP and area closures would provide additional protection to benthic communities. FMP 4.1 is rated as significantly beneficial to structural habitat diversity.

- **Persistent Past Effects.** Bottom-trawling by the pre-MSA international groundfish fisheries, groundfish fisheries after passage of the MSA in 1976, and State of Alaska scallop fisheries have all contributed to the damage or depletion of the structural habitat functional guild in past years. Because little is known about the taxonomic structure of benthic communities of the BSAI and GOA, any past effects of trawling and other fishing-related activities on the species diversity of these communities cannot be quantified. Long-term climatic trends may also have influenced HAPC species through effects on their productivity and distribution, but in the absence of data no conclusions can be made.

- **Reasonably Foreseeable Future External Effects.** The State of Alaska scallop fishery will employ bottom dredges that will continue to damage or remove structural habitat provided by sessile invertebrates such as corals, sea anemones, and sponges. This effect is not likely to be reduced in the future. In addition, a large oil or fuel spill from commercial shipping could contact areas covered by these sensitive bottom-dwelling organisms and damage or kill them. A climatic regime shift could change the mean annual seawater temperature sufficiently to increase or retard the growth of benthic organisms, thereby altering structural habitat diversity.

- **Cumulative Effects.** The implementation of FMP 4.1 would produce a conditionally significant beneficial cumulative effect on structural habitat diversity. The direct/indirect contribution of FMP 4.1 could be offset under at least three conditions. First, the contribution of the scallop fishery, which employs bottom dredges, could partially offset the reduction in bottom trawling by the groundfish fisheries, continuing to damage and remove HAPC biota. Second, a large petroleum spill could also damage these sensitive organisms. Third, a change in seawater temperature resulting from a climatic regime shift in the reasonably foreseeable future could reduce the productivity (and thus population size, growth, and ability to recover from damage) as well as distribution of sensitive bottom-dwelling invertebrates that provide ecologically important structural habitat.

<u>Change in Genetic Diversity</u>

- **Direct/Indirect Effects.** Under FMP 4.1 it is not expected that target species would fall below MSST, and spatial/temporal management of TAC, other catch, and selectivity patterns in the fisheries would be similar to present conditions. Fishing pressure would not focus on specific spawning aggregations or systematically target older age classes that tend to have greater genetic diversity. Therefore, effects of the groundfish fisheries on genetic diversity would be insignificant under FMP 4.1. However, baseline genetic diversity remains unknown for most species, and the actual effects of fishing on genetic diversity under this FMP are also largely unknown.

- **Persistent Past Effects.** The pre-MSA international groundfish fisheries, the domestic groundfish fisheries after passage of the MSA in 1976, and the IPHC, State of Alaska, and subsistence fisheries have cumulatively removed large quantities of fish from the BSAI and GOA ecosystems in the past, but data has not been available to indicate whether genetic diversity was measurably affected. As discussed in Section 3.10.3, if a fishery concentrates on certain spawning aggregations or on older (larger) age classes of a target species that tend to have greater genetic diversity (dating from an earlier period when fishing was less intensive), then genetic diversity will tend to decline in fished versus unfished systems. It is possible that genetic diversity has already declined in the BSAI and GOA ecosystems, but this cannot be known in the absence of data. Genetic assessments of North Pacific pollock populations and subpopulations conducted by Bailey *et al*. (1999) have found genetic variations among different stocks, but these studies have not found genetic variability across time within the same stocks that might indicate effects from commercial fishing. Heavy exploitation of certain spawning aggregations existed historically (e.g., Bogoslof pollock), but recent and current spatial/temporal management of groundfish has been designed to reduce fishing pressure on spawning aggregations.

- **Reasonably Foreseeable Future External Effects.** Several external factors have the potential to affect the genetic diversity of the BSAI and GOA ecosystems. Atlantic salmon escapes from coastal net-pen farms in Washington State and British Columbia could establish Alaskan runs and viable populations (ADF&G 2002a, Fay 2002). Subsistence harvests of fish could concentrate effort on the same specific subpopulations from year to year, inadvertently but selectively depleting genetically distinct stocks. Similarly, subsistence harvests of some marine mammal species (Section 3.8), particularly those with relatively small and geographically distinct subpopulations (e.g, belugas, harbor seals), may also deplete genetic diversity. The potential for introduced exotic invertebrates to establish viable populations in the BSAI and GOA will unavoidably continue with fishing vessel and commercial shipping traffic in the future. Such exotics may also include pathogens introduced by Pacific salmon that have escaped from fish farms (Fay 2002, ADF&G 2002a, Brodeur and Busby 1998). Future climate changes could alter the productivity and distribution of individual species and enable introduced exotics to establish viable populations.

- **Cumulative Effects.** The implementation of FMP 4.1 is predicted to have an insignificant cumulative effect on genetic diversity. Several external factors, such as Atlantic salmon escapes, subsistence harvests of marine mammals that concentrate on the same subpopulations year after year, exotic species introduced through commercial shipping traffic, and climatic facilitation of viable exotic populations, have the potential to produce changes in the genetic diversity of the BSAI and GOA ecosystems. None of these, however, would directly involve the genetic diversity of species targeted or taken incidentally by the groundfish fisheries. Thus, external sources for potential change in genetic diversity would not be additive or interactive with the groundfish fisheries in the future.

Direct/Indirect Effects FMP 4.2

The following discussions assess the potential direct/indirect effects of FMP 4.2 on the BSAI and GOA ecosystems.

FMP 4.2 would close the BSAI and GOA to all commercial fishing for groundfish and initiate a process whereby fisheries could be reopened after being certified as having no adverse effect on the environment. It is assumed that a substantial research program would be initiated to determine foraging needs of dependent species and life-history parameters, genetic characteristics, and abundance and distribution of species proposed for target fisheries. Fishery bycatch of non-target species and gear effects on habitat would also be evaluated before a fishery could be opened. Natural levels of ecosystem variability and the influence of climate on ecosystem production would also have to be determined. Therefore, we determine that FMP 4.2 would produce significantly or conditionally significant beneficial effects on many biological aspects of the marine ecosystem, relative to the baseline. Potential effects of this FMP would be beneficial with respect to pelagic forage availability to marine mammals such as Steller sea lions and northern fur seals. There would be no significant change with respect to forage availability to target species and birds. Significantly beneficial effects to spatial/temporal concentration of fisheries on forage would accrue to Steller sea lions and northern fur seals, but there would be no significant change in this regard for seabirds. FMP 4.2 would bring significantly or conditionally significant improvements to removal of top predator species, introduction of non-native species, energy removal and redirection, species diversity, and functional (trophic and structural habitat) diversity. FMP 4.2 would not significantly affect genetic diversity. However, baseline genetic diversity remains unknown for most species and the actual effects that fisheries would eventually have on genetic diversity under this FMP are largely unknown.

Cumulative Effects Analysis FMP 4.2

The potential cumulative effects resulting from implementation of FMP 4.2 are similar to those predicted for FMP 4.1. Ratings of potential direct/indirect effects predicted for FMP 4.1 would remain the same under FMP 4.2, along with the same contributions from persistent past effects and reasonably foreseeable future external effects. These contributing factors and potential cumulative effects are summarized for both FMP 4.1 and FMP 4.2 in Table 4.8-7.

4.8.11 Summary of Alternative 4 Analysis

The direct, indirect and cumulative ratings for all resource categories analyzed under this alternative are summarized in Tables 4.8-7.

Table number	Resource category	Components	Section 4.8 reference
4.8-1	Target groundfish species	Bering Sea and Aleutian Islands (BSAI) and Gulf of Alaska (GOA) walleye pollock, BSAI and GOA Pacific cod, BSAI and GOA sablefish, BSAI and GOA Atka mackerel, BSAI yellowfin sole, GOA shallow water flatfish, BSAI rock sole, BSAI and GOA flathead sole, BSAI and GOA arrowtooth flounder, BSAI Greenland turbot, GOA deepwater flatfish, BSAI Alaska plaice, BSAI other flatfish, GOA rex sole, BSAI and GOA Pacific ocean perch, GOA thornyhead rockfish, BSAI and GOA northern rockfish, BSAI and GOA shortraker/ rougheye rockfish, BSAI other rockfish, GOA slope rockfish, GOA pelagic shelf rockfish, GOA demersal shelf rockfish.	4.8.1
4.8-2	Prohibited, other, forage and non-specified species	Pacific halibut, Pacific salmon and steelhead trout, Pacific herring, crab. Other species category. Forage fish category. Grenadier.	4.8.2 4.8.3 4.8.4 4.8.5
4.8-3	Habitat	BSAI, GOA	4.8.6
4.8-4	Seabirds	Black-footed albatross, laysan albatross, short-tailed albatross, northern fulmar, shearwaters, storm-petrels, cormorants, spectacled eider, Steller's eider, jaegers, gulls, kittiwakes, terns, murres, guillemots, murrelets, auklets, puffins.	4.8.7

Table number	Resource category	Components	Section 4.8 reference
4.8-5	Marine mammals	Steller sea lion, northern fur seals, Pacific walrus, harbor seals, spotted seal, bearded seal, ringed seal, ribbon seal, northern elephant, sea otter, blue whale, fin whale, sei whale, minke whale, humpback whale, gray whale, northern right whale, bowhead whale, sperm whale, beaked whales (Baird's, Cuvier's and Stejneger's), Pacific white-sided dolphin, killer whale, beluga whale, harbor porpoise, Dall's porpoise.	4.8.8
4.8-6	Socioeconomics	Harvesting and processing sector (catcher vessels, catcher processors , inshore processors and motherships). Regional socioeconomic profiles (population, processing ownership and activity, catcher vessel ownership and activity, tax revenue, employment and income). Community development quota (CDQ) allocations. Subsistence (subsistence use of groundfish, subsistence use of Steller sea lions, salmon subsistence fisheries, indirect subsistence factors: income and joint production). Environmental justice. Market channels and benefits to United States consumers (product quantity, product year-round availability, product quality, product diversity). Non-market goods (benefits derived from marine ecosystems and associated species).	4.8.9.1 4.8.9.2 4.8.9.3 4.8.9.4 4.8.9.5 4.8.9.6 4.8.9.7
4.8-7	Ecosystem	Forage fish availability, spatial/temporal concentration of fisheries, introduction of non-native species, removal of top predators, energy redirection, energy removal, species diversity, guild diversity, genetic diversity.	4.8.10

4.9 Analysis of Preferred Alternative

The following discussions describe the analyses of expected direct, indirect, and cumulative effects of the Preferred Alternative (PA) on all of the resource categories. The potential effects of two policy "bookends" are analyzed, PA.1 and PA.2. These bookends represent the policy boundaries of the PA. As actually implemented, the PA could include policy measures anywhere within the range between the two bookends. The PA is described in detail in Section 2.6.9.

4.9.1 Target Groundfish Species

This section examines the potential direct, indirect, and cumulative effects that the implementation of the PA is expected to have on the target groundfish species. The impact analyses start with the baseline (2002) status of the BSAI and GOA target groundfish stocks described in Section 3.5.1, including past trends that are likely to persist into the foreseeable future. Then, a computer-based analytic model is used to project how specific characteristics of the target groundfish stocks would respond directly and indirectly to management actions under PA.1 and PA.2. These projections from the model are the predicted direct and indirect effects (impacts) of the FMP on the target groundfish stocks. Section 4.1.5 describes the analytic model and explains how it is applied.

The model output for each target groundfish stock is defined in terms of collected data and calculated measures that are standards used by fisheries managers to regulate the number of fish removed from the sea so that the fisheries will be sustainable over the long-term. These data and measures include the fishing mortality rate (F), the overfishing level (OFL), total and spawning biomass levels (B), the minimum stock size threshold (MSST), maximum sustainable yield (MSY), mean age of the stock in years, and the sex ratio of the stock (number of males compared to number of females). As discussed in the following subsections, relevant data are not always available for all stocks. When data gaps prevent application of the model to a specific stock, the projected direct or indirect effect is evaluated as unknown (U).

Each target groundfish stock is modeled with respect to the following direct and indirect effects:

Direct Effects

Fishing Mortality: This is the rate at which the stock is depleted by direct mortality imposed by removing the fish from the sea.

Change in Biomass Level: This is the change over time in the biomass of the stock, as measured in metric tons (mt). Two measures are used: total biomass, which is the estimated biomass of the entire stock, and spawning biomass, which is the estimated biomass of all of the spawning females in the stock.

Spatial/Temporal Concentration of Catch: This is the degree to which the fishery will concentrate in a particular geographic area during a particular period of time each season. This pattern in space and time can affect fishing mortality and can also influence habitat suitability for spawning, rearing, and feeding.

Direct and/or Indirect Effects

Habitat Suitability: This is the degree to which habitat has the right characteristics to support the target stock at one or more life-history stages (spawning, rearing of juveniles, availability of food at all stages, availability of refuge areas to allow escape from predators at all stages). Habitat suitability can be affected directly, for example by mechanical damage from bottom trawling, or influenced indirectly, for example by the gradual depletion of corals that provide hard substrate.

Prey Availability: This is the extent to which prey species are present in the environment and available as food to the target stock. Like habitat suitability, this measure can be affected directly, for example by the direct removal of prey species by the fishery, or indirectly, for example by a change in the structure of the food web.

To determine their probable significance, the projected direct and indirect effects in each of the impact categories listed above are evaluated against significance criteria. The criteria are designed to be relevant and meaningful in terms of the target groundfish stocks. Each significance criterion includes a threshold value above (or below) which the projected effect would be considered significant. Each criterion also includes a definition of what would constitute a beneficial (positive, +) or adverse (negative, -) effect. The possible evaluations are significant and beneficial (S+), Insignificant (I), significant and adverse (S-), and Unknown (U). Evaluations of Conditionally Significant (CS + or -) are not made for projected direct and indirect effects on target groundfish species, because the model can show only whether the significance threshold is or is not exceeded. The significance criteria used for the target groundfish stocks are presented in Appendix A, Table 4.1-1.

Each of the following subsections presents the model results and rationale for the expected direct and indirect effects of PA.1 and PA.2 on the target groundfish stocks. The significance ratings for these potential direct and indirect effects are presented in Appendix A, Table 4.9-1. Following the direct and indirect effects discussions on each stock, the expected cumulative effects on that stock are evaluated and discussed. The evaluation of potential cumulative effects builds on the direct and indirect effects evaluations as a starting point, and then brings in persistent past effects as well as reasonably foreseeable future natural events and human activities external to fisheries management. The cumulative effects assessment method uses the same impact categories and significance criteria discussed above for direct and indirect effects. This method is described further in Section 4.1.4.

4.9.1.1 Pollock

This section provides the direct, indirect and cumulative effects analysis for EBS and Aleutian Islands and GOA pollock for each of the bookends under the PA. Numerous fishery management actions have been implemented that affect the pollock fisheries in the EBS and GOA. These actions are described in more detail in Section 3.5.1.1 of this Programmatic SEIS. Pollock is managed as separate stocks in the BSAI and GOA, and falls under Tier 1 in both the BSAI and GOA groundfish FMPs.

Direct/Indirect Effects of PA.1

Total Biomass

Total biomass (ages 1 through 15+) of EBS pollock at the start of 2002 is estimated to be 12.97 million mt. Model projections of future total EBS pollock biomass are shown in Table H.4-42 of Appendix H. Under PA.1, model projections indicate that EBS pollock biomass is expected to decrease to a value of about 11.3 million mt in 2004, then stabilize to about 11.7 million mt. The 2003-2007 average total biomass is 11.5 million mt.

In the Aleutian Islands region, the assessments are based on trawl surveys that occur every other year. The most recent assessment indicates a biomass level of 175,000 mt. Assuming that under PA.1 there is no directed fishing for pollock in this region (the exploitation level is quite low, <1 percent or an average annual catch of 1,700 mt from 2003-2007), the expectation is that the stock will remain stable or increase in the future. A similar pattern is expected for the Bogoslof Island.

For GOA pollock, the age 2-10+ biomass is expected to increase under this PA.1 from a 2003 low of 799,000 mt to1,263,000 mt by 2007. The average biomass over this period is expected to be 1,052,000 mt. This increase is anticipated primarily because recruitment is expected to improve from the recent series of relatively low levels (Table H.4-64 of Appendix H).

Spawning Biomass

Female spawning biomass of EBS pollock in 2002 is estimated to be about 3.68 million mt. Model projections of future levels are shown in Table H.4-42 of Appendix H. Under PA.1, projections indicate that EBS pollock spawning biomass will decrease to about 83 percent of the 2002 level by 2007. The projected average for 2003-2007 is 3.07 million mt.

In the Aleutian Islands region, spawning biomass is monitored by biannual trawl surveys. In the Bogoslof Island region, spawning stock is monitored by echo-integration trawl surveys. Assuming that under PA.1 these regions continue to be managed as bycatch-only, it is expected that the spawning stock size will remain stable or increase in these regions. The 2002 GOA female spawning biomass is estimated at about 136,000 mt and is anticipated to increase steadily to 249,000 mt by 2007 under PA.1. This is above the estimated B_{MSY} level, with an annual average spawning biomass of 193,000 mt from 2003-2007. Model projections of future levels are shown in Table H.4-64 of Appendix H.

Fishing Mortality

The estimated fishing mortality for the EBS pollock stock in 2002 is 0.187. Model projections show this fishing mortality will increase to an average 0.230 for the period 2003-2007. These values are below the $F_{35\%}$ level of 0.448 and the $F_{40\%}$ level of 0.342, which are taken as proxies for F_{ABC} and F_{OFL}, respectively. This pattern in fishing mortality is due to the fact that the projected catch is expected to come closer to the actual ABC in future years (Table H.4-42 of Appendix H). Fishing mortality for the Bogoslof and Aleutian Islands region is expected to remain at less than one percent under PA.1 for as long as these areas are managed as bycatch only regions. Average catch in the Aleutian Islands regions from 2003-2007 is estimated at 1,700 mt (Table H.4-43 of Appendix H).

For the GOA, fishing mortality in 2002 is estimated at 0.174 with projections suggesting a decrease to 0.107 in 2003 followed by increases to 0.164 by 2007. The SPR rate in 2002 is estimated at 55 percent and averages about 63 percent for the period 2003-2007 (Table H.4-64 of Appendix H). Under PA.1, harvest control rules reduce the TAC and subsequently reduce the ABC values due to uncertainty in GOA pollock stock biomass information.

Spatial/Temporal Concentration of Fishing Mortality

The harvest of EBS pollock occurs largely along the western edge of the EBS shelf during the summer and around the southern areas east of 170°W during the winter season (Jan 20-March). Under FMP PA.1, an average of 1.41 million mt of EBS pollock is projected to be harvested annually from 2003-2007 with spatial and temporal allocations as presented in Section 3.5.1.1. The Bogoslof and Aleutian Island concentration of fishing mortality is anticipated to remain unchanged over this projection period for as long as pollock are managed as a bycatch-only fishery. EBS pollock fisheries may be limited somewhat by Pacific halibut PSC limits and bycatch hotspot areas. PSC limits for Pacific halibut are expected to decrease by 0 to 10 percent in the BSAI under PA.1. These measures may contribute to the spatial/temporal concentration of the fishery, although it is unlikely to be significant.

In the GOA pollock fishery, in a broad variety of locales and regional quotas are allocated by season as presented in Section 3.5.1.1. Under PA.1, an average of 69,300 mt of GOA pollock is projected to be harvested annually during 2003-2007 with the largest catch expected to be 108,300 mt in 2007. As the density and quotas of pollock change during this period, the concentration of the pollock fishery will likely change from the 2002 pattern. The effect of these changes is unknown. The GOA pollock fishery may be limited by Pacific halibut bycatch hotspot areas; however, the effects on the spatial and temporal characteristics of the stock due to this measure should not vary from the baseline.

Status Determination

Under PA.1, the ABC is set at a lower level than the OFL, creating a buffer between these two harvest regulations. Model projections of future catches of EBS pollock are below the ABC and OFL levels in all years. The EBS pollock are above their respective MSST in the year 2002 and in all subsequent projection years. Under PA.1, the BSAI target fish OY is specified between 1.4 and 2.0 million mt (same as FMP 1 and FMP 3.1). If the sum of the TAC is greater than 2.0 million mt, then the TAC will be adjusted down. This may reduce the EBS pollock TAC, and subsequently the ABC values in future years.

For PA.1, GOA pollock spawning biomass is below the B_{MSY} (taken as $B_{35\%}$) in 2002 and remains below this level until 2007. However, based on 10-year status determinations projections, the stock is above the MSST for all years 2003-2007. As mentioned above, harvest control rules implemented under PA.1 reduce the TAC, ABC and OFL values for GOA pollock due to uncertainty in biomass estimates.

Age and Size Composition

Under PA.1, the mean age of the EBS pollock stock at the end of 2007, as computed in model projections, is 2.52 years. This compares with a mean age in an equilibrium unfished stock of 3.16 years. For GOA pollock the 2007 value is 3.09 years compared with an unfished estimate of 3.60 years (note that the GOA pollock assessment is modeled from age 2-10+ while the EBS pollock is modeled from age 1-15+).

Sex Ratio

In the models, the sex ratio of GOA and BSAI pollock is assumed to be 50:50. However, observer data and information from surveys are routinely collected and used to monitor the sex ratios of these stocks. Based on these data, it is unlikely that the sex ratio will be affected under PA.1.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change under PA.1.

Current closure areas would remain under this preferred alternative bookend, including the eastern GOA trawl closure and the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. The Seguam Pass area would be closed to fishing, 3 nm no transit zones would be established around rookeries, and nearshore and critical habitat areas would be closed to trawl and fixed gear as Steller sea lion protection measures. All these measures may help reduce adverse impacts to important pollock habitat.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. An evaluation of potential trophic interactions is presented in Section 3.10. It seems unlikely that significant qualitative changes in predator-prey interactions would be a result of actions taken under PA.1 (for the period 2003-2007).

A direct fishery for forage fish would continue to be banned under PA.1, and the $B_{20\%}$ rule would remain since pollock is an important prey species for many members of the BSAI and GOA ecosystem.

See Table 4.9-1 for a summary of the direct/indirect effects on EBS, Aleutian Islands and GOA pollock.

Cumulative Effects of PA.1 – EBS and Aleutian Islands pollock

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the EBS and Aleutian Islands pollock stock is insignificant under PA.1 (see Section 4.9.1.1 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects of the foreign, JV, and domestic fisheries are not expected for the EBS pollock stock. While large removals of pollock did occur in the past, there does not appear to be a lingering effect on the EBS pollock populations (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** Removals of pollock occur in the Russian pollock fishery, and the catch is not accounted for in the annual harvest rates set for the US fishery. Therefore, the removals can be considered a potentially adverse effect on fishing mortality. Catch and bycatch of pollock in the State of Alaska pollock fisheries are not considered to be contributors to fishing mortality in the cumulative case. Removals in these fisheries are accounted for when setting annual harvest levels for pollock and do not add additional fishing mortality. Marine pollution is also identified as having a reasonably foreseeable potentially adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not considered contributors to pollock mortality.

- **Cumulative Effects.** Cumulative effects are identified for mortality of EBS and Aleutian Islands pollock, but the effects are judged to be insignificant. Pollock are fished at less than the OFL and are above the MSST. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

<u>Change in Biomass</u>

- **Direct/Indirect Effects.** Change in biomass of the EBS and Aleutian Islands pollock stock is expected to be insignificant under PA.1 (see direct/indirect effects discussion in this section).

- **Persistent Past Effects.** While past large removals of pollock and other past effects on biomass have been identified (see Section 3.5.1.1), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects.** Future external effects on biomass are indicated due to removals in the Russian and State of Alaska pollock fisheries. However, the effects of any future removals are not expected to affect the ability of the stock to maintain MSST. Marine pollution is identified as having a reasonably foreseeable potentially adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not considered contributors to pollock mortality, and therefore would not directly affect biomass.

- **Cumulative Effects.** Cumulative effects for change in biomass are identified under PA.1, however, the effects are insignificant since the combination of internal and external factors is not expected to sufficiently reduce the pollock biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

<u>Spatial/Temporal Concentration of Catch</u>
   – Change in Genetic Structure of Population
   – Change in Reproductive Success

- **Direct/Indirect Effects.** The spatial and temporal distribution of catch should have an insignificant effect on the genetic structure and reproductive success of the population (see Section 4.9.1.1 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure since the past large removals of pollock and other past effects (see Section 3.5.1.1) have not had a lingering effect on the ability of the stock to sustain itself above MSST. However, since past fisheries could have had a beneficial effect on pollock recruitment by reducing the adult pollock biomass, lingering beneficial effects are identified for change in reproductive success. In addition, past commercial whaling and sealing also removed large predators of pollock adding to the potential for reproductive success of the stock. Lingering past effects are also identified due to climate changes and regime shifts (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** The Russian and State of Alaska pollock fisheries have the potential to cause adverse effects. However, the removals are not expected to be sufficiently concentrated to alter the genetic structure of the population. On the other hand, removals in these fisheries, with the exception of the herring fishery, could have a potentially beneficial effect on pollock recruitment by reducing the adult pollock biomass. Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment.

- **Cumulative Effects.** Cumulative effects are possible under PA.1 for spatial and temporal concentration; however, the effects are insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** Any predation-mediated impacts of PA.1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see the direct/indirect effects above). However, it is determined that PA.1 would have an insignificant effect on pollock prey availability.

- **Persistent Past Effects.** While lingering population level effects from past foreign and domestic fisheries catch and bycatch of pollock prey species are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on pollock prey species (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects**. Future external effects of climate changes and regime shifts on pollock prey species could have potentially beneficial or potentially adverse effects. A strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Likewise, a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. Marine pollution has also been identified as a reasonably foreseeable external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The other fisheries shown on Table 4.5-1 are determined to be potentially adverse contributors since catch and bycatch of prey species are likely to continue.

- **Cumulative Effects.** Cumulative effects are identified for prey availability under PA.1; however, the effects are insignificant since the combination of internal and external removals of prey species is not expected to decrease prey availability such that the pollock stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1, as with prey-mediated impacts, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see direct/indirect effects discussion). However, it is determined that PA.1 would have insignificant effects on pollock habitat suitability.

- **Persistent Past Effects.** Past effects identified for EBS and Aleutian Islands pollock stock include past foreign, JV, and domestic fisheries, and climate changes and regime shifts (see Section 3.5.1.1). Intense bottom trawling for pollock in the past fisheries likely disrupted habitat in areas of the EBS and Aleutian Islands. It is possible that some of these areas have not recovered from the intense efforts (see Section 3.6).

- **Reasonably Foreseeable Future External Effects.** Future external effects are possible from the Russian and State of Alaska fisheries, since any of these may impact bottom habitat through use of fishing gear. Impacts on habitat from climate changes and regime shifts on the EBS and Aleutian Islands pollock stocks could be either beneficial or adverse since a strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Marine pollution has also been identified as a potentially adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** Cumulative effects are identified for habitat suitability; however, their significance on the EBS and Aleutian Islands pollock stocks is insignificant since the combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the pollock stock to sustain itself at or above MSST is jeopardized.

See Table 4.5-1 for a summary of the cumulative effects on EBS and Aleutian Islands pollock under PA.1.

GOA Pollock

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA pollock stock is insignificant under PA.1 (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects of the foreign, JV, domestic, State, and bait fisheries are not expected for the GOA pollock stock. While large removals of pollock did occur in the past, there does not appear to be a lingering effect on the GOA pollock populations (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** Catch and bycatch of pollock in the State of Alaska pollock fisheries, and State of Alaska shrimp fisheries are not considered to be contributors to fishing mortality in the cumulative case. Removals in these fisheries are accounted for when setting annual harvest levels for pollock and do not add additional fishing mortality. Marine pollution is identified as having a potentially adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not identified as being contributors to pollock mortality.

- **Cumulative Effects.** Cumulative effects are identified for mortality of GOA pollock, but the effects are judged to be insignificant for PA.1. Pollock are fished at less than the OFL and are above the MSST. The combined effect of internal removals and removals due to reasonably foreseeable external events is to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the GOA pollock stock is expected to be insignificant under PA.1 (see the direct/indirect effects discussion).

- **Persistent Past Effects.** While past large removals of pollock and other past effects on biomass have been identified (see Section 3.5.1.1), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects**. Future external effects on biomass are indicated due to removals in the State of Alaska pollock fisheries. However, any future removals are not expected to affect the ability of the stock to maintain MSST. Marine pollution is identified as having a potentially adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not considered contributors to pollock mortality, therefore would not directly affect biomass.

- **Cumulative Effects**. Cumulative effects for change in biomass are identified, and are considered insignificant. The combination of internal and external factors is not expected to sufficiently reduce the pollock biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch
– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** As the density and quotas of pollock change during the modeled period, the concentration of the pollock fishery will change from the 2002 pattern; it is not possible to predict exactly how the pattern will change. However, for GOA pollock under PA.1, the stock is expected to be above MSST for the years 2003-2007 (see the direct/indirect effects discussion). Therefore, impacts of the spatial and temporal changes should have an insignificant effect on the genetic structure and reproductive success of the population.

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure since the past large removals of pollock and other past effects (see Section 3.5.1.1) have not had a lingering effect on the ability of the stock to sustain itself above MSST. However, there are lingering past effects due to climate changes and regime shifts (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** State of Alaska pollock fisheries and the State of Alaska shrimp fishery are identified as potential adverse contributors. However, these fisheries are unlikely to be sufficiently concentrated to alter the genetic structure of the population. Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment.

- **Cumulative Effects.** Cumulative effects are possible for spatial/temporal concentration under PA.1, and are considered insignificant. The combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** Any predation-mediated impacts of PA.1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see the direct/indirect effects section above). However, it is determined that PA.1 would have insignificant effects on pollock prey availability.

- **Persistent Past Effects.** While lingering population level effects from past foreign, state, and domestic fisheries catch and bycatch of pollock prey species, and the effects of EVOS on these species, are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on pollock prey species (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** As described for EBS and Aleutian Islands pollock, climate changes and regime shifts could have potentially adverse or beneficial effects on pollock prey species. Marine pollution has been identified as a reasonably foreseeable external contributing factor. The other fisheries shown on Table 4.5-2 are determined to be potentially adverse contributors since bycatch and catch of forage species is likely to continue.

- **Cumulative Effects.** Cumulative effects are identified for prey availability and are considered insignificant. The combination of internal and external removals of prey is not expected to decrease prey availability such that the pollock stock is unable to sustain itself at or above MSST.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** Under PA.1, as with prey-mediated impacts, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see direct/indirect effects discussion). However, it is determined that PA.1 would have insignificant effects on pollock habitat suitability.

- **Persistent Past Effects.** Past effects on habitat suitability identified for GOA pollock stock include past foreign, JV, State, and domestic fisheries, EVOS, and climate changes and regime shifts (see Section 3.5.1.1). Intense bottom trawling for pollock in the past fisheries likely disrupted habitat in areas of the GOA. It is possible that some of these areas have not recovered from the intense efforts (see Section 3.6).

- **Reasonably Foreseeable Future External Effects.** Future external effects are possible from the State of Alaska pollock and shrimp fisheries, since any of these may impact bottom habitat through use of fishing gear. Impacts on habitat from climate changes and regime shifts on the GOA pollock stock would be either beneficial or adverse as described for EBS and Aleutian Islands pollock. Marine pollution has also been identified as a potentially adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** Cumulative effects are identified for habitat suitability under PA.1; however, the effects on the GOA pollock stock are insignificant since the combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the pollock stock to sustain itself at or above MSST is jeopardized.

See Table 4.5-2 for a summary of the cumulative effects on GOA pollock under PA.1.

Direct/Indirect Effects of PA.2

Total Biomass

Total biomass (ages 1 through 15+) of EBS pollock at the start of 2002 is estimated to be 12.97 million mt. Model projections of future total EBS pollock biomass are shown in Table H.4-42 of Appendix H. Under PA.2, model projections indicate that EBS pollock biomass is expected to decrease to a value of about 11.26 million mt in 2005, then stabilize to about 11.56 million mt. The 2003-2007 average total biomass is estimated at 11.44 million mt.

In the Aleutian Islands region, the assessments are based trawl surveys that occur every other year. The most recent assessment indicates a biomass level of 175,000 mt. Assuming that there is no directed fishing for pollock in this region (the exploitation level is quite low, <1 percent), the expectation is that the stock will remain stable or increase in the future. A similar pattern is expected for the Bogoslof Island.

For GOA pollock, the age 2-10+ biomass is expected to increase under PA.2 from a 2003 low of 799,000 mt to 1,275,000 mt by 2007. The average biomass over this period is expected to be 1,057,000 mt. This increase is anticipated primarily because recruitment is expected to improve from the recent series of relatively low levels (Table H.4-64 of Appendix H).

Spawning Biomass

Female spawning biomass of EBS pollock in 2002 is estimated to be about 3.68 million mt. Model projections of future levels are shown in Table H.4-42 of Appendix H. Under PA.2, projections indicate that EBS pollock spawning biomass will decrease to about 2.91 million mt by 2007. The projected average for 2003-2007 is 3.03 million mt.

In the Aleutian Islands region, spawning biomass is monitored by biannual trawl surveys. In the Bogoslof Island region, spawning stock is monitored by echo-integration trawl surveys. Under PA.2 these areas are expected to be managed at bycatch-only levels, thus, we expect the spawning stock size to remain stable or increase in these regions.

The 2002 GOA female spawning biomass is estimated at about 136,000 mt and is anticipated to increase steadily to 254,000 mt by 2007 under PA.2. This is above the estimated B_{MSY} level, with an average annual spawning biomass of 194,700 mt from 2003-2007. Model projections of future levels are shown in Table H.4-64 of Appendix H. Under PA.2, the methods and tools used to collect the biological information necessary to determine spawning stock biomass estimates would be improved. This would reduce uncertainty in stock estimates, and could subsequently induce changes in catch limits, especially for the GOA pollock stock.

Fishing Mortality

The estimated fishing mortality for the EBS pollock stock in 2002 is 0.187. Model projections show this fishing mortality will increase to an average 0.239 for the period 2003-2007. These values are below the $F_{35\%}$ level of 0.448 and the $F_{40\%}$ level of 0.342, which are taken as proxies for F_{ABC} and F_{OFL}, respectively. This pattern in fishing mortality is due to the fact that the projected catch is expected to come closer to the actual ABC in future years. The proportion of SPR conserved under these mortality rates is 50 percent in 2003, decreasing to 48 percent by 2007; the average implied SPR rate of fishing from 2003-2007 is 48 percent (Table H.4-42 of Appendix H). Under PA.2, pollock are maintained at bycatch-only status, thus the fishing mortality for the Bogoslof and Aleutian Islands region is expected to remain at less than 1 percent (Table H.4-43 of Appendix H).

For the GOA, fishing mortality in 2002 is estimated at 0.174 with projections suggesting a decrease to 0.101 in 2003 followed by increases to 0.142 by 2007. The values for $F_{35\%}$ and $F_{40\%}$ are 0.350 and 0.294, respectively. The SPR rate in 2002 is estimated at 55 percent and averages about 65 percent for the period 2003-2007. This fishing mortality rate pattern is due to the fact that under this bookend, the F_{ABC} is adjusted while the spawning stock is below $B_{40\%}$ (Table H.4-64 of Appendix H).

Spatial/Temporal Concentration of Fishing Mortality

The harvest of EBS pollock occurs largely along the western edge of the EBS shelf during the summer and around the southern areas east of 170°W during the winter season (Jan 20-March). Under PA.2, an average of 1.44 million mt of EBS pollock is projected to be harvested annually from 2003-2007 with spatial and temporal allocations as presented in Section 3.5.1.1. The Bogoslof and Aleutian Island concentration of fishing mortality is anticipated to remain unchanged over this projection period (with an annual average catch of 1,444 mt from 2003-2007). The EBS pollock pelagic trawl fishery may be limited by Pacific halibut PSC limits which are projected to be reduced by 0 to 20 percent in the BSAI under PA.2. Inseason bycatch closures will be reevaluated under this preferred alternative analysis, and has the potential to further restrict the pollock fishery from areas where Pacific halibut bycatch is high.

In the GOA pollock fishery, a broad variety of locales and regional quotas are allocated by season as presented in Section 3.5.1.1. Under PA.2, an average of 64,035 mt of GOA pollock is projected to be harvested annually during 2003-2007 with the largest catch expected to be 96,353 mt in 2007. As the density and quotas of pollock change during this period, the concentration of the pollock fishery will likely change from the 2002 pattern. The effect of these changes is unknown. The GOA pollock fishery may be limited by Pacific halibut PSC limits which are projected to be reduced by 0-10 percent in the GOA under PA.2. Inseason bycatch closures will be developed in the GOA under this preferred alternative analysis, and have the potential to further restrict the pollock fishery from areas where Pacific halibut bycatch is high.

Status Determination

Under PA.2, the ABC is set at a lower level than the OFL, creating a buffer between these two harvest regulations. Model projections of future catches of EBS pollock are below the ABC and OFL levels in all years. The EBS pollock are above their respective MSST in the year 2002 and in all subsequent projection years.

For PA.2, GOA pollock spawning biomass is below the B_{MSY} (taken as $B_{35\%}$) in 2002 and remains below this level until 2007. However, based on 10-year status determinations projections, the stock is above the MSST for all years 2003-2007.

Under PA.2, the calculation of OY caps would be determined based on their relevance to current environmental conditions and knowledge of current stock levels. Procedures to account for the uncertainty in estimating ABC for EBS and GOA pollock under PA.2 would be updated as necessary, and may be modified to account for ecosystem interactions and production patterns/trends. Ecosystem indicators will also be developed and implemented as part of the TAC-setting process, as appropriate. These changes may increase or reduce catch limits for EBS and GOA pollock in the future. TAC values must be set at levels equal to or less than the ABC for all target species under PA.2.

Age and Size Composition

Under PA.2, the mean age of the EBS pollock stock at the end of 2007, as computed in model projections, is 2.51 years. This compares with a mean age in an equilibrium unfished stock of 3.16 years. For GOA pollock the 2007 value is 3.13 years compared with an unfished estimate of 3.60 years (note that the GOA pollock assessment is modeled from age 2-10+ while the EBS pollock is modeled from age 1-15+).

Sex Ratio

In the models, the sex ratio of GOA and BSAI pollock is assumed to be 50:50. However, observer data and information from surveys are routinely collected and used to monitor the sex ratios of these stocks. Based on these data, it is unlikely that the sex ratio will be affected under PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.2 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change under PA.2.

Under PA.2, NPFMC and NOAA Fisheries would consider adopting 0-20 percent of the Bering Sea and the Aleutian Islands and GOA as MPAs and no-take reserves across a range of different habitat types (similar to FMP 3.2). Existing closures would be reviewed to see if areas may qualify for MPAs under established criteria. Existing areas may be redefined as gear- or fishery-specific. EFH and HAPC designation would continue under PA.2, as would investigations as to whether fishing has adverse impacts on habitats; mitigation measures would be implemented as necessary. An Aleutian Islands management area would be established under PA.2 to protect coral and live bottom habitats. The 2002 Steller sea lion closures and Aleutian Islands critical habitat designations would be reviewed and modified as suggested by new scientific information. Pollock bottom trawling would be prohibited in the BSAI and GOA under PA.2. Please see the FMP 3.2 map (Figure 4.2-5) described in Section 4.2 for more information. All of these measures may reduce the adverse impacts of fishing gear on important pollock habitat.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.2 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. An evaluation of potential trophic interactions is presented in Section 3.10. It seems unlikely that significant qualitative changes in predator-prey interactions would be a result of actions taken under PA.2 (for the period 2003-2007). Forage fish commercial fisheries would continue to be banned under PA.2.

Please see Table 4.9-1 for a summary of the direct/indirect effects on EBS, Aleutian Islands and GOA pollock.

Cumulative Effects of PA.2 – EBS and Aleutian Islands Pollock

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the EBS and Aleutian Islands pollock stock is insignificant under PA.2 (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on EBS and Aleutian Islands pollock mortality are the same as those indicated under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on EBS and Aleutian Islands pollock mortality are the same as those considered under PA.1.

- **Cumulative Effects.** Cumulative effects are identified for mortality of EBS and Aleutian Islands pollock, but the effects are judged to be insignificant. Pollock are fished at less than the OFL and are above the MSST. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the EBS and Aleutian Islands pollock stock is expected to be insignificant under the PA.2 (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on the EBS and Aleutian Islands pollock change in biomass level are the same as those described under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on EBS and Aleutian Islands pollock change in biomass level are the same as those considered under PA.1.

- **Cumulative Effects.** Cumulative effects for change in biomass are identified under PA.2; however, the effects are insignificant since the combination of internal and external factors is not expected to sufficiently reduce the pollock biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch

- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects**. The spatial and temporal distribution of catch should have an insignificant effect on the genetic structure and reproductive success of the population (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects under PA.2 are identical to those described for PA.1 and include lingering beneficial effects on reproductive success.

- **Reasonably Foreseeable Future External Effects.** Future external effects under PA.2 are the same as those described for the spatial and temporal characteristics of EBS and Aleutian Islands pollock under PA.1.

- **Cumulative Effects**. Cumulative effects are possible for the spatial/temporal concentration; however, the effects are insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** Any predation-mediated impacts of PA.2 would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see direct/indirect effects discussion). However, it is determined that PA.2 would have an insignificant effect on pollock prey availability.

- **Persistent Past Effects.** Past effects on EBS and Aleutian Islands prey availability are the same as those described under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on EBS and Aleutian Islands prey availability are the same as those considered under PA.1.

- **Cumulative Effects.** Cumulative effects are identified for prey availability under PA.2; however, the effects are insignificant since the combination of internal and external removals of prey species is not expected to decrease prey availability such that the pollock stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under the PA..2, as with prey-mediated impacts, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, as described in the direct/indirect effects section, PA.2 would have insignificant effects on pollock habitat suitability.

- **Persistent Past Effects**. Past effects identified for EBS and Aleutian Islands habitat suitability are the same as those described under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on EBS and Aleutian Islands habitat suitability are the same as those indicated under PA.1.

- **Cumulative Effects.** Cumulative effects are identified for habitat suitability under PA.2; however, their significance on the EBS and Aleutian Islands pollock stock is insignificant since the combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the pollock stock to sustain itself at or above MSST is jeopardized.

See Table 4.5-1 for a summary of the cumulative effects on EBS and Aleutian Islands pollock under PA.2.

GOA Pollock

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA pollock stock is insignificant under PA.2 (see Section 4.9.1.1 direct/indirect effects discussion).

- **Persistent Past Effects**. Past effects identified for GOA pollock mortality are the same as those described under PA.1.

- **Reasonably Foreseeable Future External Effects**. Future external effects on GOA pollock mortality are the same as those considered under PA.1.

- **Cumulative Effects**. Cumulative effects are identified for mortality of GOA pollock, but the effects are judged to be insignificant under PA.2. Pollock are fished at less than the OFL and are above the MSST. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the GOA pollock stock is expected to be insignificant under PA.2 (see direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on the GOA change in biomass are identical to those discussed under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on GOA pollock change in biomass are the same as those considered under PA.1.

- **Cumulative Effects.** Cumulative effects for change in biomass are identified and are considered insignificant. The combination of internal and external factors is not expected to sufficiently reduce the pollock biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

<u>Spatial/Temporal Concentration of Catch</u>
  – Change in Genetic Structure of Population
  – Change in Reproductive Success

- **Direct/Indirect Effects.** For GOA pollock, the stock is expected to be above MSST for the years 2003-2007 (see direct/indirect effects discussion). Therefore, impacts of the spatial and temporal changes should have an insignificant effect on the genetic structure and reproductive success of the population.

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure since the past large removals of pollock and other past effects (see Section 3.5.1.1) have not had a lingering effect on the ability of the stock to sustain itself above MSST. However, there are lingering past effects due to climate changes and regime shifts (see Section 3.5.1.1).

- **Reasonably Foreseeable Future External Effects.** Future external effects on the spatial and temporal characteristics of GOA pollock are the same as those described under PA.1.

- **Cumulative Effects.** Cumulative effects are possible for spatial/temporal concentration and are considered insignificant. The combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** Any predation-mediated impacts of PA.2 would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see the direct/indirect effects discussion). However, it is determined that PA.2 would have an insignificant effect on pollock prey availability.

- **Persistent Past Effects.** Past effects identified for the change in prey availability of GOA pollock are the same as those indicated under PA.1.

- **Reasonably Foreseeable Future External Effects**. Future external effects on the change in prey availability of GOA pollock are the same as those considered under PA.1.

- **Cumulative Effects.** Cumulative effects are identified for prey availability under PA.2 and are considered insignificant. The combination of internal and external removals of prey is not expected to decrease prey availability such that the pollock stock is unable to sustain itself at or above MSST.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** Under PA.2, as with prey-mediated impacts, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see direct/indirect effects discussion). However, it is determined that PA.2 would have insignificant effects on pollock habitat suitability.

- **Persistent Past Effects.** Past effects on habitat suitability identified for GOA pollock stock are the same as those indicated under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects identified for the change in habitat suitability of GOA pollock are the same as those considered under PA.1.

- **Cumulative Effects.** Cumulative effects are identified for habitat suitability; however, their significance on the GOA pollock stock is considered insignificant since the combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the pollock stock to sustain itself at or above MSST is jeopardized.

Refer to Table 4.5-2 for a summary of the cumulative effects on GOA pollock under PA.2.

4.9.1.2 Pacific Cod

This section provides the direct, indirect and cumulative effects analysis for BSAI and GOA Pacific cod for each of the bookends under the preferred alternative.

Direct/Indirect Effects of PA.1

<u>Total Biomass</u>

Total (ages 1 through 12+) biomass of BSAI Pacific cod at the start of 2002 is estimated to be 1,933,000 mt. Model projections of future total BSAI biomasses are shown in Table H.4-44 of Appendix H. Under PA.1, model projections indicate that total BSAI Pacific cod biomass is expected to increase steadily to a value of 2,125,000 mt in 2007, with a 2003-2007 average value of 2,089,000 mt. These values for BSAI Pacific cod total biomass are nearly identical to those predicted under FMP 3.1.

Total (ages 1 through 12+) biomass of GOA Pacific cod at the start of 2002 is estimated to be 568,000 mt. Model projections of future total GOA Pacific cod biomasses are shown in Table H.4-65 of Appendix H. Under PA.1, model projections indicate that total GOA Pacific cod biomass is expected to increase steadily to a value of 675,000 mt in 2007, with a 2003-2007 average value of 622,000 mt. These values for GOA Pacific cod total biomass are nearly identical those predicted under FMP 3.1.

Spawning Biomass

Spawning biomass of female BSAI Pacific cod at the start of 2002 was estimated to be 404,500 mt. Model projections of future BSAI Pacific cod spawning biomasses are shown in Table H.4-44 of Appendix H. Under PA.1, model projections indicate that BSAI Pacific cod spawning biomass is expected to decrease to a value of 403,000 mt in 2003, then increase to a value of 447,300 mt in 2006, then decrease to a value of 445,300 mt in 2007, with a 2003-2007 average value of 431,600 mt. Projected spawning biomass never dips below the B_{MSY} proxy value for the years 2003-2007.

Spawning biomass of female GOA Pacific cod at the start of 2002 was estimated to be 97,900 mt. Model projections of future GOA spawning biomasses are shown in Table H.4-65 of Appendix H. Under PA.1, model projections indicate that GOA spawning biomass is expected to decrease to a value of 79,100 mt in 2005, then increase to a value of 85,700 mt in 2007, with a 2003-2007 average value of 83,100 mt. Projected spawning biomass never dips below the B_{MSY} proxy value for the years 2003-2007.

Under PA.1, the harvest control rules used to set catch limits will be modified to reduce the TAC, and subsequently the ABC values for BSAI and GOA Pacific cod in an effort to maintain a spawning stock biomass with the potential to produce sustained yields on a continuing basis. The harvest control rules will be modified for GOA pollock and BSAI and GOA Pacific cod under this preferred alternative bookend due to the uncertainty associated with the biomass estimates.

Fishing Mortality

The fishing mortality rate imposed on the BSAI Pacific cod stock in 2002 was estimated to be 0.228. Model projections of future BSAI fishing mortality rates are shown in Table H.4-44 of Appendix H. Under PA.1, model projections indicate that BSAI fishing mortality will increase to a value of 0.284 in 2003, then decrease to a value of 0.266 in 2005, then increase to a value of 0.270 in 2006, then decrease to a value of 0.265 in 2007, with a 2003-2007 average of 0.272. These values are well below the F_{MSY} proxy value (the rate associated with the overfishing level for stocks above $B_{40\%}$).

The fishing mortality rate imposed on the GOA Pacific cod stock in 2002 was estimated to be 0.255. Model projections of future GOA fishing mortality rates are shown in Table H.4-65 of Appendix H. Under PA.1, model projections indicate that GOA fishing mortality is expected to increase to a value of 0.324 in 2003, then decrease to a value of 0.289 in 2005, then increase to a value of 0.312 in 2007, with a 2003-2007 average of 0.304. These values are well below the F_{MSY} proxy value; the rate associated with the overfishing level for stocks above $B_{40\%}$.

Spatial/Temporal Concentration of Fishing Mortality

Current area closures would remain under PA.1, thus the spatial characteristics of the Pacific cod fishery are unlikely to change substantially. BSAI Pacific cod catch limits would continue to be allocated by gear. Catches of Pacific cod are projected to increase in both the BSAI and GOA. Under PA.1, it is likely that fishing for BSAI and GOA Pacific cod would tend, to some extent, to be concentrated in space and time so as to coincide with concentrations of spawning fish. Evaluating the effects of such concentrations of fishing mortality is difficult for two reasons: 1) Such concentrations of fishing mortality have already been in place for many years. Although the stocks currently appear to be healthy despite such concentrations, the absence of a "control" treatment makes it difficult to determine which population characteristics are attributable specifically to the existing spatial/temporal concentrations of fishing mortality; 2) Pacific cod undergo large migrations and a large degree of genetic mixing appears to exist. Compared to a sedentary species with readily identifiable genetic subunits, this means that the effects of spatial/temporal concentrations of fishing effort are probably diluted to some extent, but also that their evaluation involves a larger number of difficult-to-estimate parameters.

BSAI Pacific cod fisheries may be limited by Pacific halibut PSC limits which are projected to be reduced by 0-10 percent in the BSAI under PA.1.

Status Determination

Model projections of future catches of BSAI and GOA Pacific cod are below their respective overfishing levels in all years under PA.1. The BSAI and GOA Pacific cod stocks are projected to be above $B_{35\%}$ and therefore above their respective MSSTs in every year throughout the period 2003-2007 (Tables H.4-44 and H.4-65 of Appendix H).

Under PA.1, the ABC must be set below the OFL values. The OY range is specified to be between 1.4 and 2 million mt in the BSAI and between 116,000 and 800,000 mt in the GOA. In the BSAI, if the sum of TAC exceeds 2 million mt, then the TAC must be adjusted down. This means that the TAC, ABC and OFL values may all be reduced in the future for BSAI Pacific cod under this preferred alternative bookend (same as FMP 1 and FMP 3.1). As mentioned above, the TAC for BSAI and GOA Pacific cod will also be reduced through modification of the harvest control rules due to uncertainty in the biomass estimates. Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future, as well.

Age and Size Composition

Under PA.1, the projected mean age of the BSAI Pacific cod stock in 2008 is 2.78 years. This compares with a mean age in the equilibrium unfished BSAI stock of 3.20 years.

Under PA.1, the projected mean age of the GOA Pacific cod stock in 2008 is 2.75 years. This compares with a mean age in the equilibrium unfished GOA stock of 3.19 years.

Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

The sex ratio of Pacific cod in both the BSAI and GOA is assumed to be 50:50. No information is available to suggest that this would change under PA.1.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this preferred alternative bookend.

Current closure areas would remain under this preferred alternative bookend, including the eastern GOA trawl closure and the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. The Seguam Pass area would be closed to fishing, 3 nm no transit zones would be established around rookeries, and nearshore and critical habitat areas would be closed to trawl and fixed gear as Steller sea lion protection measures. All these measures may help reduce adverse impacts to important Pacific cod habitat.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 on Pacific cod would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under this bookend.

A direct fishery for forage fish would continue to be banned under PA.1, and the $B_{20\%}$ rule would remain since Pacific cod (juvenile Pacific cod) is an important prey species for many members of the BSAI and GOA ecosystem.

See Table 4.9-1 for a summary of the direct/indirect effects of PA.1 on BSAI and GOA Pacific cod.

Cumulative Effects of PA.1 – BSAI Pacific Cod

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI Pacific cod stock is insignificant under the PA.1 (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects of the foreign, JV, domestic, and State of Alaska bait fisheries are identified for the BSAI stock. Large removals of Pacific cod did occur in the past and could have a lingering effect on the present-day stock, the biomass of which is below $B_{40\%}$ (see Section 3.5.1.2).

- **Reasonably Foreseeable Future External Effects.** While bycatch and removals of Pacific cod are predicted to continue in the IPHC longline fishery, State of Alaska crab fishery and subsistence/personal use fishery in the BSAI, these are not expected to be contributing factors to fishing mortality in the cumulative case. Removals in these fisheries are accounted for when setting annual harvest levels for pollock and do not add additional fishing mortality. Marine pollution is identified as having a reasonably foreseeable potentially adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not considered contributors to Pacific cod mortality.

- **Cumulative Effects.** Cumulative effects under PA.1 are identified for mortality of BSAI Pacific cod, but the effects are judged to be insignificant. Pacific cod are fished at less than the OFL and all catch and bycatch are accounted for in the management of the stock. The combined effect of internal removals and removals due to reasonably foreseeable external events is to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the BSAI Pacific cod stocks is expected to be insignificant under PA.1 (see the Pacific cod PA.1 direct/indirect effects discussion).

- **Persistent Past Effects.** While past large removals of Pacific cod and other past effects on biomass have been identified (see Section 3.5.1.2), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects.** Future external effects on biomass are indicated due to bycatch in the IPHC longline and State of Alaska crab fisheries, and bycatch and removals in the subsistence/personal use fishery in the BSAI. However, these removals are not expected to affect the ability of the stock to maintain maximum stock size. Marine pollution is identified as having a reasonably foreseeable potentially adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not considered contributors to Pacific cod mortality, thereby would not directly affect biomass.

- **Cumulative Effects.** Cumulative effects for change in biomass are identified under PA.1; however, the effects are insignificant since the combination of internal and external factors is not expected to sufficiently reduce the Pacific cod biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch
- – Change in Genetic Structure of Population
- – Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1, the spatial and temporal distribution of catch should have an insignificant effect on the genetic structure and reproductive success of the population (see direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure since the past large removals of Pacific cod and other past effects (see Section 3.5.1.2) have not had a lingering effect on the ability of the stock to sustain itself above MSST. However, since past fisheries could have had an adverse effect on Pacific cod recruitment, lingering effects are identified for change in reproductive success. Lingering past effects (either beneficial or adverse depending on the regime) are also identified due to Climate Changes and Regime Shifts (see Section 3.5.1.2).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline and State of Alaska crab fisheries, and subsistence use in the BSAI have the potential to cause adverse effects. However, the removals are not expected to be sufficiently concentrated to alter the genetic structure of the population. Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment.

- **Cumulative Effects.** Cumulative effects are possible for the spatial/temporal concentration under PA.1; however, the effects are insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Any predation-mediated impacts of PA.1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify (see direct/indirect effects discussion). However, it is determined that the PA.1 would have insignificant effects on Pacific cod prey availability.

- **Persistent Past Effects.** While lingering population level effects from past foreign and domestic and state fisheries catch and bycatch of Pacific cod prey species are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on Pacific cod prey species (see Section 3.5.1.2).

- **Reasonably Foreseeable Future External Effects**. Future external effects of climate changes and regime shifts on Pacific cod prey species could be either beneficial or adverse since a strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Likewise, a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. Marine pollution has also been identified as a reasonably foreseeable external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The other fisheries shown on Table 4.5-3 are determined to be potentially adverse contributors since catch and bycatch of prey species are likely to continue.

- **Cumulative Effects.** Cumulative effects are identified for prey availability; however, the effects are insignificant since the combination of internal and external removals of prey is not expected to decrease prey availability such that the Pacific cod stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, the effect is rated as insignificant (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects identified for BSAI Pacific cod stocks include past foreign, JV, and domestic fisheries, the State of Alaska crab and bait fisheries, IPHC longline, and climate changes and regime shifts (see Section 3.5.1.2). Past fishing for Pacific cod in the past fisheries likely disrupted habitat in areas of the BSAI. It is possible that some of these areas have not recovered (see Section 3.6 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Future external effects are possible from the State of Alaska fisheries, subsistence, and the IPHC fishery since any of these may impact bottom habitat through use of fishing gear. As described above for prey availability, impacts on habitat from climate changes and regime shifts on the BSAI Pacific cod stocks could be either beneficial or adverse depending on water temperatures. Marine pollution has also been identified as a potentially adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects**. Cumulative effects are identified for habitat suitability under and are considered insignificant. The combination of internal and external impacts on habitat is not expected to jeopardize the Pacific cod stock such that it is unable to sustain itself at or above MSST and the effect is judged insignificant.

See Table 4.5-3 for a summary of the cumulative effects on BSAI Pacific cod under PA.1.

GOA Pacific Cod

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA Pacific cod stock is insignificant under PA.1 (see GOA Pacific cod PA.1 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects of the foreign, JV, domestic, and State of Alaska bait fisheries are identified for the GOA Pacific cod stocks. Additionally, the State of Alaska groundfish fishery contributed to past removals in the GOA. Large removals of Pacific cod did occur in the past and could have a lingering effect on the present-day stock, the biomass of which is below $B_{40\%}$ (see Section 3.5.1.2).

- **Reasonably Foreseeable Future External Effects.** While bycatch and removals of Pacific cod are predicted to continue in the IPHC longline fishery, State of Alaska crab fishery, subsistence/personal use fishery, and in the State of Alaska groundfish fisheries, these are not expected to be contributing factors to fishing mortality in the cumulative case. Removals in these fisheries are accounted for when setting annual harvest levels for pollock and do not add additional fishing mortality. Marine pollution is identified as having a reasonably foreseeable potentially adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not considered contributors to Pacific cod mortality.

- **Cumulative Effects.** A cumulative effect under PA.1 is identified for mortality of GOA Pacific cod, but the effect is judged to be insignificant. Pacific cod are fished at less than the OFL and all catch and bycatch are accounted for in the management of the stock. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the GOA Pacific cod stocks is expected to be insignificant under the PA.1 (see GOA Pacific cod PA.1 direct/indirect effects discussion).

- **Persistent Past Effects.** While past large removals of Pacific cod and other past effects on biomass have been identified (see Section 3.5.1.2), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects.** Future external effects on biomass are indicated due to bycatch in the IPHC longline and State of Alaska crab fisheries, and bycatch and removals in the subsistence/personal use fishery and in the State of Alaska groundfish fisheries. However, these removals are not expected to affect the ability of the stock to maintain MSST. Marine pollution is identified as having a reasonably foreseeable potentially adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not considered contributors to Pacific cod mortality, thereby would not directly affect biomass.

- **Cumulative Effects.** A cumulative effect for change in biomass is identified for PA.1; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently reduce the Pacific cod biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch
- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1, the spatial and temporal distribution of catch should have an insignificant effect on the genetic structure and reproductive success of the population (see direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure since the past large removals of Pacific cod and other past effects (see Section 3.5.1.2) have not had a lingering effect on the ability of the stock to sustain itself above MSST. However, since past fisheries could have had an adverse effect on Pacific cod recruitment particularly in the GOA where the state groundfish fishery is very localized, lingering effects are identified for change in reproductive success. Lingering past effects (either beneficial or adverse depending on the regime) are also identified due to climate changes and regime shifts (see Section 3.5.1.2).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline and State of Alaska crab fisheries, subsistence use, and the State of Alaska groundfish fisheries all have the potential to cause adverse effects. However, the removals are not expected to be sufficiently concentrated to alter the genetic structure of the population. Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration under PA.1; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Any predation-mediated impacts of PA.1 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, it is determined that PA.1 would have insignificant effects on Pacific cod prey availability (see the GOA Pacific cod PA.1 direct/indirect effects discussion).

- **Persistent Past Effects.** While lingering population level effects from past foreign and domestic and state fisheries catch and bycatch of Pacific cod prey species are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on Pacific cod prey species (see Section 3.5.1.2).

- **Reasonably Foreseeable Future External Effects.** As described for the Bering Sea, the effects of climate changes and regime shifts on Pacific cod prey species could be either beneficial or adverse depending on water temperature. Marine pollution has also been identified as a reasonably foreseeable external contributing factor, and the other fisheries shown on Table 4.5-4 are determined to be potential adverse contributors since catch and bycatch of prey species are likely to continue.

- **Cumulative Effects.** Cumulative effects are identified for prey availability under the PA.1; however, the effects are insignificant since the combination of internal and external removals of prey is not expected to decrease prey availability such that the Pacific cod stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, the effect is rated as insignificant (see the GOA Pacific cod PA.1 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects identified for GOA Pacific cod stocks include past foreign, JV, and domestic fisheries, the state crab and bait fisheries, IPHC longline, and climate changes and regime shifts (see Section 3.5.1.2). Additionally, the State of Alaska groundfish fishery contributed to habitat impacts in the GOA. Past fishing for Pacific cod in the past fisheries likely disrupted habitat in areas of the GOA. It is possible that some of these areas have not recovered (see Section 3.6 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Future external effects are possible from the State of Alaska fisheries, subsistence, and the IPHC fishery since any of these may impact bottom habitat through use of fishing gear as described for the Bering Sea, impacts on habitat from climate changes and regime shifts on GOA Pacific cod stocks could be either beneficial or adverse and marine pollution could be a potential adverse contributing factor.

- **Cumulative Effects.** Cumulative effects are identified for habitat suitability under PA.1 and are considered insignificant. The combination of internal and external impacts on habitat is not expected to jeopardize the Pacific cod stock such that it is unable to sustain itself at or above MSST and the effect is judged insignificant.

See Table 4.5-4 for a summary of the cumulative effects on GOA Pacific cod under PA.1.

Direct/Indirect Effects of PA.2

Total Biomass

Total (ages 1 through 12+) biomass of BSAI Pacific cod at the start of 2002 is estimated to be 1,933,000 mt. Model projections of future total BSAI biomasses are shown in Table H.4-44 of Appendix H. Under PA.2, model projections indicate that total BSAI biomass is expected to increase steadily to a value of 2,167,000 mt in 2007, with a 2003-2007 average value of 2,113,000 mt.

Total (ages 1 through 12+) biomass of GOA Pacific cod at the start of 2002 is estimated to be 568,000 mt. Model projections of future total GOA biomasses are shown in Table H.4-65 of Appendix H. Under PA.2, model projections indicate that total GOA biomass is expected to increase steadily to a value of 688,000 mt in 2007, with a 2003-2007 average value of 631,000 mt. The GOA Pacific cod total biomass values are nearly identical to those projected for FMP 3.2.

Spawning Biomass

Spawning biomass of female BSAI Pacific cod at the start of 2002 was estimated to be 404,500 mt. Model projections of future BSAI spawning biomasses are shown in Table H.4-44 of Appendix H. Under PA.2, model projections indicate that BSAI spawning biomass is expected to decrease to a value of 403,800 mt in 2003, then increase to a value of 461,500 mt in 2007, with a 2003-2007 average value of 440,900 mt. Projected spawning biomass never dips below the B_{MSY} proxy value for the years 2003-2007.

Spawning biomass of female GOA Pacific cod at the start of 2002 was estimated to be 97,900 mt. Model projections of future GOA spawning biomasses are shown in Table H.4-65 of Appendix H. Under PA.2, model projections indicate that GOA spawning biomass is expected to decrease to a value of 82,400 mt in 2005, then increase to a value of 90,100 mt in 2007, with a 2003-2007 average value of 85,900 mt. Projected spawning biomass never dips below the B_{MSY} proxy value of 79,000 mt for the years 2003-2007. The GOA Pacific cod spawning biomass values are nearly identical as those projected for FMP 3.2.

Fishing Mortality

The fishing mortality rate imposed on the BSAI Pacific cod stock in 2002 was estimated to be 0.228. Model projections of future BSAI fishing mortality rates are shown in Table H.4-44 of Appendix H. Under PA.2, model projections indicate that BSAI fishing mortality will increase to a value of 0.268 in 2003, then decrease to a value of 0.245 in 2005, then increase to a value of 0.252 in 2006 and decrease to a value of 0.250 in 2007, with a 2003-2007 average of 0.254. These values are well below the F_{MSY} proxy value of 0.409, which is the rate associated with the OFL for stocks above $B_{40\%}$.

The fishing mortality rate imposed on the GOA Pacific cod stock in 2002 was estimated to be 0.255. Model projections of future GOA fishing mortality rates are shown in Table H.4-65 of Appendix H. Under PA.2, model projections indicate that GOA fishing mortality is expected to increase to a value of 0.282 in 2003, then decrease to a value of 0.260 in 2005, then increase to a value of 0.281 in 2007, with a 2003-2007 average of 0.271. These values are well below the F_{MSY} proxy value of 0.421, which is the rate associated with the OFL for stocks above $B_{40\%}$.

Spatial/Temporal Concentration of Fishing Mortality

Current closures would remain under PA.2, although these closures would be reviewed to see if some areas may qualify as MPAs. Some areas may also be redesignated as gear- or fishery-specific regions. The BSAI and GOA Pacific cod fisheries may be limited by Pacific halibut PSC limits which are projected to be reduced by 0-20 percent in the BSAI and 0-10 percent in the GOA. Inseason bycatch closures will be reevaluated in the BSAI and developed in the GOA, and has the potential to further restrict the Pacific cod fishery from areas where Pacific halibut bycatch is high.

Under PA.2, catches of Pacific cod are projected to increase in both the BSAI and GOA, meaning that the imposition of Pacific cod fishery closed areas will tend to increase the amount of catch taken from the remaining open areas. Under PA.2, it is likely that fishing for BSAI and GOA Pacific cod would tend, to some extent, to be concentrated in space and time so as to coincide with concentrations of spawning fish. Evaluating the effects of such concentrations of fishing mortality is difficult for two reasons: 1) Such concentrations of fishing mortality have already been in place for many years. Although the stocks currently appear to be healthy despite such concentrations, the absence of a "control" treatment makes it difficult to determine which population characteristics are attributable specifically to the existing spatial/temporal concentrations of fishing mortality. 2) Pacific cod undergo large migrations and a large degree of genetic mixing appears to exist. Compared to a sedentary species with readily identifiable genetic subunits, this means that the effects of spatial/temporal concentrations of fishing effort are probably diluted to some extent, but also that their evaluation involves a larger number of difficult-to-estimate parameters.

Status Determination

Model projections of future catches of BSAI and GOA Pacific cod are below their respective OFLs in all years under PA.2. The BSAI and GOA Pacific cod stocks are projected to be above $B_{35\%}$ and therefore above their respective MSSTs in every year throughout the period 2003-2007 (Tables H.4-44 and H.4-65 of Appendix H).

Under PA.2, OY cap calculations would be revisited to determine their relevancy to current environmental conditions and knowledge of existing stock levels. Procedures to account for the uncertainty in estimating ABC for BSAI and GOA Pacific cod under PA.2 would be updated as necessary, and may be modified to account for ecosystem interactions and production patterns/trends. Ecosystem indicators will also be developed and implemented as part of the TAC-setting process, as appropriate. These changes may increase or reduce catch limits for BSAI and GOA Pacific cod in the future. TAC values must be set at levels equal to or less than the ABC for all target species under PA.2.

Age and Size Composition

Under PA.2, the projected mean age of the BSAI Pacific cod stock in 2008 is 2.8 years. This compares with a mean age in the equilibrium unfished BSAI stock of 3.2 years.

Under PA.2, the projected mean age of the GOA Pacific cod stock in 2008 is 2.8 years. This compares with a mean age in the equilibrium unfished GOA stock of 3.2 years.

Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

The sex ratio of Pacific cod in both the BSAI and GOA is assumed to be 50:50. No information is available to suggest that this would change under PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.2 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under PA.2.

Under PA.2, NPFMC and NOAA Fisheries would consider adopting 0-20 percent of the Bering Sea, Aleutian Islands and GOA as MPAs and no-take reserves across a range of different habitat types (similar to FMP 3.2). Existing closures would be reviewed to see if areas may qualify for MPAs under established criteria. Existing areas may be redefined as gear- or fishery-specific. EFH and HAPC designation would continue under PA.2, as would investigations as to whether fishing has adverse impacts on habitats; mitigation measures would be implemented as necessary. An Aleutian Islands management area would be established under PA.2 to protect coral and live bottom habitats. The 2002 Steller sea lion closures and Aleutian Islands critical habitat designations would be reviewed and modified as is called for by new scientific information. Pollock bottom trawling would be prohibited in the BSAI and GOA under PA.2. Please see the FMP 3.2 maps (Figure 4.2-5) described in Section 4.2 for more information. All of these measures may reduce the adverse impacts of fishing gear on important Pacific cod habitat.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.2 on Pacific cod would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under this FMP. Forage fish commercial fisheries would continue to be banned under PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects on BSAI and GOA Pacific cod under PA.2.

Cumulative Effects of PA.2 – BSAI Pacific Cod

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI Pacific cod stocks is insignificant under PA.2 (see Section 4.9.1.2 direct/indirect effects discussion).

- **Persistent Past Effects**. Past effects on Pacific cod mortality are the same as those described under PA.1.

- **Reasonably Foreseeable Future External Effects**. Future external effects on Pacific cod mortality are the same as those described under PA.1.

- **Cumulative Effects**. Cumulative effects under PA.2 are identified for mortality of BSAI Pacific cod, but the effects are judged to be insignificant. Pacific cod are fished at less than the OFL and all catch and bycatch are accounted for in the management of the stock. The combined effect of internal removals and removals due to reasonably foreseeable external events is to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the BSAI Pacific cod stocks is expected to be insignificant under PA.2 (see the BSAI Pacific cod PA.2 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on the BSAI Pacific cod change in biomass are the same as those described under PA.1.

- **Reasonably Foreseeable Future External Effects**. Future external effects on the BSAI Pacific cod change in biomass are the same as those described under PA.1.

- **Cumulative Effects.** Cumulative effects for change in biomass are identified under PA.2; however, the effects are insignificant since the combination of internal and external factors is not expected to sufficiently reduce the Pacific cod biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch
- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.2, the spatial and temporal distribution of catch should have an insignificant effect on the genetic structure and reproductive success of the BSAI Pacific cod population (see the BSAI Pacific cod PA.2 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on the spatial and temporal characteristics of BSAI Pacific cod are the same as those indicated under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the spatial and temporal characteristics of BSAI Pacific cod are the same as those indicated under PA.1.

- **Cumulative Effects.** Cumulative effects are possible for the spatial/temporal concentration under PA.2; however, the effects are insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** Any predation-mediated impacts of PA.2 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, it is determined that PA.2 would have insignificant effects on Pacific cod prey availability (see the Pacific cod PA.2 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on the BSAI Pacific cod change in prey availability are the same as those described under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the BSAI Pacific cod change in prey availability are the same as those described under PA.1.

- **Cumulative Effects**. Cumulative effects are identified for prey availability; however, the effects are insignificant since the combination of internal and external removals of prey is not expected to decrease prey availability such that the BSAI Pacific cod stock is unable to sustain itself at or above MSST.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** Under PA.2, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, it is determined that PA.2 would have insignificant effects on Pacific cod habitat suitability (see the BSAI Pacific cod PA.2 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects identified for BSAI Pacific cod habitat suitability are the same as those indicated under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects identified for BSAI Pacific cod habitat suitability are the same as those indicated under PA.1.

- **Cumulative Effects.** Cumulative effects are identified for habitat suitability under the PA.2 and are considered insignificant. The combination of internal and external impacts on habitat is not expected to jeopardize the BSAI Pacific cod stock such that it is unable to sustain itself at or above MSST.

See Table 4.5-3 for a summary of the cumulative effects on BSAI Pacific cod under PA.2.

GOA Pacific Cod

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA Pacific cod stocks is insignificant under PA.2 (see the GOA Pacific cod direct/indirect effects section).

- **Persistent Past Effects.** Past effects on GOA Pacific cod mortality are the same as those indicated under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on GOA Pacific cod mortality are the same as those indicated under PA.1.

- **Cumulative Effects.** A cumulative effect under PA.2 is identified for mortality of GOA Pacific cod, but the effect is judged to be insignificant. Pacific cod are fished at less than the OFL and all catch and bycatch are accounted for in the management of the stock. The combined effect of internal removals and removals due to reasonably foreseeable external events is to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the GOA Pacific cod stocks is expected to be insignificant under PA.2 (see the GOA Pacific cod PA.2 direct/indirect effects section).

- **Persistent Past Effects.** Past effects on the GOA Pacific cod change in biomass are the same as those indicated under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the GOA Pacific cod change in biomass are the same as those indicated under PA.1.

- **Cumulative Effects**. A cumulative effect for the GOA Pacific cod change in biomass is identified for the FMP; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently reduce the Pacific cod biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch
– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.2, the spatial and temporal distribution of catch should have an insignificant effect on the genetic structure and reproductive success of the population (see direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on the spatial and temporal characteristics of GOA Pacific cod are the identical to those described under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the spatial and temporal characteristics of GOA Pacific cod are the identical to those described under PA.1.

- **Cumulative Effects**. A cumulative effect is possible for the spatial/temporal concentration under PA.2; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the GOA Pacific cod population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Any predation-mediated impacts of PA.2 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, it is determined that PA.2 would have insignificant effects on Pacific cod prey availability (see the GOA Pacific cod PA.2 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on GOA Pacific cod prey availability are the same as those indicated under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on GOA Pacific cod prey availability are the same as those indicated under PA.1.

- **Cumulative Effects**. Cumulative effects are identified for prey availability under PA.2; however, they are insignificant since the combination of internal and external removals of prey is not expected to decrease prey availability such that the GOA Pacific cod stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.2, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, it is determined that PA.2 would have insignificant effects on GOA Pacific cod habitat suitability (see the GOA Pacific cod PA.2 direct/indirect effects discussion).

- **Persistent Past Effects**. Past effects on GOA Pacific cod habitat suitability are the same as those considered under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on GOA Pacific cod habitat suitability are the same as those considered under PA.1.

- **Cumulative Effects.** A cumulative effect is identified for habitat suitability under PA.2 and is considered insignificant. The combination of internal and external impacts on habitat is not expected to jeopardize the GOA Pacific cod stock such that it is unable to sustain itself at or above MSST.

See Table 4.5-4 for a summary of the cumulative effects on GOA Pacific cod under PA.2.

4.9.1.3 Sablefish

This section provides the direct, indirect and cumulative effects analysis for sablefish for each of the bookends under the preferred alternative. Sablefish are managed as one stock in the BSAI and GOA; therefore, BSAI and GOA areas are discussed together in this section. For further information regarding persistent past effects listed below in the text and in the table (see Section 3.5.1.3).

Direct/Indirect Effects of PA.1 and PA.2

<u>Catch/ABC</u>

PA.1 is projected to have an insignificant impact on average sablefish yield compared to the baseline. Similar yields are projected because PA.1 assumptions mostly replicate baseline conditions.

PA.2 is projected to significantly decrease sablefish yield compared to the baseline. Similar to FMP 3.2, PA.2 applies a risk-averse adjustment to F_{ABC}. The amount of adjustment is affected by recruitment variability and uncertainty in abundance estimation. Sablefish abundance is estimated with reasonable certainty, but recruitment is highly variable, so that the adjustment is substantial. As a result, projected yield is significantly reduced for PA.2 (Tables H.4-52 and H.4-71 of Appendix H).

<u>Total Biomass</u>

PA.1 is projected to have an insignificant impact on total biomass (age 2-31+) compared to the baseline. Total biomass increases from 2002-2007 under PA.1 because long-term average recruitment (1977-present) is used to project biomass and is higher than most recent recruitments (Tables H.4-52 and H.4-71 of Appendix H).

PA.2 is projected to have an insignificant impact on total biomass (age 2-31+) compared to the baseline. Fishing mortality is lower for this alternative compared to baseline, but not enough to significantly increase total biomass (Tables H.4-52 and H.4-71 of Appendix H).

<u>Spawning Biomass</u>

PA.1 is projected to have an insignificant impact on spawning biomass compared to the baseline. PA.1 assumptions mostly replicate baseline conditions. Spawning biomass increases from 2002-2007 under PA.1 because long-term average recruitment (1977-present) is used to project biomass and is higher than recent recruitment (Table H.4-52 of BSAI sablefish and H.4-71 of GOA sablefish found in Appendix H).

PA.2 is projected to have an insignificant impact on spawning biomass compared to the baseline. Fishing mortality is lower for this alternative compared to baseline, but not enough to significantly increase spawning biomass (Table H.4-52 for BSAI sablefish and Table H.4-71 for GOA sablefish found in Appendix H).

Spawning biomass is projected to decrease from 2002-2007 while total biomass is projected to increase during the same interval. Total biomass includes ages 2-30+ while spawning biomass includes ages 6.5-30+ (initial age is average age of first spawning for females) so that spawning biomass trends due to changing recruitment lag total biomass trends. Spawning biomass will likely increase for a longer projection.

Fishing Mortality

Under PA.1 and PA.2, the fishing mortalities imposed on the sablefish stock are well below the F_{MSY} proxy value of 0.14 which is the rate associated with the OFL (Tables H.4-52 and H.4-71 of Appendix H).

Spatial/Temporal Concentration of Fishing Mortality

Sablefish fishing is concentrated along the upper continental slope and deepwater gullies. PA.1 is projected to have an insignificant impact on the spatial/temporal concentration of fishing mortality compared to the baseline. PA.1 closed areas are the same as baseline. Similarly, existing gear and fishing restrictions would remain under PA.1, including the GOA sablefish pot ban. Sablefish catch limits will continue to be allocated by gear in the BSAI and GOA.

Under PA.2, NPFMC and NOAA Fisheries would consider adopting 0-20 percent of the Bering Sea and the Aleutian Islands and GOA as MPAs and no-take reserves across a range of different habitat types (similar to FMP 3.2). Inseason bycatch closures will be reevaluated in the BSAI and developed in the GOA. The proposed closed areas for this alternative may cover some of the areas where the sablefish fishery, both longline and trawl, currently operate, and could thus restrict the fishery to the remaining open areas. Sablefish undergo large migrations (e.g. Heifetz and Fujioka 1991) and substantial genetic mixing is expected for this stock. The degree of spatial and temporal concentration of the fishery is not likely to result in depletion of sub-populations of sablefish if they exist. For this reason, it is not likely that the amount of spatial and temporal concentration of fishing effort would inhibit the stock's ability to remain above the MSST.

Status Determination

Under PA.1, sablefish is not overfished nor approaching an overfished condition. Under PA.1, the ABC must be set below the OFL values. The OY range is specified to be between 1.4 and 2 million mt in the BSAI and between 116,000 and 800,000 mt in the GOA. In the BSAI, if the sum of TAC exceeds 2 million mt, then the TAC must be adjusted down. This means that the TAC, ABC and OFL values may all be reduced in the future for BSAI sablefish under this preferred alternative bookend (same as FMP 1 and FMP 3.1). Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future, as well.

Under PA.2, sablefish is not overfished nor approaching an overfished condition. The OY caps would be revisited to determine relevancy to current environmental conditions and our knowledge of current stocks. Procedures to account for the uncertainty in estimating ABC for BSAI and GOA sablefish under PA.2 would be updated as necessary, and may be modified to account for ecosystem interactions and production patterns/trends. Ecosystem indicators will also be developed and implemented as part of the TAC-setting process, as appropriate. These changes may increase or reduce catch limits for BSAI and GOA sablefish in the future. TAC values must be set at levels equal to or less than the ABC for all target species under both bookends.

Age and Size Composition

PA.1 and PA.2 are projected to have an insignificant impact on mean age compared to the baseline. The mean ages actually observed in 2008 (as opposed to projections of mean ages) will be driven largely by incoming recruitment strengths during the intervening years.

BSAI mean age likely is overestimated. The model assumes that the lower exploitation rate for the BSAI compared to the GOA will translate into greater mean age for the BSAI. However sablefish migration is substantial enough to erase the effects of differential exploitation rates between the GOA and BSAI. The mean age for the GOA best represents the mean age for the BSAI/GOA because sablefish abundance is much greater for the GOA.

Sex Ratio

The sex ratio of the adult population is 40 males:60 females, based on sex ratio data collected during sablefish longline surveys. PA.1 and PA.2 probably would have no significant effect on the sex ratio compared to the baseline.

Habitat Suitability

PA.1 would have no significant effect on habitat suitability compared to the baseline because exploitation rates for PA.1 are similar to baseline.

Current closure areas would remain under this preferred alternative bookend, including the eastern GOA trawl closure, the ban on bottom trawling for pollock in the BSAI and the ban on sablefish pot fishing in the GOA. Definitions and methodology for establishing MPAs would be developed. The Seguam Pass area would be closed to fishing, 3 nm no transit zones would be established around rookeries and nearshore and critical habitat areas would be closed to trawl and fixed gear as Steller sea lion protection measures. These implemented measures may help reduce adverse impacts to important sablefish habitat when overlap occurs.

PA.2 would decrease exploitation rates overall, but could also significantly increase the spatial/temporal concentration of fishing mortality compared to the baseline if sablefish fishery areas are further restricted (similar to FMP 3.2). This could eliminate the local fishing mortality rates on sablefish in the closed areas, but effort also would increase in some areas or times as a result of area closures, thus concentrating the fishery at certain fishing locations and increasing fishing mortality rates on sablefish at these locations. Under PA.2, average catch is projected to decrease by about 1/3 compared to baseline. As long as at least 2/3 of the areas remain open, the remaining catch should not decrease habitat suitability in the open areas and the habitat suitability of closed areas should improve, to the extent that fishing affects habitat suitability.

Existing closures under PA.2 would be reviewed to see if areas may qualify for MPAs under established criteria. Existing areas may be redefined as gear- or fishery-specific. EFH and HAPC designation would continue under PA.2, as would investigations as to whether fishing has adverse impacts on habitats; mitigation measures would be implemented as necessary. An Aleutian Islands management area would be established under PA.2 to protect coral and live bottom habitats. The 2002 Steller sea lion closures and Aleutian Islands critical habitat designations would be reviewed and modified as is called for by new scientific information. Pollock bottom trawling would be prohibited in the BSAI and GOA under PA.2.

Please see the FMP 3.2 map (Figure 4.2-5) described in Section 4.2 for more information. All of these measures may reduce the adverse impacts of fishing gear on important sablefish habitat where overlap occurs.

Predator-Prey Relationships

PA.1 and PA.2 are projected to have an insignificant impact on total biomass (age 2-31+) compared to the baseline, so PA.1 and PA.2 should have an insignificant effect on the amount of sablefish biomass available to the ecosystem and the amount of predation due to sablefish (Table 4.9-1). A directed forage fish fishery would continue to be banned under each of these bookends.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the sablefish stock is insignificant under PA.1 and PA.2 (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects of the foreign, JV, domestic, and State of Alaska groundfish fisheries are identified for sablefish. Large removals of sablefish occurred, particularly in the JV and domestic fisheries. Catches that were under reported during the late 1980s may have contributed to abundance declines in the 1990s (see Section 3.5.1.3).

- **Reasonably Foreseeable Future External Effects.** While bycatch and removals of sablefish are predicted to continue in the IPHC longline fishery, and State of Alaska groundfish fishery, these are not expected to be contributing factors to fishing mortality in the cumulative case. Removals in these fisheries are accounted for when setting annual harvest levels and do not add additional fishing mortality. Due the highly migratory nature of sablefish, Canadian fisheries fishing within Canadian waters could be harvesting sablefish considered to be part of the GOA population. These removals are not accounted for in the TAC setting process and can be considered as having a potentially adverse contribution to the cumulative case. Likewise, marine pollution is identified as having a reasonably foreseeable, potentially adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not considered contributors to direct sablefish mortality.

- **Cumulative Effects.** Cumulative effects under PA.1 and PA.2 are identified for mortality of sablefish, but the effects are judged to be insignificant. Sablefish are fished at less than the OFL and all catch and bycatch are accounted for (with the exception of any fish taken in Canadian waters) in the management of the stock. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the sablefish stock is expected to be insignificant under PA.1 and PA.2 (see direct/indirect effects discussion).

- **Persistent Past Effects.** While past large removals of sablefish and other past effects on biomass have been identified (see Section 3.5.1.3), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects.** Future external effects on biomass are indicated due to catch and bycatch in the IPHC longline and State of Alaska groundfish fisheries, and in the Canadian fisheries. Marine pollution is identified as having a reasonably foreseeable, potentially adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not considered contributors to sablefish mortality, and therefore would not directly affect biomass.

- **Cumulative Effects.** Cumulative effects for change in biomass are identified; however, the effects are insignificant since the combination of internal and external factors is not expected to sufficiently reduce the sablefish biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch
- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the spatial and temporal distribution of catch should have an insignificant effect on the genetic structure and reproductive success of the population (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure or reproductive success. While spatial/temporal concentration of catch occurred in the state directed sablefish fisheries, there are no lingering effects due to the migratory nature of the fish (see Section 3.5.1.3).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline and State of Alaska groundfish fisheries, and Canadian fisheries all have the potential to cause adverse effects. However, the removals are not expected to be sufficiently concentrated to alter the genetic structure of the population or affect recruitment. Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Any predation-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, it is determined that PA.1 and PA.2 would have insignificant effects on sablefish prey availability (see the direct/indirect effects discussion).

- **Persistent Past Effects.** While lingering population level effects from past foreign and domestic and state fisheries catch and bycatch of sablefish prey species are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on sablefish prey species (see Section 3.5.1.3).

- **Reasonably Foreseeable Future External Effects.** Future external effects of climate changes and regime shifts on sablefish prey species could be either beneficial or adverse since strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Likewise, a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment (see Section 3.5.1.3). Marine pollution has also been identified as a reasonably foreseeable external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The other fisheries shown on Table 4.5-5 are determined to be potentially adverse contributors since catch and bycatch of prey species are likely to continue.

- **Cumulative Effects.** Cumulative effects are identified for prey availability; however, the effects are insignificant since the combination of internal and external removals of prey is not expected to decrease prey availability such that the sablefish stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, any habitat-mediated impacts would be governed by a complex web of direct and indirect interactions which are difficult to quantify. PA.1 is not expected to impact habitat compared to baseline. Therefore, it is determined that PA.1 and PA.2 would have insignificant effects on sablefish habitat suitability (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects identified for sablefish include past foreign, JV, and domestic fisheries, the State of Alaska crab and bait fisheries, IPHC longline, and climate changes and regime shifts (see Section 3.5.1.3). Past fishing for sablefish in the past fisheries likely disrupted habitat in areas of the GOA and possibly the BSAI. It is possible that some of these areas have not recovered (see Section 3.6 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Future external effects are possible from the State of Alaska fisheries, and the IPHC fishery since any of these may impact bottom habitat through use of fishing gear. As described above for prey availability, impacts on habitat from climate changes and regime shifts on the sablefish stock could be either beneficial or adverse depending on water temperature. Marine pollution has also been identified as a potentially adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** Cumulative effects are identified for habitat suitability; however, the effects on the sablefish stock are insignificant since the combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the sablefish stock to sustain itself at or above MSST is jeopardized.

See Table 4.5-5 for a summary of the cumulative effects on BSAI and GOA sablefish under PA.1.

4.9.1.4 Atka Mackerel

This section provides the direct, indirect and cumulative effects analysis for Aleutian Islands and GOA Atka mackerel for each of the bookends under the preferred alternative. For further information regarding persistent past effects listed below in the text and in the tables see Section 3.5.1.4.

External effects and the resultant cumulative effects associated with PA.1 and PA.2 are depicted on Tables 4.5-6 and 4.5-7. For further information regarding persistent past effects listed below in the text and in the tables see Section 3.5.1.4.

Direct/Indirect Effects of PA.1

Model projections of future Aleutian Islands Atka mackerel catch and biomass levels under PA.1 assume the maximum permissible fishing mortality rate according to Amendment 56 ABC/OFL definitions.

GOA Atka mackerel are managed in Tier 6 because current estimates of total and spawning biomass are unknown for GOA Atka mackerel. Age structured models were not available for evaluation of impacts for the GOA; therefore, model projections of future biomass levels were not produced.

Catch and Fishing Mortality

The average expected yield for Aleutian Islands Atka mackerel for the period 2003-2007 is 62,700 mt (Table H.4-58 of Appendix H). The catch and ABC values, which are nearly equivalent in the projections, are expected to decrease through 2006. The average fishing mortality imposed on the Aleutian Islands Atka mackerel stock in 2002 is 0.251. Model projections show this value will increase to 0.436 in 2004, then decrease in 2005 and increase to 0.401 in 2007. Overall, the projections show a 60 percent increase in the average fishing mortality from 2002 to 2007. These values are well below the F_{MSY} proxy ($F_{35\%}$) value of 0.564 which is the rate associated with the OFL.

Projections of GOA Atka mackerel under PA.1 indicate that catches will likely average about 350 mt through 2007 (Table H.4-79 of Appendix H). Annual changes in the GOA Atka mackerel catches reflect shifts in catches of other species which catch Atka mackerel as bycatch (e.g. Pacific ocean perch, pollock, northern rockfish, and Pacific cod).

Total Biomass

Total (ages 1-15+) biomass of Aleutian Islands Atka mackerel at the start of 2002 is estimated to be 480,000 mt. Model projections of future total Aleutian Islands total biomasses are shown in Table H.4-58 of Appendix H. Under PA.1, model projections indicate that total Aleutian Islands Atka mackerel is expected to decline to a value of 415,000 mt by 2005, then increase to a value of 442,000 mt by 2007, with a 2003-2007 average value of 435,000 mt. Overall, the projections show an 8 percent decrease in total biomass from 2002 to 2007 under PA.1. These values for Aleutian Islands Atka mackerel total biomass are nearly identical to those projected under FMP 3.1.

Spawning Biomass

Spawning biomass of female Aleutian Islands Atka mackerel at the start of 2002 is estimated at 118,500 mt. Model projections of future Aleutian Islands spawning biomasses are shown in Table H.4-58 of Appendix H. Under PA.1, model projections indicate that Aleutian Islands spawning biomass is expected to decline to a value of 78,500 mt by 2005, then increase to a value of 88,000 mt by 2007, with a 2003-2007 average value of 88,900 mt. Overall, the projections show about a 26 percent decrease in female spawning biomass from 2002 to 2007 under PA.1. Projected spawning biomass exceeds the proxy B_{MSY} value ($B_{35\%}$) of 77,800 mt for the projection years (2003-2007). These values for Aleutian Islands Atka mackerel spawning biomass are nearly identical to those projected under FMP 3.1.

Spatial/Temporal Concentration of Fishing Mortality

Under PA.1, the current network of spatial and temporal closed areas is in place. The closures designated in the Steller sea lion protection measures probably have the largest impact relative to Atka mackerel. The 2002 Steller sea lion closures implemented under PA.1 include no fishing in Seguam Pass, 3 nm no transit zones around rookeries, and trawl and fixed gear closures in nearshore and Steller sea lion critical habitats.

The directed fishery for Atka mackerel is prosecuted by catcher processor bottom trawlers. The patterns of the fishery generally reflect the behavior of the species in that the fishery is highly localized, occurring in the same few locations each year, at depths that typically range between 100 and 200 m. The localized pattern of fishing for Atka mackerel apparently does not affect fishing success from one year to the next since local populations in the Aleutian Islands appear to be replenished by immigration and recruitment. In addition, management measures are in place which have the effect of spreading out the harvest in time and space. The overall Aleutian Islands TAC is allocated to three management areas (western, central, and Bering Sea/eastern Aleutians). The regional TACs are further allocated to two seasons and there are limits to the amount of catch that can be taken inside of Steller sea lion critical habitat. Because Steller sea lion critical habitat overlaps significantly with Atka mackerel habitat, these measures provide protection to Atka mackerel by reducing the risk of localized depletion through effort limitations and reductions. The temporal/spatial concentration of the catch under PA.1 does not appear to affect the sustainability of the stock either through changes in the genetic structure of the population or changes in reproductive success, as measured by the ability of the stock to maintain itself about its MSST.

Status Determination

Model projections of future catches of Aleutian Islands Atka mackerel are below the OFL in all years under PA.1 (Table H.4-58 of Appendix H). Female spawning biomass in each of the projection years (2003-2007), is above $B_{35\%}$ (B_{MSY} proxy), thus the Aleutian Islands Atka mackerel stock is not overfished and is determined to be above its MSST under PA.1.

GOA Atka mackerel are in Tier 6 and its MSST is unknown; therefore a status determination cannot be made.

Under PA.1, the ABC must be set below the OFL values. The OY range is specified to be between 1.4 and 2 million mt in the BSAI and between 116,000 and 800,000 mt in the GOA. In the BSAI, if the sum of TAC exceeds 2 million mt, then the TAC must be adjusted down. This means that the TAC, ABC and OFL values may all be reduced in the future for Aleutian Islands Atka mackerel under this preferred alternative bookend (same as FMP 1 and FMP 3.1). Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future, as well.

Age and Size Composition

Under PA.1, the mean age of Aleutian Islands Atka mackerel in 2007, as computed in model projections, is 2.73 years. This compares with a mean age in the equilibrium unfished Aleutian Islands stock of 3.82 years. Note that the mean ages and sizes actually observed in 2007 (as opposed to the model projections of mean age in 2007) will be driven largely by the strengths of incoming recruitments during the intervening years. The selectivity of the fishery has cumulative impacts on the age composition due to fishing mortality, and the current composition is also the result of its being a fished population with a greater than 30-year catch history. In the short-term, however, the impacts of the current fishing mortality levels on the stock would be overshadowed by the magnitude of incoming year-classes, which in turn are highly dependent on environmental conditions. The cumulative long-term impacts of the fishing mortality rates could cause a shift in the age and size compositions.

The level of catch of GOA Atka mackerel is low and projected to remain at a low level; therefore, it is unlikely that the age and size compositions would change in the future under PA.1. Changes in the age and size compositions of GOA Atka mackerel are more likely driven by variation in recruitment than due to the effects of fishing.

Sex Ratio

A 50:50 sex ratio is assumed for the Aleutian Islands Atka mackerel stock assessment and model projections. It is unknown what the true population sex ratio is, and what change, if any, would occur in the future. The current population sex ratio of GOA Atka mackerel is unknown. The true GOA population sex ratio, and what changes, if any, would occur in the future is unknown.

Habitat Suitability

Because Steller sea lion critical habitat overlaps significantly with Atka mackerel habitat, Steller sea lion protection measures may provide habitat protection for Atka mackerel through effort limitations and reductions. The level of habitat disturbance caused by the fishery under PA.1 does not appear to affect the sustainability of the stock as measured by the ability of the stock to maintain itself above its MSST. Current area closures would remain under PA.1, including the eastern GOA trawl closures. Programs to identify EFH and HAPC would continue and a process for establishing MPAs would be developed.

Predator-Prey Relationships

The trophic interactions of Atka mackerel are governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1. In a study conducted by Yang (1996), more than 90 percent of the total stomach contents weight of Atka mackerel in the study was made up of invertebrates, with less than 10 percent made up of fish. Based on the low proportion of fish found in the diet of Atka mackerel, it is presumed that PA.1 will not impact prey availability for Aleutian Islands and GOA Atka mackerel. The $B_{20\%}$ rule will remain under PA.1 since Akta mackerel are an important prey species for many members of the Aleutian Islands and GOA ecosystem (same as FMP 1 and FMP 3.1).

See Table 4.9-1 for a summary of the direct/indirect effects on Aleutian Islands and GOA Atka mackerel under PA.1.

Cumulative Effects of PA.1 – Aleutian Islands Atka Mackerel

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the Aleutian Islands Atka mackerel stock is insignificant under PA.1 (see the direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects of the foreign, JV, and domestic fisheries are not expected for the Aleutian Islands Atka mackerel stock. While large removals of Atka mackerel did occur in the past, there does not appear to be a lingering effect on the Aleutian Islands Atka mackerel populations (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Marine pollution has been identified as the only external event that could cause effects on the Aleutian Islands Atka mackerel population. Acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not considered contributors to Atka mackerel mortality.

- **Cumulative Effects.** Cumulative effects under PA.1 are identified for mortality of Aleutian Islands Atka mackerel, but the effects are judged to be insignificant. Atka mackerel are fished at less than the OFL and are above the MSST. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the Aleutian Islands Atka mackerel stock is expected to be insignificant under PA.1 (see the Atka mackerel PA.1 direct/indirect effects discussion).

- **Persistent Past Effects.** While past large removals of Atka mackerel and other past effects on biomass have been identified (see Section 3.5.1.4), these do not appear to have had a lingering effect on the ability of the stock to sustain itself above the MSST.

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as having a reasonably foreseeable, potentially adverse contribution to change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are not considered contributors to Atka mackerel mortality, and therefore would not directly affect biomass.

- **Cumulative Effects**. A cumulative effect for change in biomass is identified; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently reduce the Atka mackerel biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch
  – Change in Genetic Structure of Population
  – Change in Reproductive Success

- **Direct/Indirect Effects.** The temporal/spatial concentration of the catch under PA.1 does not appear to affect the sustainability of the stock either through changes in the genetic structure of the population or changes in reproductive success, as measured by the ability of the stock to maintain itself about its MSST and the effect is judged insignificant (see the Atka mackerel PA.1 direct/indirect effects section above).

- **Persistent Past Effects.** Since the Atka mackerel fishery was highly localized, past foreign, JV, and domestic fisheries are found to have had lingering effects on the spatial/temporal distribution of the fish. However, the effect of this change in distribution on genetic structure is unknown. Past commercial whaling and sealing removed large predators of Atka mackerel adding to the potential for reproductive success of the stock. Lingering past effects are also identified due to climate changes and regime shifts (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment. Climate changes and regime shifts could have potentially beneficial or potentially adverse effects on Atka mackerel reproductive success. A shift toward colder waters favors recruitment and survival of Atka mackerel. Conversely, warmer waters are potentially adverse.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration; however, the effect is insignificant since the combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** Based on the low proportion of fish found in the diet of Atka mackerel, it is presumed that PA.1 will have an insignificant effect on prey availability for Aleutian Islands Atka mackerel (see the Atka mackerel PA.1 direct/indirect effects discussion).

- **Persistent Past Effects.** While lingering population level effects from past foreign and domestic fisheries catch and bycatch of Atka mackerel prey species are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on Atka mackerel prey species (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Climate changes and regime shifts could have potentially beneficial or potentially adverse effects on Atka mackerel reproductive success. A shift toward colder waters favors recruitment and survival of Atka mackerel. Conversely, warmer waters are potentially adverse. Marine pollution has also been identified as a reasonably foreseeable external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** Cumulative effects are identified for prey availability; however, the effect is insignificant since the combination of internal and external removals of prey species is not expected to decrease prey availability such that the Atka mackerel stock is unable to sustain itself at or above MSST.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** Habitat disturbances caused by the fishery under PA.1 do not appear to affect the sustainability of the stock as measured by the ability of the stock to maintain itself above its MSST ,and the effect is judged insignificant (see the Atka mackerel PA.1 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects identified for Aleutian Islands Atka mackerel stocks include past foreign, JV, and domestic fisheries, and climate changes and regime shifts (see Section 3.5.1.4). Intense bottom trawling for Atka mackerel in the past fisheries likely disrupted habitat in areas of the Aleutian Islands. It is possible that some of these areas have not recovered from the intense efforts (see Section 3.6 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Impacts on habitat from the climate changes and regime shifts could be either beneficial or adverse. Marine pollution has also been identified as a potentially adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for habitat suitability; however, the effect on the Aleutian Islands Atka mackerel stock is insignificant since the combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the Atka mackerel stock to sustain itself at or above MSST is jeopardized.

See Table 4.5-6 for a summary of cumulative effects on Aleutian Islands Atka mackerel under PA.1.

GOA Atka Mackerel

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA Atka mackerel stock is unknown under PA.1. The fishing mortality rate and the MSST for GOA Atka mackerel is unknown, thus the effect of fishing mortality is unknown under PA.1.

- **Persistent Past Effects**. Past effects of the past foreign, JV, and domestic, fisheries are likely for the GOA Atka mackerel stock. Large, concentrated removals of Atka mackerel occurred in the foreign, domestic, JV, and fisheries, have had a lingering effect on the GOA Atka mackerel population that has not yet recovered (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as having a potentially adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the population is jeopardized. Climate changes and regime shifts are not considered contributors to Atka mackerel mortality.

- **Cumulative Effects.** A cumulative effect under PA.1 is identified for mortality of GOA Atka mackerel, but the significance of the effect is unknown. GOA Atka mackerel are in Tier 6 and their MSST is unknown; therefore a status determination cannot be made.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the GOA Atka mackerel stock is unknown PA.1. Current reliable estimates of total and spawning biomass are unknown for GOA Atka mackerel.

- **Persistent Past Effects**. Past effects of the past foreign, JV, and domestic fisheries are identified for the GOA Atka mackerel stock. Large, concentrated removals of Atka mackerel occurred in the foreign, JV, domestic fisheries and are determined to have had a lingering effect on the GOA Atka mackerel population, which has not yet recovered (see Section 3.5.1.4)

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as having a potentially adverse contribution to the change in biomass since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the population is affected. Climate changes and regime shifts are not considered contributors to Atka mackerel mortality, and therefore would not directly affect biomass.

- **Cumulative Effects.** A cumulative effect is identified for the change in biomass; however, the significance of the effect is unknown.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** As the MSST cannot be estimated for GOA Atka mackerel which are in Tier 6, the significance of the spatial temporal concentration effects are also unknown under PA.1.

- **Persistent Past Effects.** Since the Atka mackerel fishery was highly localized, past foreign, JV, and domestic fisheries are found to have had lingering effects on the spatial/temporal distribution of the fish. However, the effect of this change in distribution on genetic structure is unknown. The past highly localized fisheries are found to have had lingering effects on the spatial/temporal distribution of the fish. Also, there are lingering past effects due to climate changes and regime shifts (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Marine pollution could contribute adversely to genetic changes and reduced recruitment since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment. Also, climate changes and regime shifts are could impact spawning success since a shift toward colder waters favors recruitment and survival of Atka mackerel. Conversely, warmer waters are potentially adverse.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration; however, the significance of the effect is unknown.

Change in Prey Availability

- **Direct/Indirect Effects.** Due to the low proportion of fish found in the diet of Atka mackerel, it is presumed that PA.1 will not impact prey availability for GOA Atka mackerel and the impact to the prey availability effect is determined to be insignificant.

- **Persistent Past Effects.** While lingering population level effects on the invertebrate prey of Atka mackerel from past foreign, state, and domestic fisheries, and EVOS are not expected, past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on Atka mackerel prey species (see Section 3.5.1.4).

- **Reasonably Foreseeable Future External Effects.** Future external effects of climate changes and regime shifts on Atka mackerel prey species could be either beneficial or adverse depending on the direction of change. Marine pollution has also been identified as a reasonably foreseeable external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself.

- **Cumulative Effects.** A cumulative effect is identified for prey availability; however, the significant effects are unknown since the direction of external effects is unknown.

Change in Habitat Suitability

- **Direct/Indirect Effects.** As the MSST cannot be estimated for GOA Atka mackerel which are in Tier 6, the significance of the habitat suitability effects are also unknown under PA.1.

- **Persistent Past Effects.** Past effects on habitat suitability identified for GOA Atka mackerel stocks include past foreign, JV, and domestic fisheries, EVOS, and climate changes and regime shifts (see Section 3.5.1.4). Intense bottom trawling for Atka mackerel in the past fisheries likely disrupted habitat in areas of the GOA. It is possible that some of these areas have not recovered from the intense efforts (see Section 3.6 for additional information on the effects of trawling on benthic habitat).

- **Reasonably Foreseeable Future External Effects.** Impacts on habitat from the climate changes and regime shifts on the GOA Atka mackerel could be either favorable or unfavorable depending on the direction of change. Marine pollution has also been identified as a potentially adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** Cumulative effects are identified for habitat suitability; however, the significance of the effects on the Aleutian Islands Atka mackerel stock are unknown.

See Table 4.5-7 for a summary of the cumulative effects on GOA Atka mackerel under PA.1.

Direct/Indirect Effects of PA.2

Model projections of future Aleutian Islands Atka mackerel catch and biomass levels under PA.2 assume an uncertainty correction applied to the maximum permissible fishing mortality rate according to Amendment 56 ABC/OFL definitions.

GOA Atka mackerel are managed in Tier 6 because current estimates of total and spawning biomass are unknown for GOA Atka mackerel. Age structured models were not available for evaluation of impacts for the GOA, therefore model projections of future biomass levels were not produced.

Catch and Fishing Mortality

The average expected yield for Aleutian Islands Atka mackerel for the period 2003-2007 is 52,390 mt. The catch and ABC values (which are nearly equivalent after 2004) are expected to decrease through 2006. The average fishing mortality imposed on the Aleutian Islands Atka mackerel stock in 2002 is 0.251 (Table H.4-58 of Appendix H). Model projections show this value will increase to 0.309 in 2005, then decrease to 0.304 in 2007. Overall, the projections show a 21 percent increase in the average fishing mortality from 2002 to 2007. These values are well below the F_{MSY} proxy ($F_{35\%}$) value, which is the rate associated with the OFL.

Projections of GOA Atka mackerel under PA.2 indicate that catches will likely average a little over 150 mt through 2007 (Table H.4-79 of Appendix H). Annual changes in the GOA Atka mackerel catches reflect shifts in catches of other species which catch Atka mackerel as bycatch (e.g. Pacific ocean perch, pollock, northern rockfish, and Pacific cod).

Total Biomass

Total (ages 1-15+) biomass of Aleutian Islands Atka mackerel at the start of 2002 is estimated to be 480,000 mt. Model projections of future total Aleutian Islands total biomasses are shown in Table H.4-58 of Appendix H. Under PA.2, model projections indicate that total Aleutian Islands Atka mackerel biomass is expected to decline to a value of 451,000 mt by 2004, then increase to a value of 470,000 mt by 2007, with a 2003-2007 average value of 459,000 mt. Overall, the projections show a 2 percent decrease in total biomass from 2002 to 2007 under PA.2. These values for Aleutian Islands Atka mackerel total biomass are nearly identical to those projected for FMP 3.2.

Spawning Biomass

Spawning biomass of female Aleutian Islands Atka mackerel at the start of 2002 is estimated at 118,500 mt. Model projections of future Aleutian Islands spawning biomasses are shown in Table H.4-58 of Appendix H. Under PA.2, model projections indicate that Aleutian Islands spawning biomass is expected to decline to a value of 93,500 mt by 2005, then increase to a value of 100,700 mt by 2007, with a 2003-2007 average value of 101,700 mt. Overall, the projections show a 15 percent decrease in spawning biomass from 2002 to 2007 under PA.2. Projected spawning biomass exceeds the B_{MSY} proxy value ($B_{35\%}$) of 77,800 mt for the projection years (2003-2007). These values for Aleutian Islands Atka mackerel spawning biomass are nearly identical to those projected for FMP 3.2.

Spatial/Temporal Concentration of Fishing Mortality

Under PA.2, NPFMC and NOAA Fisheries would consider establishing 0-20 percent of the Bering Sea, Aleutian Islands and GOA as MPAs and no-take marine reserves across a range of habitat types (similar to FMP 3.2). The spatial closures illustrated in the FMP 3.2 map (Figure 4.2-5, Section 4.2) in the Aleutian Islands under PA.2 would likely impact the directed fishery for Atka mackerel. Based on locations of historical Atka mackerel fishing effort, some catches of Atka mackerel are likely to be displaced under PA.2, but it is assumed that these catches could be taken (at least in the short-term) in the remaining open areas. As such, the temporal/spatial concentration of the catch will likely increase under PA.2. Because Atka mackerel are a patchily distributed fish and the harvest is concentrated in specific locations, there is an increased risk of localized depletion that may occur under this preferred alternative bookend. However, PA.2 is not likely to adversely affect the sustainability of the stock (at least in the short-term) either through changes in the genetic structure of the population or changes in reproductive success, as measured by the ability of the stock to maintain itself above its MSST.

Status Determination

Model projections of future catches of Aleutian Islands Atka mackerel are below the OFL in all years under PA.2 (Table H.4-58 of Appendix H). Estimates of female spawning biomass in each of the projection years (2003-2007), are above $B_{35\%}$ (B_{MSY} proxy), thus the Aleutian Islands Atka mackerel stock is not overfished and is determined to be above its MSST under PA.2.

GOA Atka mackerel are in Tier 6 and its MSST is unknown; therefore a status determination cannot be made.

Calculation of the OY caps for the BSAI and GOA would be revisited to determine relevance to current environmental conditions and current stock information. Procedures to account for the uncertainty in estimating ABC for Aleutian Islands and GOA Atka mackerel under PA.2 would be updated as necessary, and may be modified to account for ecosystem interactions and production patterns/trends. Ecosystem indicators will also be developed and implemented as part of the TAC-setting process, as appropriate. Programs designed to collect biological information necessary to determine spawning stock biomass estimates would be improved under PA.2, which could affect the catch limits of GOA Atka mackerel, currently a Tier 6 species with no biomass data available. These changes may increase or reduce catch limits for Aleutian Islands and GOA Atka mackerel in the future. TAC values must be set at levels equal to or less than the ABC for all target species under PA.2.

Age and Size Composition

Under PA.2, the mean age of Aleutian Islands Atka mackerel in 2007, as computed in model projections, is 2.85 years. This compares with a mean age in the equilibrium unfished Aleutian Islands stock of 3.82 years. Note that the mean ages and sizes actually observed in 2007 (as opposed to the model projections of mean age in 2007) will be driven largely by the strengths of incoming recruitments during the intervening years. The selectivity of the fishery has cumulative impacts on the age composition due to fishing mortality, and the current composition is also the result of its being a fished population with a greater than 30-year catch history. In the short-term however, the impacts of the current fishing mortality levels on the stock would be overshadowed by the magnitude of incoming year-classes, which in turn are highly dependent on environmental conditions. The cumulative long-term impacts of the fishing mortality rates could cause a shift in the age and size compositions.

The level of catch of GOA Atka mackerel is low and projected to remain at a low level; therefore, it is unlikely that the age and size compositions would change in the future under PA.2. Changes in the age and size compositions of GOA Atka mackerel are more likely driven by variation in recruitment than due to the effects of fishing.

Sex Ratio

A 50:50 sex ratio is assumed for the Aleutian Islands Atka mackerel stock assessment and model projections. It is unknown what the true population sex ratio is, and what change, if any, would occur in the future. The current population sex ratio of GOA Atka mackerel is unknown. The true GOA population sex ratio, and what changes, if any, would occur in the future is unknown.

Habitat Suitability

The spatial closures in the Aleutian Islands under PA.2 could eliminate some Atka mackerel fishery areas while increasing effort in the fewer remaining open areas (similar to FMP 3.2). The level of habitat disturbance would decrease in the closed areas, but increase in the remaining open areas. However, PA.2 is not likely to adversely affect the sustainability of the stock (at least in the short-term) as measured by the ability of the stock to maintain itself above its MSST. The removal of directed fishing in some areas may lead to habitat improvement, but whether this would translate into improved reproductive success is uncertain.

Under PA.2, the 2002 Steller sea lion closures and Aleutian Islands critical habitat designations would be modified as deemed necessary and as new scientific information becomes available. Existing fishery closures would be reviewed to determine if some areas qualify as MPAs; others may be redesignated as fishery- or gear-specific. Programs to identify and designate EFH and HAPC would continue and an Aleutian Islands management area would be established to protect coral and live bottom habitats. All these measures may help protect important Atka mackerel habitat where overlap occurs.

Predator-Prey Relationships

The trophic interactions of Atka mackerel are governed by a complex web of indirect interactions, which are currently difficult to quantify. Under PA.2, elimination of the directed fishery for Atka mackerel in some areas and increased effort in other areas could impact the amount of Atka mackerel available to the ecosystem. In a study conducted by Yang (1996), more than 90 percent of the total stomach contents weight of Atka mackerel in the study was made up of invertebrates, with less than 10 percent made up of fish. Based on the low proportion of fish found in the diet of Atka mackerel, it is presumed that PA.2 will not impact prey availability for Aleutian Islands and GOA Atka mackerel. The $B_{20\%}$ rule will remain under PA.2 since Atka mackerel is an important prey species for many members of the Aleutian Islands and GOA ecosystem.

See Table 4.9-1 for a summary of the direct/indirect effects on Aleutian Islands and GOA Atka mackerel under PA.2.

Cumulative Effects of PA.2 – Aleutian Islands Atka Mackerel

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the Aleutian Islands Atka mackerel stock is insignificant under PA.2 (see the Atka mackerel PA.2 direct/indirect effects discussion).

- **Persistent Past Effects.** on Atka mackerel mortality are the same as those described under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on Atka mackerel mortality are the same as those described under PA.1.

- **Cumulative Effects**. A cumulative effect under PA.2 is identified for mortality of Aleutian Islands Atka mackerel, but the effect is judged to be insignificant. Atka mackerel are fished at less than the OFL and are above the MSST. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the Aleutian Islands Atka mackerel stock is expected to be insignificant under PA.2 (see the Atka mackerel PA.2 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on the change in biomass of Atka mackerel are the same as those indicated under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in biomass of Atka mackerel are the same as those indicated under PA.1.

- **Cumulative Effects.** A cumulative effect for change in biomass is identified. The effect is determined to be insignificant since the combination of internal and external factors is not likely to decrease the Aleutian Islands Atka mackerel biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** PA.2 is not likely to adversely affect the sustainability of the Aleutian Islands stock (at least in the short-term) either through changes in the genetic structure of the population or changes in reproductive success, as measured by the ability of the stock to maintain itself above its MSST and the effect is judged to be insignificant (see the Atka mackerel PA.2 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on the spatial and temporal characteristics of Aleutian Islands Atka mackerel are the same as those described under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the spatial and temporal characteristics of Atka mackerel are the same as those described under PA.1.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration; the effect is insignificant for change in the genetic structure of the population because there is no evidence of genetic sub-population structure. The cumulative effect on reproductive success is also judged insignificant.

Change in Prey Availability

- **Direct/Indirect Effects.** Any predation-mediated impacts of PA.2 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. However, the effect is judged insignificant (see the Atka mackerel PA.2 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects on the change in prey availability of Atka mackerel are the same as those indicated under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in prey availability of Atka mackerel are the same as those indicated under PA.1.

- **Cumulative Effects.** Cumulative effects are identified for prey availability; however, the effects are insignificant since the combination of internal and external removals of prey species is not expected to decrease prey availability such that the Aleutian Islands Atka mackerel stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** The reduction of the fishery under this PA.2 may lead to habitat improvement, but the effect on the stock's ability to maintain itself above its MSST is judged insignificant (see Aleutian Islands Atka mackerel PA. 2 direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects identified for Aleutian Islands Atka mackerel stocks are the same as those indicated under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects identified for Aleutian Islands Atka mackerel stocks are the same as those indicated under PA.1.

- **Cumulative Effects**. A cumulative effect is identified for habitat suitability; however, the effect on the Aleutian Islands Atka mackerel stock is insignificant since the combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the Atka mackerel stock to sustain itself at or above MSST is jeopardized.

See Table 4.5-6 for a summary of the cumulative effects on Aleutian Islands Atka mackerel under PA.2.

GOA Atka Mackerel

GOA Atka mackerel are managed in Tier 6 because current estimates of total and spawning biomass are unknown for GOA Atka mackerel. Age structured models were not available for evaluation of impacts for the GOA, therefore model projections of future biomass levels were not produced. Therefore, the direct and indirect effects of the PA.2 are unknown for all categories with the exception of prey availability. In addition, the external effects and cumulative effects are the same as those described above for PA.1 in the GOA. Since all of the internal effects on mortality, biomass, spatial/temporal concentration, and habitat are unknown, the cumulative effects on GOA Atka mackerel are also unknown (see Table 4.5-14).

The internal effects of the PA.2 on change in prey availability is judged insignificant because the main prey items for Atka mackerel are invertebrates. However, the cumulative effect for this category is also judged unknown since the direction of the external effects is unknown.

As part of PA.2, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future change in Tier designation for GOA Atka mackerel. Procedures to account for uncertainty in estimating ABC would be revised and updated as necessary and ecosystem interactions would be considered when determining catch limits. All these measures may affect the TAC, ABC and OFL values of GOA Atka mackerel in the future under PA.2. Although, as stated above, impacts to Atka mackerel mortality and biomass levels are unknown.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the GOA as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and pollock bottom trawling would be banned in the entire GOA. Inseason bycatch closures will be developed in the GOA under PA.2. EFH and HAPC identification, designation, and assessment would continue and mitigation measures instituted as needed. 2002 SSL closures may also be modified as seen necessary under this preferred alternative bookend. These measures may help reduce adverse impacts to GOA Atka mackerel habitat where overlap occurs; although, as stated above, impacts to Atka mackerel habitat suitability are unknown.

4.9.1.5 Yellowfin Sole and Shallow Water Flatfish

Numerous fishery management actions have been implemented that affect the yellowfin sole fisheries in the BSAI. These actions are described in more detail in Section 3.5.1.5 of this Programmatic SEIS. Yellowfin sole is managed as its own stock under the Aleutian Islands Groundfish FMP under the Tier 3 management category, thus MSSTs are defined for these species by the National Standard Guidelines.

Eight flatfish species inhabit shallow waters and are managed in the shallow water flatfish assemblage in the GOA. They include: northern and southern rock sole, yellowfin sole, starry flounder, butter sole, English sole, Alaska plaice and sand sole. Survey results from 2001 indicate that over half of the estimated biomass (54 percent) of this assemblage are northern and southern rock sole. The shallow water group is managed as Tier 4 and Tier 5 species in the GOA (Turnock *et al.* 2001).

External effects associated with the preferred alternative bookends, PA.1 and PA.2, are depicted on Tables 4.5-8 and 4.5-9 for BSAI yellowfin sole and GOA shallow water flatfish, respectively. For further information regarding persistent past effects listed below in the text and in Tables 4.5-8 and 4.5-9, refer to Section 3.5.1.5.

BSAI Yellowfin Sole – Direct/Indirect Effects of PA.1 and PA.2

Total Biomass

The total biomass of yellowfin sole at the start of 2002 is estimated to be 1,552,000 mt. Model projections of future total BSAI biomass estimates are shown in Table H.4-45 of Appendix H. Under PA.1, model projections indicate that the total BSAI biomass is expected to decline to 1,520,000 in 2007 with a 2003-2007 average total biomass of 1,532,000 mt. Under PA.2, model projections indicate that the total BSAI biomass is expected to decline to 1,519,000 in 2007 with a 2003-2007 average value is 1,532,000 mt.

Spawning Biomass

Spawning biomass of female yellowfin sole at the start of 2002 is estimated to be 450,700 mt. Model projections of future yellowfin sole spawning biomass estimates are shown in Table H.4-45 of Appendix H. Under PA.1, model projections indicate that female spawning biomass is expected to decline to 408,900 mt by 2007, with a 2003-2007 average value of 433,800 mt. Under PA.2, model projections indicate that female spawning biomass is expected to decline to the 2002 value to 408,600 mt by 2007, with a 2003-2007 average value of 434,000 mt. Projected female spawning biomass is estimated to be above the B_{MSY} proxy value of 336,900 mt throughout the five year projection.

Fishing Mortality

The average annual fishing mortality imposed on the yellowfin sole stock in 2002 is 0.064. Under PA.1, model projections show this value will steadily increase to 0.099 in 2007. Under PA.2, model projections show this value will increase to 0.101 in 2007 with an average value of 0.084 from 2003-2007. These values are well below the F_{MSY} proxy value of 0.138, the rate associated with the OFL (Table H.4-45 of Appendix H). BSAI yellowfin sole may be limited somewhat by Pacific halibut PSC limits which could undergo a reduction between 0 and 10 percent under PA.1 and between 0 and 20 percent under PA.2.

Spatial/Temporal Concentration of Fishing Mortality

It is unknown what spatial/temporal characteristics of the annual BSAI yellowfin sole harvest would be affected under PA.1 since it is unknown what MPA efficacy methodology would be developed under this bookend. Bycatch management would include closing hot-spot areas which could disperse fishing locations in both time and space (including high Pacific halibut bycatch areas). Existing closures would be retained under PA.1, including existing inseason bycatch closures. As stated above, BSAI yellowfin sole may be limited temporally by Pacific halibut PSC limits.

As part of PA.1, an IR/IU program would be initiated for BSAI yellowfin sole. The IR/IU program is designed to reduce discard waste of BSAI yellowfin sole by allowing the fishing industry to develop new methods for avoiding unwanted bycatch and/or through the development of new markets for the bycatch. This program was previously initiated by NOAA Fisheries on January 1, 2003 (BSAI FMP Amendment 75), but was suspended on February 7, 2003 due to the need for clarification in the regulation. Discards occur mostly in the directed yellowfin sole fishery, and also occur in the Pacific cod, rock sole, flathead sole and other flatfish fisheries (Wilderbuer and Nichol 2002).

It is unknown what goals, objectives and criteria would be developed under PA.2 to allocate TAC in space and time. Since PSC limits are reduced and fishing is restricted to previous areas, it is unlikely that fishing effort would expand in space and time but would rather tend to be more concentrated then the baseline 2002 fishery. Closure areas under PA.2 are similar to those described under FMP 3.2 and are illustrated in the FMP 3.2 map (Figure 4.2-5) described in Section 4.2.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the Bering Sea, Aleutian Islands and GOA as MPAs and no-take marine reserves across a range of habitats (Figure 4.2-5, FMP 3.2 map). Programs to identify, designate and assess EFH and HAPC would be continue under this preferred alternative bookend. These measures, among others, may help reduce adverse impacts to BSAI yellowfin sole habitat where overlap occurs.

Status Determination

Model projections of future catches of BSAI yellowfin sole are below the OFLs in all years under PA.1 and PA.2. The yellowfin sole stock is above the MSST level in 2002.

Under PA.1, the ABC must be set below the OFL values. The OY range is specified to be between 1.4 and 2 million mt in the BSAI. In the BSAI, if the sum of TAC exceeds 2 million mt, then the TAC must be adjusted down. This means that the TAC, ABC and OFL values may all be reduced in the future for BSAI yellowfin sole under this preferred alternative bookend (same as FMP 1 and FMP 3.1). Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future, as well.

Procedures to account for the uncertainty in estimating ABC for BSAI yellowfin sole under PA.2 would be updated as necessary, and may be modified to account for ecosystem interactions and production patterns/trends. Ecosystem indicators will also be developed and implemented as part of the TAC-setting process, as appropriate. These changes may increase or reduce catch limits for BSAI yellowfin sole in the future. TAC values must be set at levels equal to or less than the ABC for all target species under PA.2. PA.2 would reconsider OY caps in relation to existing environmental and stock status conditions.

Age and Size Composition

Under PA.1 and PA.2, the mean age of the BSAI yellowfin sole stock in 2008, as computed in model projections (Table H.4-45 of Appendix H), is 6.23 years. This compares with a mean age in the equilibrium unfished BSAI stock of 8.04 years. Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

The sex ratio of yellowfin sole in the BSAI is assumed to be 50:50. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this preferred alternative.

Current closure areas would remain under PA.1. Definitions and methodology for establishing MPAs would be developed. The Seguam Pass area would be closed to fishing, 3 nm no transit zones would be established around rookeries, and nearshore and critical habitat areas would be closed to trawl and fixed gear as Steller sea lion protection measures. These implemented measures may help reduce adverse impacts to important yellowfin sole habitat when overlap occurs.

As stated above, NOAA Fisheries and NPFMC would consider adopting 0 to 20 percent of the Bering Sea as MPAs and no-take marine reserves under PA.2. Existing fishery closures would be reviewed to determine if some areas qualify as MPAs; others may be redesignated as fishery- or gear-specific. Programs to identify and designate EFH and HAPC would also be continued. All these measures may help protect important yellowfin habitat where overlap occurs.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 on yellowfin sole would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1 and PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects on EBS yellowfin sole under PA.1 and PA.2.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the yellowfin sole is rated as insignificant under PA.1 and PA.2 (see the EBS yellowfin sole direct/indirect effects discussion). Under PA.1 and PA.2, the annual fishing mortality values are below the F_{MSY} proxy value of 0.138. Therefore, PA.1 and PA.2 are expected to have insignificant impacts on these stocks.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the yellowfin sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potentially adverse contributions of marine pollution since acute and/or chronic pollution events could cause yellowfin sole mortality. Climate changes and regime shifts are not considered as contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of yellowfin sole.

- **Cumulative Effects.** A cumulative effect is possible for mortality of BSAI yellowfin sole, but is rated as insignificant. Fishing mortality at projected levels is below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

- **Direct/Indirect Effects.** PA.1 or PA.2 are expected to result in insignificant effects to these stocks (see the BSAI yellowfin sole direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects have not been identified for the change in biomass in the yellowfin sole stock.

- **Reasonably Foreseeable Future External Effects**. Future external effects on the change in biomass are indicated due to the potentially adverse contributions of marine pollution since acute and/or chronic pollution events could cause yellowfin sole mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse contributions to the yellowfin sole biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. For more information on climate changes and regime shifts, please see Sections 3.5.1.5 and 3.10.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI yellowfin sole, but is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock and the spawning biomass is above the B_{MSY} value. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1and PA.2, the effect of the spatial/temporal concentration of catch is considered insignificant for the stock (see the BSAI yellowfin sole direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects are not identified for spatial/temporal concentration of BSAI yellowfin sole catch.

- **Reasonably Foreseeable Future External Effects.** As described for biomass, effects on the reproductive success of yellowfin sole due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as having a potentially adverse contribution since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of yellowfin sole.

- **Cumulative Effects**. A cumulative effect is possible for the spatial/temporal concentration of the yellowfin sole catch; the effect is ranked as insignificant. The spatial and temporal distribution of yellowfin sole catch is not expected to change significantly. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects**. Under PA.1 and PA.2, the change in prey availability for the yellowfin sole is ranked as insignificant (see the yellowfin sole direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects are identified for the change in prey availability of the yellowfin sole stock and include climate changes and regime shifts. Crab and shrimp have shown variation in abundance associated with changes in climate and water temperatures. However, studies on most benthic invertebrates have not been conducted (see Sections 3.5.1.5 and 3.10).

- **Reasonably Foreseeable Future External Effects.** As described for biomass, effect of the climate changes and regime shifts on the EBS yellowfin sole stock are potentially beneficial or adverse. Marine pollution has also been identified as having a potentially adverse contribution.

- **Cumulative Effects.** Cumulative effects are identified for change in prey availability; however, these effects are considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the yellowfin sole is ranked as insignificant (see the yellowfin sole direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects identified for yellowfin sole include climate changes and regime shifts. In the past, when the Aleutian Low was strong and water temperatures warm, catch tended to be dominated by flatfish species, implying increased recruitment. In contrast, when the Aleutian Low was weak and water temperatures cooler, catch tended to be dominated by shrimp. Persistent past contributions of the foreign, JV, and domestic fisheries gear impacts are described in Section 3.5.1.5 and Section 3.6.

- **Reasonably Foreseeable Future External Effects.** As described above, the effects of the climate changes and regime shifts on the yellowfin sole stock are potentially beneficial or adverse.

- **Cumulative Effects.** Cumulative effects are identified for yellowfin sole habitat suitability; however, these effects are considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the yellowfin sole stock to sustain itself at or above the MSST is jeopardized.

See Table 4.5-8 for a summary of the cumulative effects on yellowfin sole under PA.1 and PA.2.

GOA Shallow Water Flatfish – Direct/Indirect Effects of PA.1 and PA.2

Total and Spawning Biomass

Estimated total and spawning biomass is not available for GOA shallow water flatfish.

Fishing Mortality

The catch of GOA shallow water flatfish in 2002 was estimated to be 6,800 mt. Model projections of future catch are shown in Table H.4-68 of Appendix H. Under PA.1, model projections indicate that the catch is expected to decrease from 5,900 mt in 2003 to 4,900 mt in 2007. The 2003-2007 average value is 5,600 mt. However, the shallow water flatfish fishery is likely to be limited by Pacific halibut PSC limits. Under PA.2, model projections indicate that the catch is expected to decrease to 5,000 in 2007 with a 2003-2007 average of 5,000 mt. GOA shallow water flatfish catch is likely to be limited by Pacific halibut PSC limits, which are projected to be reduced by 0-10 percent under PA.2

There is a danger within stock complexes to fish one species disproportionately to the other and create localized depletions. As part of PA.2, the Observer Program would continue with improvements. These improvements include the enhancement of training programs that would increase the number of species identified by observers. Observer uncertainty estimates for target species data would also be developed. Criteria for the ‘splitting and lumping’ of stock complexes and procedures to account for uncertainty when establishing ABC values would be developed, implemented, and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future changes in Tier designation for GOA shallow water flatfish.

The anticipated low levels of exploitation of GOA shallow water flatfish under PA.1 and PA.2 would have insignificant effects on these stocks through mortality.

Spatial/Temporal Concentration of Fishing Mortality

It is unknown what spatial/temporal characteristics of the annual GOA shallow water flatfish harvest would be affected under PA.1 since it is unknown what MPA efficacy methodology would be developed under this bookend. Bycatch management would include closing hot-spot areas which could disperse fishing locations in both time and space. Existing closures would remain under PA.1, including inseason bycatch closures.

As part of PA.1, an IR/IU program for GOA shallow water flatfish would be implemented. The IR/IU program is designed to reduce discard waste by encouraging the fishing industry to develop methods to avoid high bycatch areas and/or develop markets for the bycatch. This program was previously initiated by NOAA Fisheries on January 1, 2003 (BSAI FMP Amendment 75), but was suspended on February 7, 2003 due to the need for clarification in the regulation. As mentioned above, the shallow water flatfish fishery is likely to be limited temporally due to the attainment of Pacific halibut PSC limits.

Under PA.1, the Observer Program would continue, although training programs designed to increase species identifications would not be included, and station improvements as described under FMP 3.2 would not occur in the immediate future. However, uncertainty estimates would be developed and revised.

The shallow water flatfish fishery may be restricted by Pacific halibut PSC limits, which are projected to be reduced by 0-20 percent in the GOA under PA.2. This in combination with the development of inseason bycatch closures (for hotspot areas) could temporally and spatially restrict the fishery. However, the effects of these measures on the spatial and temporal characteristics of the stock complex is unknown.

Status Determination

The available information for flatfish species in the shallow water complex requires that they are classified into either the Tier 4 or Tier 5 management category. As a result, no MSSTs are defined for these species in the National Standard Guidelines. Therefore, it is not possible to determine their status. Under PA.1 and PA.2, the ABC must be set below the OFL; under PA.1 the sum of the TACs must be within the OY (116,000-800,000 mt for the GOA). Under PA.2, OY caps would be reconsidered in light of their relevancy to current environmental conditions and knowledge of stock levels.

Age and Size Composition

Age and size composition projections are not available for GOA shallow water flatfish.

Sex Ratio

The sex ratio of shallow water flatfish in the GOA is assumed to be 50:50. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions which are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this preferred alternative.

Current closure areas would remain under PA.1, including the eastern GOA trawl closure. Definitions and methodology for establishing MPAs would be developed. The Seguam Pass area would be closed to fishing, 3 nm no transit zones would be established around rookeries, and nearshore and critical habitat areas would be closed to trawl and fixed gear as Steller sea lion protection measures. These implemented measures may help reduce adverse impacts to important shallow water flatfish habitat when overlap occurs.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the GOA as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and pollock bottom trawling would be banned in the entire GOA. EFH and HAPC identification, designation, and assessment would continue and mitigation measures instituted as needed. These measures may help reduce adverse impacts to GOA shallow water flatfish habitat where overlap occurs, although, as stated above, impacts to shallow water flatfish habitat suitability are unknown.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 on shallow water flatfish would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1 or PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects on GOA shallow water flatfish under PA.1 and PA.2.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA shallow water flatfish is rated as insignificant under PA.1 and PA.2 (see the direct/indirect effects discussion).

- **Persistent Past Effects**. Past JV and domestic fisheries have been identified as having lingering past negative effects on the GOA shallow water flatfish complex (see Section 3.5.1.5).

- **Reasonably Foreseeable Future External Effects**. Future external effects on mortality are indicated due to potential adverse contributions of marine pollution since acute and/or chronic pollution events could cause shallow water flatfish species mortality. Climate changes and regime shifts are considered non-contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of shallow water flatfish. The State of Alaska scallop fishery is identified as a non-contributing factor since shallow water flatfish species bycatch is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for mortality of GOA shallow water flatfish, but is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to maintain current population levels.

Change in Biomass

- **Direct/Indirect Effects.** Since the total and spawning biomass estimates for GOA shallow water species are unavailable, the effects of PA.1 and PA.2 on change in biomass are unknown (see the GOA shallow water flatfish direct/indirect effects discussion).

- **Persistent Past Effects.** The past JV and domestic fisheries are identified as having past lingering negative effects on the biomass levels of GOA shallow water flatfish (see Section 3.5.1.5).

- **Reasonably Foreseeable Future External Events.** As described above for mortality, effects on biomass are indicated due to the potentially adverse contributions of marine pollution. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse contributions on the shallow water flatfish species biomass level. However, the State of Alaska scallop fishery is not considered to be contributing factor since bycatch of shallow water flatfish species is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for change in biomass of GOA shallow water flatfish, but is rated as unknown. Fishing mortality at projected levels is well below the OFL for this stock. It is unknown if the combined effects of internal removals and removals are likely to jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch
- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** It is unknown how the spatial and temporal distribution of the annual GOA shallow water flatfish harvest will be affected under PA.1 and PA.2 relative to the 2002 baseline year.

- **Persistent Past Effects.** Past effects have not been identified for the change in genetic structure or the change in reproductive success of GOA shallow water flatfish.

- **Reasonably Foreseeable Future External Effects**. Future external effects on the reproductive success of shallow water flatfish species due to climate changes and regime shifts are potentially beneficial or adverse as described for mortality. Marine pollution has been identified as having a potentially adverse contribution, and the State of Alaska scallop fishery is not a contributing factor.

- **Cumulative Effects**. A cumulative effect is possible for change in genetic structure and reproductive success of GOA shallow water flatfish, but the effect is rated as unknown. It is unknown if the combined effects of internal removals and removals due to reasonably foreseeable future external events are likely to jeopardize the capacity of the stock to maintain current population levels.

Change in Prey Availability

- **Direct/Indirect Effects**. Under PA.1 and PA.2, the change in prey availability for GOA shallow water flatfish is determined to be unknown (see the GOA shallow water flatfish direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects are identified for the change in prey availability of the GOA shallow water flatfish stock complex and include climate changes and regime shifts. Crab and shrimp have shown variation in abundance associated with changes in climate and water temperatures. However, studies on most benthic invertebrates have not been conducted (see Sections 3.5.1.5 and 3.10).

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA shallow water flatfish stock complex are potentially beneficial or adverse as described above for mortality. Marine pollution has also been identified as having a potentially adverse contribution, and the State of Alaska scallop fishery is not considered to be a contributing factor.

- **Cumulative Effects.** Cumulative effects for change in prey availability are unknown. The predation-mediated impacts of PA.1 and PA.2 on shallow water flatfish are governed by a complex web of indirect interactions which are currently difficult to quantify.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the GOA shallow water flatfish complex is considered to be unknown (see the GOA shallow water flatfish direct/indirect effects discussion).

- **Persistent Past Effects.** Past effects identified for GOA shallow water flatfish include climate changes and regime shifts as described for prey availability. Persistent past effects of the foreign, JV, and domestic fisheries gear impacts are described in Sections 3.5.1.5 and 3.6.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA shallow water flatfish stock complex are potentially beneficial or adverse as discussed above for mortality. Marine pollution has also been identified as having a potentially adverse contribution. The State of Alaska scallop fishery is also identified as a potential adverse contributor to GOA shallow water flatfish habitat suitability. See Section 3.6 for information of the impacts of fishery gear on EFH.

- **Cumulative Effects.** Cumulative effects are identified for GOA shallow water flatfish habitat suitability; however, these effects are unknown. It is unknown if the combination of internal and external habitat disturbances will to lead to a detectable change in spawning or rearing success such that the ability of the GOA shallow water flatfish stock to maintain current population levels is jeopardized.

See Table 4.5-9 for a summary of the cumulative effects on GOA shallow water flatfish under PA.1 and PA.2.

4.9.1.6 Rock Sole

Rock sole is described in more detail in Section 3.5.1.6 of this Programmatic SEIS. Rock sole is managed as its own stock under the BSAI Groundfish FMP under the Tier 3 management category, thus MSSTs are defined for these species.

Direct/Indirect Effects of PA.1 and PA.2

Total Biomass

The total biomass of rock sole at the start of 2002 is estimated to be 970,000 mt. Model projections of future total BSAI biomass estimates are shown in Table H.4-48 of Appendix H. Under PA.1, model projections indicate that the total BSAI biomass is expected to decline to 710,000 mt by 2007 with a 2003-2007 average total biomass of 779,000 mt. Under PA.2, model projections indicate that the total BSAI biomass is expected to decline to 690,000 in 2007, with a 2003-2007 average value of 771,000 mt.

Spawning Biomass

Spawning biomass of female rock sole at the start of 2002 is estimated to be 331,000 mt. Model projections of future rock sole spawning biomass estimates are shown in Table H.4-48 of Appendix H. Under PA.1, model projections indicate that female spawning biomass is expected to decline to 189,000 mt by 2007, with a 2003-2007 average value of 244,500 mt. Under PA.2, model projections indicate that female spawning biomass is expected to decline to 180,400 mt by 2007, with a 2003-2007 average value of 240,700 mt. Projected female spawning biomass is estimated to be above the B_{MSY} proxy value of 136,700 mt throughout the five year projection.

Fishing Mortality

The average annual fishing mortality imposed on the rock sole stock in 2002 is 0.055. Under PA.1, model projections show this value will steadily increase to 0.104 in 2007. Under PA.2, model projections show this value will steadily increase to 0.126 by 2007. These values are well below the F_{MSY} proxy value of 0.21, the rate associated with the OFL (Table H.4-48 of Appendix H). Catch rates of BSAI rock sole may be limited by Pacific halibut PSC limits, which could be reduced by 0-10 percent in the BSAI under PA.1 and by 0-20 percent in the BSAI under PA.2.

Spatial/Temporal Concentration of Fishing Mortality

It is unknown what spatial/temporal characteristics of the annual BSAI rock sole harvest would be affected under PA.1 since it is unknown what MPA efficacy methodology would be developed under this preferred alternative bookend or what the effect of hot-spot management of PSC would have on fishing behavior. As stated above, the rock sole fishery may also be limited temporally by Pacific halibut PSC limits.

As part of PA.1, an IR/IU program would be initiated for BSAI rock sole. The IR/IU program is designed to reduce discard waste of BSAI rock sole by allowing the fishing industry to develop new methods for avoiding unwanted bycatch and/or through the development of new markets for the bycatch. This program was previously initiated by NOAA Fisheries on January 1, 2003 (BSAI FMP Amendment 75), but was suspended on February 7, 2003 due to the need for clarification in the regulation. Discards occur mostly in the directed rock sole fishery, yellowfin sole, flathead sole, Pacific cod, and bottom pollock fisheries (Wilderbuer and Walters 2002).

It is unknown what goals, objectives and criteria would be developed under this preferred alternative bookend to allocate TAC in space and time. Existing closure areas would remain and will be reviewed under PA.2 to see if these areas qualify for MPAs or can be redesignated as fishery- or gear-specific areas. NOAA Fisheries and NPFMC would also consider adopting 0-20 percent of the Bering Sea and the Aleutian Islands as MPAs. These area closures are similar to those discussed under FMP 3.2 and are illustrated in the FMP 3.2 map (Figure 4.2-5) in Section 4.2.

Status Determination

Model projections of future catches of BSAI rock sole are below the OFLs in all years under PA.1 and PA.2, and the female spawning stock size is below the MSST. The rock sole stock is above the MSST level in 2002.

Under PA.1, the ABC must be set below the OFL values. The OY range is specified to be between 1.4 and 2 million mt in the BSAI. In the BSAI, if the sum of TAC exceeds 2 million mt, then the TAC must be adjusted down. This means that the TAC, ABC and OFL values may all be reduced in the future for BSAI rock sole under this preferred alternative bookend (same as FMP 1 and FMP 3.1). Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future, as well.

Similar to PA.1, under PA.2 the ABC must be set below the OFL values, but OY caps would be revisited to determine relevancy to current environmental conditions and knowledge of stock levels. Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future, as well.

Age and Size Composition

Under PA.1, the mean age of the BSAI rock sole stock in 2008, as computed in model projections is 4.82 years (Table H.4-48 of Appendix H). Under PA.2, the mean age of the BSAI rock sole stock in 2008, as computed in model projections is 4.74 years (Table H.4-48 of Appendix H). This compares with a mean age in the equilibrium unfished BSAI stock of 5.90 years. Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

The sex ratio of rock sole in the BSAI is assumed to be 50:50. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this preferred alternative.

Current closure areas would remain under PA.1, including the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. The Seguam Pass area would be closed to fishing, 3 nm no transit zones would be established around rookeries, and nearshore and critical habitat areas would be closed to trawl and fixed gear as Steller sea lion protection measures. All these measures may help reduce adverse impacts to important rock sole habitat where overlap occurs.

As stated above, under PA.2 NPFMC and NOAA Fisheries would consider adopting 0-20 percent of the Bering Sea and the Aleutian Islands as MPAs and no-take reserves across a range of different habitat types (similar to FMP 3.2). Existing closures would be reviewed to see if areas may qualify for MPAs under established criteria. Existing areas may be redefined as gear- or fishery-specific. EFH and HAPC designation would continue under PA.2, as would investigations as to whether fishing has adverse impacts on habitats; mitigation measures would be implemented as necessary. An Aleutian Islands management area would be established under PA.2 to protect coral and live bottom habitats. Pollock bottom trawling would be prohibited in the BSAI under PA.2. See the FMP 3.2 maps (Figure 4.2-5) described in Section 4.2 for more information. All of these measures may reduce the adverse impacts of fishing gear on important rock sole habitat where overlap occurs.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 on rock sole would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1 or PA.2. A directed fishery for forage fish would continue to be banned under PA.1 and PA.2.

See Table 4.9-1 for a summary of the BSAI rock sole direct/indirect effects under PA.1 and PA.2.

Cumulative Effects Analysis of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of fishing mortality on the BSAI rock sole is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI rock sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause rock sole mortality. Climate changes and regime shifts are not contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of rock sole.

- **Cumulative Effects.** A cumulative effect is possible for mortality of BSAI rock sole, and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of the fisheries on the BSAI rock sole biomass is insignificant.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI rock sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause rock sole mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the rock sole biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment (see Sections 3.5.1.6 and 3.10).

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI rock sole, and is rated as insignificant. The spawning biomass is above the B_{MSY} value for all years. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch
  - Change in Genetic Structure of Population
  - Change in Reproductive Success

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of the spatial/temporal concentration of catch is considered insignificant for the stock.

- **Persistent Past Effects.** Past effects are not identified for the change in genetic structure of the BSAI rock sole. Climate changes and regime shifts have been identified as having a persistent past effect on the reproductive success of BSAI rock sole. Climate changes and regime shifts and corresponding water temperature variation could effect prey availability and habitat suitability, which in combination could effect the reproductive success of the rock sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of rock sole due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of BSAI rock sole.

- **Cumulative Effects**. A cumulative effect is possible for the spatial/temporal concentration of the rock sole catch, and is ranked as insignificant. The spatial and temporal distribution of rock sole catch is not expected to change significantly. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the change in prey availability for the BSAI rock sole is ranked as insignificant.

- **Persistent Past Effects.** Past effects include climate changes and regime shifts. Climate changes and regime shifts and corresponding water temperature variation do effect the availability of some forage species (i.e. capelin); however, studies on benthic invertebrates have not been conducted.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI rock sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability, and is considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the change in habitat suitability for the BSAI rock sole is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified for BSAI rock sole include climate changes and regime shifts. Persistent past effects of the foreign, JV, and domestic fisheries are described in Section 3.5.1.6.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI rock sole stock are potential beneficial or adverse. Marine pollution has also been identified as a potential adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for BSAI rock sole habitat suitability, and is considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the rock sole stock to sustain itself at or above the MSST is jeopardized.

See Table 4.5-10 for a summary of the cumulative effects on BSAI rock sole under PA.1 and PA.2.

4.9.1.7 Flathead Sole

Flathead sole are described in more detail in Section 3.5.1.7 of this Programmatic SEIS. Flathead sole is managed as its own stock under the BSAI Groundfish FMP under the Tier 3 management category, thus MSSTs are defined for these species. Beginning in 2002, flathead sole were managed independent of the other flatfish complex in the GOA. Until recently, GOA flathead sole were evaluated under Tier 4; beginning in 2004 they will be managed under Tier 3. However, for the purposes of this analysis, flathead sole have been modeled as a Tier 4 species.

BSAI Flathead Sole – Direct/Indirect Effects of PA.1 and PA.2

Total Biomass

Total biomass of BSAI flathead sole at the start of 2003 is estimated to be 513,000 mt. Model projections of future total BSAI flathead sole biomass are shown in Table H.4-49 of Appendix H. Under PA.1, model projections indicate that BSAI flathead sole biomass is expected to decrease to a value of 492,000 mt in 2006, then increase to 496,000 mt in 2007, with a 2003-2007 average value of 498,000 mt. Under PA.2, model projections indicate that BSAI flathead sole biomass is expected to decrease to a value of 491,000 mt in 2006, then increase to 495,000 mt in 2007, with an average of 498,000 mt from 2003-2007.

Spawning Biomass

Spawning biomass of BSAI flathead sole at the start of 2003 is estimated to be 231,200 mt. Model projections of future total BSAI flathead sole biomass are shown in Table H.4-49 of Appendix H. Under PA.1, model projections indicate that BSAI flathead sole biomass is expected to decrease to a value of 176,200 mt in 2007, with a 2003-2007 average value of 203,100 mt. Under PA.2, model projections indicate that BSAI flathead sole biomass is expected to decrease to a value of 175,200 mt in 2007, with a 2003-2007 average value of 202,900 mt.

Fishing Mortality

Under PA.1, the projected fishing mortality imposed on the BSAI flathead sole stock is 0.053 in 2003, increasing to 0.061 in 2007, with an average from 2003-2007 of 0.052. The proportion of spawner biomass per recruit conserved under these fishing mortality rates is 78 percent in 2003 and decreases to 76 percent in 2007, with an average of 79 percent from 2003-2007 (Table H.4-49 of Appendix H). The flathead sole fishery is likely to be limited by Pacific halibut PSC limits which are projected to be reduced by 0-10 percent in the BSAI under PA.1.

Under PA.2, the projected fishing mortality imposed on the BSAI flathead sole stock is approximately 0.053 in 2003, increasing to 0.067 in 2007. The proportion of spawner biomass per recruit conserved under these fishing mortality rates is 81 percent in 2003 and decreases to 74 percent in 2007, with an average of 78 percent from 2003-2007 (Table H.4-49 of Appendix H). The BSAI flathead sole fishery will likely be limited by the Pacific halibut PSC limits which are projected to decline between 0-20 percent in the BSAI under PA.2.

Spatial/Temporal Concentration of Fishing Mortality

Under PA.1, a projected average of 11,220 mt of BSAI flathead sole are caught annually from 2003 to 2007, the largest percentage of catch occurring in the EBS shelf Pacific cod fishery, followed closely by the walleye pollock fishery, and yellowfin sole fishery. The directed flathead sole fishery contributes only about 10 percent.

Under PA.1, existing closure areas would remain, including inseason bycatch hotspot closures. As stated above, the flathead sole fishery is likely to be limited temporally by Pacific halibut PSC limits.

The average annual projected harvest of flathead sole under PA.2 was 11,700 mt, of which the yellowfin sole fishery made the largest percentage, followed closely by Pacific cod, and walleye pollock. The directed flathead sole fishery contributes to only about 10 percent of the annual harvest.

Under PA.2, existing closures would remain and would be reviewed to see if areas qualify for MPAs or could be redesignated as gear- or fishery-specific areas. NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the Bering Sea and the Aleutian Islands as MPAs and no-take reserves. These example closure areas are illustrated in FMP 3.2 map (Figure 4.2-5) described in Section 4.2. As mentioned above, the flathead sole fishery may also be limited temporally due to reaching Pacific halibut PSC limits, or spatially, when avoiding bycatch hotspot areas.

Status Determination

Under PA.1 and PA.2, the ABC is set lower than the OFL, creating a buffer between these two harvest regulations. Model projections of future catches of BSAI flathead sole are below ABC and OFL levels from 2003 to 2008.

Under PA.1, the OY range is specified to be between 1.4 and 2 million mt in the BSAI. In the BSAI, if the sum of TAC exceeds 2 million mt, then the TAC must be adjusted down. This means that the TAC, ABC and OFL values may all be reduced in the future for BSAI flathead sole under this preferred alternative. Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative and may affect catch limits in the future, as well. Under PA.2 the OY calculation would be re-evaluated to determine relevancy to current environmental conditions and knowledge of stock levels. Also, under PA.2, NOAA Fisheries would develop, implement and update procedures to account for uncertainty in estimating ABC, and species-specific production patterns, as necessary.

Age and Size Composition

Under PA.1, the mean age of the BSAI flathead sole stock in 2008, as computed in model projections (Table H.4-49 of Appendix H), is 4.57 years. Under PA.2, the mean age of the BSAI flathead sole stock in 2008, as computed in model projections (Table H.4-49 of Appendix H), is 4.56 years. This compares with a mean age in the equilibrium unfished stock of 5.39 years.

Sex Ratio

The sex ratio of BSAI flathead sole is assumed to be 50:50. No information is available to suggest that this would change under PA.1 and PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change under this PA.1 or PA.2.

Current closure areas would remain under PA.1, including the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. The Seguam Pass area would be closed to fishing, 3 nm no transit zones would be established around rookeries and nearshore and critical habitat areas would be closed to trawl and fixed gear as Steller sea lion protection measures. All these measures may help reduce adverse impacts to important flathead sole habitat where overlap occurs.

As mentioned above, the existing closures would remain under PA.2, including the BSAI pollock bottom trawling ban. These closures would be reviewed to see if areas qualify for MPAs or could be redesignated as gear- or fishery-specific areas. NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the Bering Sea and the Aleutian Islands as MPAs and no-take reserves. These example closure areas are illustrated in FMP 3.2 map (Figure 4.2-5) described in Section 4.2. Existing inseason bycatch closures (e.g., Pacific halibut hotspot areas) would be evaluated for effectiveness and modified as necessary.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that trophic interactions would undergo significant qualitative change under PA.1 or PA.2. Directed forage fisheries would continue to be banned under this preferred alternative.

See Table 4.9-1 for a summary of the direct/indirect effects on BSAI flathead sole under PA.1 and PA.2.

Cumulative Effects Analysis of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI flathead sole is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI flathead sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause flathead sole mortality. Climate changes and regime shifts are not considered to be contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of flathead sole.

- **Cumulative Effects.** A cumulative effect is possible for mortality of BSAI flathead sole, but is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of the fisheries on the BSAI flathead sole biomass is insignificant.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI flathead sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause flathead sole mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the flathead sole biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. For more information on climate changes and regime shifts (see Sections 3.5.1.7 and 3.10).

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI flathead sole, and is rated as insignificant. Projected spawning biomass is projected to be above the MSST for all years. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch

- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the spatial/temporal concentration of catch is considered insignificant for the stock.

- **Persistent Past Effects.** Past effects are not identified for spatial/temporal concentration of BSAI flathead sole catch.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of flathead sole due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of BSAI flathead sole.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the flathead sole catch, and is ranked as insignificant. The spatial and temporal distribution of flathead sole catch is not expected to change significantly. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in prey availability for the BSAI flathead sole is ranked as insignificant.

- **Persistent Past Effects.** Past effects are not identified for the change in prey availability of the BSAI flathead sole stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI flathead sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability; however, this effect is considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for BSAI flathead sole is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified for BSAI flathead sole include climate changes and regime shifts. Persistent past effects of the foreign, JV, and domestic fisheries are described in Section 3.5.1.7.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI flathead sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for BSAI flathead sole habitat suitability, and is considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the flathead sole stock to sustain itself at or above the MSST is jeopardized.

See Table 4.5-11 for a summary of the cumulative effects on BSAI flathead sole under PA.1 and PA.2.

GOA Flathead Sole – Direct/Indirect Effects of PA.1 and PA.2

Total and Spawning Biomass

Estimates of total and spawning biomass are currently unavailable for this species.

Fishing Mortality

The catch of GOA flathead sole in 2002 was estimated to be 2,000 mt. Model projections of future catch are shown in Table H.4-69 of Appendix H. Under PA.1, model projections indicate that the catch is expected to decrease to 1,500 mt in 2004-2007. The 2003-2007 average value is also 1,570 mt. Under PA.2, model projections indicate that the catch is expected to decrease to 1,500 mt in 2003-2007, with a 2003-2007 average value of 1,500 mt.

Spatial/Temporal Concentration of Fishing Mortality

It is unknown what spatial/temporal characteristics of the annual GOA flathead sole harvest would be affected under PA.1 since it is unknown what MPA efficacy methodology would be developed under this preferred alternative bookend. Bycatch management would include closing hot-spot areas which could disperse fishing locations in both time and space. Current closures would remain under PA.1, including the eastern GOA pollock bottom trawl closure.

Flathead sole catch may be limited in the GOA due to Pacific halibut PSC limits which are projected to be reduced by 0-20 percent under PA.2. This, in combination with the development of inseason bycatch closures could actually spatially and temporally restrict the fishery (see FMP 3.2 map [Figure 4.2-5] described in Section 4.2); however, the effects are unknown. Procedures to account for uncertainty when establishing ABC values would be developed, implemented and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future change in tier designation for GOA flathead sole.

Status Determination

The available information for GOA flathead sole requires that they are classified into the Tier 4 management category. As a result, no MSSTs are defined for this species. Therefore, it is not possible to determine their status.

Under PA.1 and PA.2, the ABC must be set below the OFL values. Under PA.1, the OY range is specified to be between 116,000 and 800,000 mt in the GOA (same as FMP 1 and FMP 3.1). However, under PA.2, OY cap calculations would be revisited for relevancy with current environmental conditions and stock levels. Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future.

Age and Size Composition

Age and size composition estimates are currently unavailable for this species.

Sex Ratio

The sex ratio of flathead sole in the GOA is assumed to be 50:50. No information is available to suggest that this would change under PA.1 and PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this preferred alternative.

As mentioned above, current closure areas would remain under this PA.1, including the ban on bottom trawling for pollock in the eastern GOA as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. The Seguam Pass area would be closed to fishing, 3 nm no transit zones would be established around rookeries, and nearshore and critical habitat areas would be closed to trawl and fixed gear as Steller sea lion protection measures. All these measures may help reduce adverse impacts to important flathead sole habitat where overlap occurs.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the GOA as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and pollock bottom trawling would be banned in the entire GOA. EFH and HAPC identification, designation, and assessment would continue, and mitigation measures would be instituted as needed. These measures may help reduce adverse impacts to GOA flathead sole habitat where overlap occurs, although, as stated above, impacts to flathead sole habitat suitability are unknown.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 on flathead sole would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1 or PA.2. Directed forage fisheries would continue to be banned under this preferred alternative.

See Table 4.9-1 for a summary of the direct/indirect effects of PA.1 and PA.2 on GOA flathead sole.

Cumulative Effects Analysis of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA flathead sole is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects have been identified for fishing mortality in the GOA flathead sole stock and include past JV and domestic fisheries. Removals by these fisheries have had a lingering negative effect on GOA flathead sole (see Section 3.5.1.7).

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause flathead sole mortality. Climate changes and regime shifts are not considered to be contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of flathead sole. The State of Alaska scallop fishery is also not considered to be a contributing factor since GOA flathead sole bycatch is not expected in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for mortality of GOA flathead sole, but is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in biomass level is rated as unknown since MSST is unable to be determined at this time.

- **Persistent Past Effects**. Past effects have been identified for fishing mortality in the GOA flathead sole stock and include past JV and domestic fisheries. Large removals of flathead sole by these fisheries is determined to have had a lingering effect on the GOA flathead sole stock (see Section 3.5.1.7).

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause flathead sole mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the flathead sole biomass level. For more information on climate changes and regime shifts see Section 3.5.1.7 and 3.10. The State of Alaska scallop fishery is identified as a non-contributing factor for change in biomass level since flathead sole bycatch is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of GOA flathead sole, but its significance is unknown. The MSST is not able to be determined and the total and spawning biomass estimates are currently unavailable. It is unknown whether the combined effect of internal and external removals is likely to jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch
- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the spatial/temporal concentration of catch is unknown since the MSST is unable to be determined.

- **Persistent Past Effects.** Past effects are not identified for the change in genetic structure of the GOA flathead sole stock. However, climate changes and regime shifts have been identified as having a positive or negative effect on GOA flathead sole reproductive success. See Section 3.5.1.7 for more information on the effects of climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of flathead sole due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of GOA flathead sole. The State of Alaska scallop fishery is not considered to be a contributing factor to change in genetic structure and change in reproductive success since GOA flathead sole bycatch is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the flathead sole catch; however, this effect is unknown. The spatial and temporal distribution of flathead sole catch is not expected to change significantly, while it is unknown whether the combined effect of internal and external removals is likely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain current population levels is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in prey availability for the GOA flathead sole is unknown.

- **Persistent Past Effects.** Past effects are identified for the change in prey availability of the GOA flathead sole stock and include climate changes and regime shifts. For more information on the effects of climate changes and regime shifts on the GOA flathead sole stock (see Section 3.5.1.7).

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA flathead sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The State of Alaska scallop fishery is identified as a potentially adverse contributor to GOA flathead sole prey availability. The State of Alaska scallop fishery gear could impact flathead sole benthic prey availability and/or quality.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability; however, this effect is unknown. It is unknown whether the combination of internal and external removals of prey is expected to jeopardize the ability of the stock to sustain itself at current population levels.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the GOA flathead sole is unknown.

- **Persistent Past Effects.** Past effects identified for GOA flathead sole include climate changes and regime shifts. Persistent past effects of the foreign, JV, and domestic fisheries are described in Section 3.5.1.7.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA flathead sole stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. The State of Alaska scallop fishery is identified as a potentially adverse contributor to GOA flathead sole habitat suitability. For information on the effects of fishery gear on EFH, see Section 3.6.

- **Cumulative Effects.** A cumulative effect is identified for GOA flathead sole habitat suitability; however, this effect is unknown. It is unknown whether the combination of internal and external habitat disturbances is expected to lead to a detectable change in spawning or rearing success such that the ability of the flathead sole stock to sustain itself at current population levels is jeopardized.

See Table 4.5-12 for a summary of the cumulative effects on GOA flathead sole under PA.1 and PA.2.

4.9.1.8 Arrowtooth Flounder

BSAI and GOA arrowtooth flounder are described in more detail in Section 3.5.1.8 of this Programmatic SEIS. Arrowtooth flounder is managed as its own stock under the BSAI and GOA Groundfish FMPs under the Tier 3 management category, thus MSSTs are defined for these species.

BSAI Arrowtooth Flounder – Direct/Indirect Effects of PA.1 and PA.2

Total Biomass

The total biomass of BSAI arrowtooth flounder at the start of 2002 is estimated to be 811,000 mt. Model projections of future total BSAI biomass estimates are shown in Table H.4-47 of Appendix H. Under PA.1, model projections indicate that the total BSAI biomass is expected to decline to 598,000 mt by 2007, with a 2003-2007 average total biomass of 675,000 mt. Under PA.2, model projections indicate that the total BSAI biomass is expected to decline to 605,000 mt in 2007, with a 2003-2007 average value of 679,000 mt.

Spawning Biomass

Spawning biomass of female BSAI arrowtooth flounder at the start of 2002 is estimated to be 475,900 mt. Model projections of future BSAI arrowtooth flounder spawning biomass estimates are shown in Table H.4-47 of Appendix H. Under PA.1, model projections indicate that female spawning biomass is expected to decline 30 percent of the 2002 value to 330,000 mt by 2007, with a 2003-2007 average value of 388,100 mt. Under PA.2, model projections indicate that female spawning biomass is expected to decline 30 percent of the 2002 value to 334,600 mt by 2007, with a 2003-2007 average value of 390,800 mt. Projected female spawning biomass is estimated to be above the B_{MSY} proxy value of 182,900 mt throughout the five year projection.

Fishing Mortality

The average annual fishing mortality imposed on the BSAI arrowtooth flounder stock in 2002 is 0.015. Under PA.1, model projections show this value will steadily increase to 0.024 in 2007. Under PA.2, model projections show this value will slowly increase to 0.020 by 2007. These values are well below the F_{MSY} proxy value of 0.38, the rate associated with the OFL (Table H.4-47 of Appendix H).

Spatial/Temporal Concentration of Fishing Mortality

It is unknown what spatial/temporal characteristics of the annual BSAI arrowtooth flounder harvest would be affected under PA.1 since it is unknown what MPA efficacy methodology would be developed under this preferred alternative bookend. Bycatch management would include closing hot-spot areas which could disperse fishing locations in both time and space. Current closure areas would remain under PA.1.

It is unknown what goals, objectives and criteria would be developed under PA.2 to allocate TAC in space and time. Since PSC limits are reduced and fishing is restricted to previous areas, it is unlikely that fishing effort would expand in space and time but would rather tend to be more concentrated than the baseline 2002 fishery. NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the Bering Sea and Aleutian Islands as MPAs and no-take reserves. These closure examples are illustrated in FMP 3.2 map (Figure 4.2-5) discussed in Section 4.2.

Status Determination

Model projections of future catches of BSAI arrowtooth flounder are below the OFLs in all years under PA.1 and PA.2. The arrowtooth flounder stocks are above the MSST level throughout the five year projection, as in the 2002 baseline year.

Under PA.1 and PA.2, the ABC must be set below the OFL values. Under PA.1, the OY range is specified to be between 1.4 and 2 million mt in the BSAI. In the BSAI, if the sum of TAC exceeds 2 million mt, then the TAC must be adjusted down. This means that the TAC, ABC and OFL values may all be reduced in the future for BSAI arrowtooth flounder under this preferred alternative bookend (same as FMP 1 and FMP 3.1). However, under PA.2, calculation of OY caps would be reanalyzed in light of current environmental conditions and knowledge of stock levels. Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future, as well. Under PA.2, NOAA Fisheries would also develop, implement and update procedures to account for uncertainty in estimating ABC, and species-specific production patterns, as necessary.

Age and Size Composition

Under PA.1 and PA.2, the mean age of the BSAI arrowtooth flounder stock in 2008, as computed in model projections is 4.81 years (Table H.4-47 of Appendix H). This compares with a mean age in the equilibrium unfished BSAI stock of 5.43 years. Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

Fishery-independent resource assessment surveys in the BSAI have found that populations of arrowtooth flounder are comprised of a higher percentage of females than males. It is believed that this is a function of a higher natural mortality rate for males than females. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this preferred alternative.

Current closure areas would remain under this preferred alternative bookend, including the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. These measures may help reduce adverse impacts to important arrowtooth flounder habitat where overlap occurs.

As mentioned above, the existing closures would remain under PA.2, including the BSAI pollock bottom trawling ban. These closures would be reviewed to see if areas qualify for MPAs or could be redesignated as gear- or fishery-specific areas. NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the

Bering Sea and Aleutian Islands as MPAs and no-take reserves. These example closure areas are illustrated in FMP 3.2 map (Figure 4.2-5) described in Section 4.2. Existing inseason bycatch closures (e.g., Pacific halibut hotspot areas) would be evaluated for effectiveness and modified as necessary.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 on BSAI arrowtooth flounder would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1 or PA.2. A directed fishery for forage fish would continue to be banned under PA.1 and PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects of PA.1 and PA.2 on BSAI arrowtooth flounder.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of PA.1 and PA.2 on fishing mortality of BSAI arrowtooth flounder is rated as insignificant.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI arrowtooth flounder stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause arrowtooth flounder mortality. Climate changes and regime shifts are not considered contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of arrowtooth flounder. The IPHC longline fishery is identified as a potentially adverse contributor to BSAI arrowtooth flounder mortality since arrowtooth flounder are caught as bycatch in this fishery. The State of Alaska herring fishery is not considered a contributing factor to BSAI arrowtooth flounder mortality since bycatch of these fish is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for mortality of BSAI arrowtooth flounder, and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

- **Direct/Indirect Effects.** The effect of PA.1 and PA.2 on the change in biomass of BSAI arrowtooth flounder is insignificant (see the direct/indirect effects section above).

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI arrowtooth flounder stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause arrowtooth flounder mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the arrowtooth flounder biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. For more information on climate changes and regime shifts, see Sections 3.5.1.8 and 3.10. The IPHC longline fishery has been identified as a potentially adverse contributor to BSAI arrowtooth flounder biomass level since bycatch is expected to occur in this fishery. The State of Alaska herring fishery is not considered to be a contributing factor since arrowtooth flounder bycatch is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is identified for the change in biomass level of BSAI arrowtooth flounder, and is rated as insignificant. The spawning biomass is above the B_{MSY} value for all years. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

<u>Spatial/Temporal Concentration of Catch</u>
– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** The effect of the PA.1 and PA.2 on the spatial/temporal concentration of catch is considered insignificant for the stock.

- **Persistent Past Effects.** Past effects are not identified for the change in genetic structure of BSAI arrowtooth flounder. Climate changes and regime shifts are identified as having had potentially adverse or beneficial effects on the reproductive success of BSAI arrowtooth flounder (see Section 3.5.1.8).

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of arrowtooth flounder due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of BSAI arrowtooth flounder. The IPHC longline fishery is not considered to be a contributing factor to the genetic structure and reproductive success of BSAI arrowtooth flounder since the removals are not expected to be significant. The State of Alaska herring fishery is also not a contributing factor in the genetic structure and reproductive success of BSAI arrowtooth flounder since bycatch is not expected in this fishery.

- **Cumulative Effects.** A cumulative effect is identified for the spatial/temporal concentration of the arrowtooth flounder catch, and is ranked as insignificant. The spatial and temporal distribution of arrowtooth flounder catch is not expected to change significantly. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in prey availability for the BSAI arrowtooth flounder is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified include the past foreign, JV, and domestic fisheries, State of Alaska groundfish fisheries, State of Alaska herring fisheries and climate changes and regime shifts (see Section 3.5.1.8).

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI arrowtooth flounder stock are potentially beneficial or adverse. Some forage species (i.e. capelin and herring), shrimp and pollock respond to variations in water temperatures which vary with the climate. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The IPHC longline fishery is not considered a contributing factor to prey availability since the bycatch of prey species is not expected in this fishery. However, the State of Alaska herring fishery is identified as a potentially adverse contributor to prey availability by reducing the availability of herring.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability; however, the effect is considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the BSAI arrowtooth flounder is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified for BSAI arrowtooth flounder include climate changes and regime shifts. Persistent past effects of the foreign, JV, and domestic fisheries are described in Section 3.5.1.8.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI arrowtooth flounder stock are potentially beneficial or adverse. A strong Aleutian Low and high water temperatures tend to favor recruitment and cause a change in the reproductive success of the stock. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. Neither the IPHC longline fishery nor the State of Alaska herring fishery are considered to be contributing factors to BSAI arrowtooth flounder habitat suitability. The impacts from the fishery gear is expected to be minimal.

- **Cumulative Effects.** A cumulative effect is identified for BSAI arrowtooth flounder habitat suitability, and is considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the arrowtooth flounder stock to sustain itself at or above the MSST is jeopardized.

See Table 4.5-13 for a summary of the cumulative effects on BSAI arrowtooth flounder under PA.1 and PA.2.

GOA Arrowtooth Flounder – Direct/Indirect Effects of PA.1 and PA.2

Total Biomass

The total biomass of GOA arrowtooth flounder at the start of 2002 is estimated to be 1,816,000 mt. Model projections of future total GOA biomass estimates are shown in Table H.4-70 of Appendix H. Under PA.1, model projections indicate that the total GOA biomass is expected to increase to 2,082,000 mt by 2007, an abundance level 15 percent more than the 2002 value. The 2003-2007 average total biomass is 1,980,000 mt. Under PA.2, model projections indicate that the total GOA biomass is expected to increase to 2,094,000 in 2007, with a 2003-2007 average value of 1,986,000 mt.

Spawning Biomass

Spawning biomass of female GOA arrowtooth flounder at the start of 2002 is estimated to be 1,113,800 mt. Model projections of future GOA arrowtooth flounder spawning biomass estimates are shown in Table H.4-70 of Appendix H. Under PA.1, model projections indicate that female spawning biomass is expected to increase to 1,152,800 mt by 2007, with a 2003-2007 average value of 1,140,900 mt. Under PA.2, model projections indicate that female spawning biomass is expected to increase 4 percent of the 2002 value to 1,161,600 mt by 2007, with a 2003-2007 average value of 1,145,700 mt. Projected female spawning biomass is estimated to be above the B_{MSY} proxy value of 432,700 mt throughout the five year projection.

Fishing Mortality

The average annual fishing mortality imposed on the GOA arrowtooth flounder stock in 2002 is 0.017. Under PA.1, model projections show this value will be 0.010 in 2007, with a 2003-2007 average of 0.010. Under PA.2, model projections show this value will be 0.009 the first year of the projection and 0.008 in the remaining years until 2007. These values are well below the F_{MSY} proxy value of 0.165, the rate associated with the OFL (Table H.4-70 of Appendix H).

Spatial/Temporal Concentration of Fishing Mortality

It is unknown what spatial/temporal characteristics of the annual GOA arrowtooth flounder harvest would be affected under PA.1 since it is unknown what MPA efficacy methodology would be developed under this bookend. Bycatch management would include closing hot-spot areas which could disperse fishing locations in both time and space. Existing closures would remain under this preferred alternative bookend, including the eastern GOA pollock bottom trawling closure.

It is unknown what goals, objectives and criteria would be developed under PA.2 to allocate TAC in space and time. Since PSC limits are reduced and fishing is restricted to previous areas, it is unlikely that fishing effort would expand in space and time but would rather tend to be more concentrated than the baseline 2002 fishery. NOAA Fisheries and NPFMC will consider adopting 0-20 percent of the GOA as MPAs and no-take reserves. This would be similar to closures illustrated under FMP 3.2 map (Figure 4.2-5) described in Section 4.2.

Status Determination

Model projections of future catches of GOA arrowtooth flounder are below the OFLs in all years under PA.1 and PA.2. The arrowtooth flounder stocks are above the MSST level throughout the five year projection, as in the 2002 baseline year.

Under PA.1 and PA.2, the ABC must be set below the OFL values. Under PA.1, the OY range is specified to be between 116,000 and 800,000 mt for the GOA. However, under PA.2, OY cap calculations would be revisited for relevancy with current environmental conditions and knowledge of current stock levels. Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future.

Age and Size Composition

Under PA.1, the mean age of the GOA arrowtooth flounder stock in 2008, as computed in model projections (Table H.4-70 of Appendix H), is 5.02 years. Under PA.2, the mean age of the GOA arrowtooth flounder stock in 2008, as computed in model projections (Table H.4-70 of Appendix H), is 5.03 years. This compares with a mean age in the equilibrium unfished BSAI stock of 5.11 years. Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

Fishery-independent resource assessment surveys in the GOA have found that populations of arrowtooth flounder are comprised of a higher percentage of females than males. It is believed that this is a function of a higher natural mortality rate for males than females. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this preferred alternative.

Current closure areas would remain under PA.1 (described under FMP 1). Definitions and methodology for establishing MPAs would be developed and inseason bycatch closures would be established. These measures may help reduce adverse impacts to important flathead sole habitat where overlap occurs.

As stated above, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the GOA as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and pollock bottom trawling would be banned in the entire GOA. Inseason bycatch closures would also be developed in the GOA under PA.2. EFH and HAPC identification, designation, and assessment would continue and mitigation measures instituted as needed. These measures may help reduce adverse impacts to GOA flathead sole habitat where overlap occurs, although, as stated above, impacts to flathead sole habitat suitability are unknown.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 on GOA arrowtooth flounder would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1 or PA.2. A directed forage fish fishery would continue to be banned under PA.1 and PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects of PA.1 and PA.2 on GOA arrowtooth flounder.

Cumulative Effects Analysis of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of PA.1 and PA.2 on fishing mortality of the GOA arrowtooth flounder is rated as insignificant.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the GOA arrowtooth flounder stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are the same as those described for BSAI arrowtooth flounder under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is possible for mortality of GOA arrowtooth flounder, and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of the fisheries on biomass is insignificant.

- **Persistent Past Effects.** Past effects have not been identified for the change in biomass in the GOA arrowtooth flounder stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are the same as those described for BSAI arrowtooth flounder under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of GOA arrowtooth flounder, and is rated as insignificant. The spawning biomass is above the B_{MSY} value for all years. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the spatial/temporal concentration of catch is considered insignificant for the stock.

- **Persistent Past Effects.** Past effects are not identified for the change in genetic structure and reproductive success of GOA arrowtooth flounder.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success and genetic structure of arrowtooth flounder are the same as those described for BSAI arrowtooth flounder under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the arrowtooth flounder catch, and is rated as insignificant. The spatial and temporal distribution of arrowtooth flounder catch is not expected to change significantly. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects**. Under PA.1 and PA.2, the change in prey availability for the GOA arrowtooth flounder is rated as insignificant.

- **Persistent Past Effects.** Past effects identified include climate changes and regime shifts (see Section 3.5.1.8).

- **Reasonably Foreseeable Future External Effects.** Future external effects on prey availability are the same as those described for BSAI arrowtooth flounder under PA.1 and PA.2.

- **Cumulative Effects**. A cumulative effect is identified for change in prey availability, and is considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the GOA arrowtooth flounder is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified for habitat suitability of GOA arrowtooth flounder are the same as those described for BSAI arrowtooth flounder under PA.1.

- **Reasonably Foreseeable Future External Effects.** Future external effects on habitat suitability are the same as those described for BSAI arrowtooth flounder under PA.1.

- **Cumulative Effects.** A cumulative effect is identified for GOA arrowtooth flounder habitat suitability, and is considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the arrowtooth flounder stock to sustain itself at or above the MSST is jeopardized.

See Table 4.5-14 for a summary of the cumulative effects on GOA arrowtooth flounder under PA.1 and PA.2.

4.9.1.9 Greenland Turbot and Deep Water Flatfish

BSAI Greenland turbot and GOA deep water flatfish are described in more detail in Section 3.5.1.9 of this Programmatic SEIS. Greenland turbot is managed as its own stock under the BSAI Groundfish FMP under the Tier 3 management category, thus MSSTs are defined for these species. The reference fishing mortality rate and ABC for the GOA deep water flatfish management group are determined by the amount of population information available. ABCs for Dover sole were calculated using Tier 5. Greenland turbot and deepsea sole are in Tier 6 in the GOA because no reliable biomass estimates exists.

BSAI Greenland Turbot – Direct/Indirect Effects of PA.1 and PA.2

Total Biomass

The total biomass of Greenland turbot at the start of 2002 is estimated to be 106,000 mt. Model projections of future total BSAI biomass estimates are shown in Table H.4-46 of Appendix H. Under PA.1, model projections indicate that the total BSAI biomass is expected to decline to 86,000 mt by 2007, an abundance level 19 percent less than the 2002 value. The 2003-2007 average total biomass is 92,000 mt. Under PA.2, model projections indicate that the total BSAI biomass is expected to decline to 90,000 in 2007. The 2003-2007 average value is 94,000 mt.

Spawning Biomass

Spawning biomass of female Greenland turbot at the start of 2002 is estimated to be 67,800 mt. Model projections of future Greenland turbot spawning biomass estimates are shown in Table H.4-46 of Appendix H. Under PA.1, model projections indicate that female spawning biomass is expected to decline 31 percent of the 2002 value to 46,800 mt by 2007, with a 2003-2007 average value of 54,100 mt. Under PA.2, model projections indicate that female spawning biomass is expected to decline to 50,500 mt by 2007, with a 2003-2007 average value of 56,500 mt. Projected female spawning biomass is estimated to be above the B_{MSY} proxy value of 47,600 mt from 2003-2006 and then drop below this level in 2007.

Fishing Mortality

The average annual fishing mortality imposed on the Greenland turbot stock in 2002 is 0.052. Under PA.1, model projections show this value will increase to 0.190 in 2004 before decreasing to 0.162 in 2007. Under PA.2, model projections indicate this value will steadily increase to 0.150 by 2007. These values are well below the F_{MSY} proxy value of 0.48, the rate associated with the OFL (Table H.4-46 of Appendix H).

Spatial/Temporal Concentration of Fishing Mortality

It is unknown what spatial/temporal characteristics of the annual BSAI yellowfin sole harvest would be affected under PA.1 since it is unknown what MPA efficacy methodology would be developed under this FMP. Bycatch management would include closing hot-spot areas which could disperse fishing locations in both time and space. Existing closures would remain under PA.1. The Greenland turbot fishery may be limited by Pacific halibut PSC limits which are projected to undergo a reduction of 0-10 percent under PA.1.

It is unknown what goals, objectives and criteria would be developed under PA.2 to allocate TAC in space and time. Since PSC limits are reduced and fishing is restricted to previous areas, it is unlikely that fishing effort would expand in space and time but would rather tend to be more concentrated thaN the baseline 2002 fishery. Existing closure areas would remain and inseason bycatch closures would be evaluated for effectiveness. See FMP 3.2 map (Figure 4.2-5) for a illustration of closures which are similar to those proposed under PA.2. A description of this map can be found in Section 4.2.

Status Determination

Model projections of future catches of BSAI Greenland turbot are below the OFL in all years under PA.1 and PA.2. The Greenland turbot female spawning stock is above the MSST level in all 5 years of the projection, as in the baseline year 2002.

Under PA.1 and PA.2, the ABC must be set below the OFL values. Under PA.1, the OY range is specified to be between 1.4 and 2 million mt in the BSAI. In the BSAI, if the sum of TAC exceeds 2 million mt, then the TAC must be adjusted down. This means that the TAC, ABC and OFL values may all be reduced in the future for BSAI Greenland turbot under this preferred alternative (same as FMP 1 and FMP 3.1). Under PA.2, OY caps would be reanalyzed in light of existing environmental conditions and availability of stock status information. Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative and may affect catch limits in the future, as well. Under PA.2, procedures to account for uncertainty in estimating ABC and species-specific patterns would be developed, implemented and updated, as necessary.

Age and Size Composition

Under PA.1, the mean age of the BSAI Greenland turbot stock in 2008, as computed in model projections (Table H.4-46 of Appendix H), is 4.56 years. Under PA.2, the mean age of the BSAI Greenland turbot stock in 2008, as computed in model projections (Table H.4-46 of Appendix H), is 4.62 years. This compares with a mean age in the equilibrium unfished BSAI stock of 5.93 years. Note that the mean ages and sizes actually observed in 2008 (as opposed to the model projections of mean age in 2008) will be driven largely by the strengths of incoming recruitments during the intervening years.

Sex Ratio

The sex ratio of Greenland turbot in the BSAI is assumed to be 50:50. No information is available to suggest that this would change under PA.1 and PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this preferred alternative.

Current closure areas would remain under this preferred alternative bookend, including the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. These measures may help reduce adverse impacts to important Greenland turbot habitat where overlap occurs.

The existing closures would remain under PA.2, including the BSAI pollock bottom trawling ban. These closures would be reviewed to see if areas qualify for MPAs or could be redesignated as gear- or fishery-specific areas. NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the Bering Sea and Aleutian Islands as MPAs and no-take reserves. These example closure areas are illustrated in FMP 3.2 map (Figure 4.2-5) described in Section 4.2. Existing inseason bycatch closures (e.g., Pacific halibut hotspot areas) would be evaluated for effectiveness and modified as necessary.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 on Greenland turbot would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1 and PA.2. Directed fisheries for forage fish will continue to be banned under this preferred alternative.

See Table 4.9-1 for a summary of the direct/indirect effects of PA.1 and PA.2 on BSAI Greenland turbot.

Cumulative Effects Analysis of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI Greenland turbot is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the BSAI Greenland turbot stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause Greenland turbot mortality. Climate changes and regime shifts are not considered contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of Greenland turbot.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI Greenland turbot, and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

- **Direct/Indirect Effects.** As stated in the direct/indirect effects section, the effect of the fisheries on the change in biomass level is insignificant.

- **Persistent Past Effects.** Past effects have not been identified for the change in biomass in the BSAI Greenland turbot stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in biomass are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause Greenland turbot mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the Greenland turbot biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. For more information on climate changes and regime shifts see Sections 3.5.1.9 and 3.10.

- **Cumulative Effects.** A cumulative effect is identified for the change in biomass level of BSAI Greenland turbot, and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock and the female spawning biomass is above the B_{MSY} value from 2003-2006. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch

- – Change in Genetic Structure of Population
- – Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the spatial/temporal concentration of catch is considered insignificant for the stock.

- **Persistent Past Effects.** Climate changes and regime shifts have been identified as persistent past effects for the spatial/temporal concentration of BSAI Greenland turbot catch. Climate changes and regime shifts are suspected of having an effect on the reproductive success of the Greenland turbot stock (see Section 3.5.1.9).

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of Greenland turbot due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of BSAI Greenland turbot.

- **Cumulative Effects.** A cumulative effect is identified for the spatial/temporal concentration of the Greenland turbot catch, and is rated as insignificant. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in prey availability for the BSAI Greenland turbot is ranked as insignificant.

- **Persistent Past Effects.** Past effects are identified for the change in prey availability of the BSAI Greenland turbot stock. Past foreign, JV, and domestic fisheries have been identified as having influenced the availability of Greenland turbot prey, mainly pollock which is their main prey item in the BSAI. Climate changes and regime shifts have also been identified as influencing Greenland turbot prey availability (see Section 3.5.1.9).

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI Greenland turbot stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability, and is considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the BSAI Greenland turbot is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified for BSAI Greenland turbot include climate changes and regime shifts. The foreign, JV, and domestic fisheries have also influenced the habitat suitability of Greenland turbot, largely through the impacts of fishing gear on benthic habitats. See Section 3.5.1.9 for more information on the persistent past effects on Greenland turbot.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI Greenland turbot stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for BSAI Greenland turbot habitat suitability, and is considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the Greenland turbot stock to sustain itself at or above the MSST is jeopardized.

See Table 4.5-15 for a summary of the cumulative effects on BSAI Greenland turbot under PA.1 and PA.2.

GOA Deep Water Flatfish – Direct/Indirect Effects of PA.1 and PA.2

Total and Spawning Biomass

Reliable estimates of total and spawning biomass are not available for these species.

Fishing Mortality

The catch of GOA deep water flatfish in 2002 was estimated to be 100 mt. Model projections of future catch are shown in Table H.4-66 of Appendix H. Under PA.1, model projections indicate that the catch is expected to increase to 1,250 mt in 2003, and decrease down to 1,091 mt by 2007, with a 2003-2007 average value of 1,139 mt. Under PA.2, model projections increase to 967 mt by 2007, with a 2003-2007 average value of 899 mt.

There is a danger within stock complexes to fish one species disproportionately to the other and create localized depletions. As part of PA.2, the Observer Program would continue with improvements. These improvements include the enhancement of training programs that would increase the number of species identified by observers. Observer uncertainty estimates for target species data would also be developed. Criteria for the 'splitting and lumping' of stock complexes and procedures to account for uncertainty when establishing ABC values would be developed, implemented and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future changes in Tier designation for GOA deep water flatfish.

Given the low level of exploitation under these preferred alternative bookends, the effect of PA.1 and PA.2 on GOA deep water flatfish is insignificant through mortality.

Spatial/Temporal Concentration of Fishing Mortality

It is unknown what spatial/temporal characteristics of the annual GOA deep water flatfish harvest would be affected under PA.1 since it is unknown what MPA efficacy methodology would be developed under this preferred alternative bookend. Bycatch management would include closing hot-spot areas which could disperse fishing locations in both time and space. Existing closures would remain under PA.1.

The shallow water flatfish fishery may be restricted by Pacific halibut PSC limits, which are projected to be reduced by 0-20 percent in the GOA under PA.2. This, in combination with the development of inseason bycatch closures (for hotspot areas), could temporally and spatially restrict the fishery. However, the effects of these measures on the spatial and temporal characteristics of the stock complex is unknown.

Status Determination

The available information for flatfish species in the deep water complex requires that they are classified into either the Tier 5 or Tier 6 management category. As a result, no MSSTs are defined for these species. Therefore, it is not possible to determine their status.

Under PA.1 and PA.2, the ABC must be set below the OFL values. Under PA.1, the OY range is specified to be between 116,000 and 800,000 mt in the GOA. However, under PA.2, OY caps would be recalculated in light of existing environmental conditions and knowledge of stock status. Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future.

Age and Size Composition

Age and size composition estimates are not available for these species.

Sex Ratio

The sex ratio of deep water flatfish in the GOA is assumed to be 50:50. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this preferred alternative.

Current closure areas would remain under this preferred alternative bookend, including the ban on bottom trawling for pollock in the eastern GOA as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. These measures may help reduce adverse impacts to important deep water flatfish habitat where overlap occurs.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the GOA as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and pollock bottom trawling would be banned in the entire GOA. EFH and HAPC identification, designation, and assessment would continue and mitigation measures instituted as needed. These measures may help reduce adverse impacts to GOA shallow water flatfish habitat where overlap occurs, although, as stated above, impacts to shallow water flatfish habitat suitability are unknown.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 on deep water flatfish would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1 or PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects of PA.1 and PA.2 on GOA deep water flatfish.

Cumulative Effects Analysis of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA deep water flatfish is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects have not been identified for fishing mortality in the GOA deep water flatfish stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause deep water flatfish mortality. Climate changes and regime shifts are not considered as contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of deep water flatfish. The State of Alaska scallop fishery is also not considered to be a contributing factor since bycatch of deep water flatfish species is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for mortality of GOA deep water flatfish, but it is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Total and spawning biomass estimates are unavailable for the deep water flatfish species, therefore, the effects of PA.1 and PA.2 on the change in biomass level are unknown.

- **Persistent Past Effects**. Past effects have not been identified for the change in biomass in the GOA deep water flatfish stock complex.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in biomass are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause deep water flatfish mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the deep water flatfish species biomass level. For more information on climate changes and regime shifts, please see Sections 3.5.1.9 and 3.10. The State of Alaska scallop fishery has not been considered as a contributing factor for change in biomass level since deep water flatfish species bycatch is not expected to occur.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of GOA deep water flatfish, but it is unknown. It is unknown whether the combined effect of internal and external removals is likely to jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch

- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the spatial/temporal concentration of catch is unknown for the stock since the MSST is unable to be determined.

- **Persistent Past Effects.** Past effects include climate changes and regime shifts which are suspected of having an effect on the reproductive success of the deep water flatfish stock complex. See Section 3.5.1.9 for more information on the effects of climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of Greenland turbot due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of GOA deep water flatfish. The State of Alaska scallop fishery is not considered to be a contributing factor to change in genetic structure and reproductive success since bycatch of GOA deep water flatfish species is not expected to occur.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the GOA deep water flatfish catch; however, this effect is unknown. It is unknown whether the combined effect of internal and external removals is likely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain current population levels is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in prey availability for the GOA deep water flatfish complex is unknown.

- **Persistent Past Effects.** Past effects are identified for the change in prey availability of the GOA deep water flatfish stock complex and include climate changes and regime shifts (see Section 3.5.1.9).

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA deep water flatfish stock complex are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The State of Alaska scallop fishery has been identified as a potentially adverse contributor to benthic prey availability. See Section 3.6 for information of the impacts of fishery gear on EFH.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability; however, this effect is unknown. It is unknown whether the combination of internal and external removals of prey is expected to jeopardize the ability of the stock to maintain current populations.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the GOA deep water flatfish complex is unknown.

- **Persistent Past Effects.** Past effects identified for GOA deep water flatfish include climate changes and regime shifts. The foreign, JV, and domestic fisheries have also influenced the habitat suitability of deep water flatfish, largely through the impacts of fishing gear on benthic habitats. See Section 3.5.1.9 for more information on the persistent past effects on deep water flatfish.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA deep water flatfish stock complex are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. The State of Alaska scallop fishery has been identified as a potential adverse contributor to habitat suitability. See Section 3.6 for more information on the impacts of fishery gear on EFH.

- **Cumulative Effects.** A cumulative effect is identified for GOA deep water flatfish habitat suitability; however, this effect is unknown. It is unknown whether the combination of internal and external habitat disturbances is expected to lead to a detectable change in spawning or rearing success such that the ability of the deep water flatfish stock complex to maintain current population levels is jeopardized.

See Table 4.5-16 for a summary of the cumulative effects on GOA deep water flatfish under PA.1 and PA.2.

4.9.1.10 Alaska Plaice, Other Flatfish and Rex Sole

BSAI Alaska plaice and other flatfish and GOA rex sole are described in more detail in Section 3.5.1.10 of this Programmatic SEIS.

BSAI Alaska Plaice – Direct/Indirect Effects of PA.1 and PA.2

Total Biomass

Total biomass of BSAI Alaska plaice at the start of 2003 is estimated to be 1,083,000 mt. Model projections of future total BSAI Alaska plaice biomass are shown in Table H.4-50 of Appendix H. Under PA.1, model projections indicate that BSAI Alaska plaice biomass is expected to increase to a value of 1,117,000 mt in 2007, with a 2003-2007 average value of 1,100,000 mt. Under PA.2, model projections indicate that BSAI Alaska plaice biomass is expected to increase to a value of 1,118,000 mt in 2007, with a 2003-2007 average value of 1,101,000 mt.

Spawning Biomass

Spawning biomass of BSAI Alaska plaice at the start of 2003 is estimated to be 276,900 mt. Model projections of future total BSAI Alaska plaice biomass are shown in Table H.4-50 of Appendix H. Under

PA.1, model projections indicate that BSAI Alaska plaice biomass is expected to increase to a value of 281,500 mt in 2007, with a 2003-2007 average value of 278,100 mt. Under PA.2, model projections indicate that BSAI Alaska plaice biomass is expected to increase to a value of 282,100 mt in 2007, with a 2003-2007 average value of 278,500 mt.

Fishing Mortality

Under PA.1, the projected fishing mortality imposed on the BSAI Alaska plaice stock is 0.017 in 2003, decreasing to 0.016 in 2004, and increasing to 0.020 in 2007, with an average from 2003-2007 of 0.018. The proportion of spawner biomass per recruit conserved under these fishing mortality rates is 92 percent in 2003 and decreases to 91 percent in 2007, with an average of 92 percent from 2003-2007 (Table H.4-50 of Appendix H).

Under PA.2, the projected fishing mortality imposed on the BSAI Alaska plaice stock is approximately 0.016 in 2003, increasing to 0.019 in 2007. The proportion of spawner biomass per recruit conserved under these fishing mortality rates is 93 percent in 2003 and declines to 91 percent in 2007, with an average of 92 percent from 2003-2007 (Table H.4-50 of Appendix H). The BSAI Alaska plaice fishery may be restricted by Pacific halibut PSC limits, which are projected to decline from 0-20 percent under PA.2.

Spatial/Temporal Concentration of Fishing Mortality

Under PA.1, a projected average of 10,040 mt of BSAI Alaska plaice are caught annually from 2003 to 2007, with the largest percentage (~73 percent) of the harvest occurring in the EBS shelf yellowfin sole fishery. The BSAI Alaska plaice fishery may be limited by Pacific halibut PSC limits, which are expected to be reduced by 0-10 percent under PA.1. Existing closure areas will remain under this preferred alternative bookend, including inseason bycatch closures.

The average annual projected harvest of Alaska plaice under PA.2 was 9,600 mt, with a majority of the harvest occurring in the EBS shelf yellowfin sole fishery. Due to the reduction in PSC limits, and proposed closures under PA.2, it is likely that the Alaska plaice fishery will become more restricted temporally and spatially (see FMP 3.2 map [Figure 4.2-5]) described in Section 4.2 for an illustration of these example closures.

Status Determination

Under PA.1 and PA.2, the ABC is set lower than the OFL, creating a buffer between these two harvest regulations. Model projections of future catches of BSAI Alaska plaice are below ABC and OFL levels from 2003 to 2008. Under PA.1, the OY range is specified to be between 1.4 and 2 million mt in the BSAI. In the BSAI, if the sum of TAC exceeds 2 million mt, then the TAC must be adjusted down. This means that the TAC, ABC and OFL values may all be reduced in the future for BSAI Alaska plaice under this preferred alternative bookend (same as FMP 1 and FMP 3.1). However, under PA.2, calculations of OY caps would be revisited for relevancy under existing environmental conditions and knowledge of current stock levels. Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future, as well. Under PA.2, procedures to account for uncertainty in ABC and species-specific production patterns would be developed, implemented and updated as necessary. These measures could affect the future catch limits of BSAI Alaska plaice in the future.

Age and Size Composition

Under PA.1 and PA.2, the mean age of the BSAI Alaska plaice stock in 2008, as computed in model projections (Table H.4-50 of Appendix H), is 4.40 years. This compares with a mean age in the equilibrium unfished stock of 4.51 years.

Sex Ratio

The sex ratio of BSAI Alaska plaice is assumed to be 50:50. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change under PA.1 or PA.2.

Current closure areas would remain under PA.1, including the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. These measures may help reduce adverse impacts to important Alaska plaice habitat where overlap occurs.

The existing closures would remain under PA.2, including the BSAI pollock bottom trawling ban. These closures would be reviewed to see if areas qualify for MPAs or could be redesignated as gear- or fishery-specific areas. NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the Bering Sea and Aleutian Islands as MPAs and no-take reserves. These example closure areas are illustrated in FMP 3.2 map (Figure 4.2-5) described in Section 4.2. Existing inseason bycatch closures (e.g., Pacific halibut hotspot areas) would be evaluated for effectiveness and modified as necessary.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that trophic interactions would undergo significant qualitative change under PA.1 or PA.2. A ban on a directed forage fishery would continue under PA.1 and PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects on BSAI Alaska plaice under PA.1 and PA.2.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects**. The effect of fishing mortality on the BSAI Alaska plaice stock is insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** No lingering past effects on BSAI Alaska plaice have been identified.

- **Reasonably Foreseeable Future External Effects.** Marine pollution has been identified as a potentially adverse contributor to mortality of BSAI Alaska plaice. Acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not considered to be contributors to mortality since a change is not expected to be significant in magnitude sufficient to cause mortality.

- **Cumulative Effects.** Under PA.1 and PA.2, a cumulative effect is identified for BSAI Alaska plaice mortality, and is considered insignificant. Alaska plaice are fished above the ABC and OFL values. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the BSAI Alaska plaice stock is expected to be insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** No lingering past effects on BSAI Alaska plaice have been identified.

- **Reasonably Foreseeable Future External Effects.** Marine pollution events are identified as potentially adverse contributors to BSAI Alaska plaice change in biomass level. Acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the stock is unable to maintain MSST. Climate changes and regime shifts are identified as potentially beneficial or adverse contributors to change in biomass level, since recruitment is affected by climate changes and regime shifts through a combination of prey availability and habitat suitability effects.

- **Cumulative Effects.** A cumulative effect is identified for BSAI Alaska plaice change in biomass, and it is rated as insignificant. The combination of internal and external factors are not expected to reduce Alaska plaice biomass such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

Spatial/Temporal Concentration of Catch
  – Change in Genetic Structure of Population
  – Change in Reproductive Success

- **Direct/Indirect Effects.** PA.1 and PA.2 would have an insignificant effect on BSAI Alaska plaice spatial and temporal characteristics.

- **Persistent Past Effects.** No persistent past effects have been identified for the genetic structure of the BSAI Alaska plaice population. Although, climate changes and regime shifts have been identified as having a potentially positive or negative effect on BSAI Alaska plaice reproductive success. In general, when the Aleutian Low is strong and corresponding water temperatures are high, flatfish recruitment tends to be favored.

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as a potentially adverse contribution to BSAI Alaska plaice genetic structure and reproductive success. Acute and/or chronic events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and could also result in reduced recruitment. Climate changes and regime shifts have been identified as potentially beneficial or adverse contributors to the reproductive success of BSAI Alaska plaice, but are not contributing factors to the genetic structure of Alaska plaice. The reproductive success is affected through a combination of climate induced changes in prey availability and habitat suitability.

- **Cumulative Effects.** A cumulative effect has been identified for the spatial and temporal concentration of BSAI Alaska plaice, and is rated as insignificant. The combined internal and external events are not expected to significantly alter the reproductive success or genetic structure such that it jeopardizes the capacity of the stock to maintain itself above MSST.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** PA.1 and PA.2 would have an insignificant effect on BSAI Alaska plaice prey availability.

- **Persistent Past Effects.** Climate changes and regime shifts have been identified as having potentially negative or positive effects on BSAI Alaska plaice prey availability. Minimal research has been conducted on benthic invertebrates, the main prey species of Alaska plaice; therefore, the magnitude and direction of the effects imposed by climate changes and regime shifts are unknown.

- **Reasonably Foreseeable Future External Effects.** Marine pollution has been identified as a potentially adverse contributor to the prey availability of BSAI Alaska plaice. Acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above the MSST. Climate changes and regime shifts are identified as potentially beneficial or adverse contributors to BSAI Alaska plaice prey availability. However, as stated above, since minimal research has been conducted on the effects of climate changes on benthic invertebrates, the magnitude and direction of the changes are unknown.

- **Cumulative Effects.** A cumulative effect has been identified for the BSAI Alaska plaice change in prey availability, and is rated as insignificant. The combination of internal and external removals of prey species is not expected to decrease prey availability such that the BSAI Alaska plaice stock is unable to maintain itself at or above MSST.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** PA.1 and PA.2 would have an insignificant effect on Alaska plaice habitat suitability.

- **Persistent Past Effects.** The past foreign, JV, and domestic fisheries have been identified as having negative effects on BSAI Alaska plaice habitat. See Sections 3.5.1.10 and 3.6 for more information on the effects of fishing gear on flatfish habitat. Climate changes and regime shifts are also identified as having a potentially negative or positive effect on Alaska plaice habitat. See Sections 3.5.1.10 and 3.10).

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as a potentially adverse contributor to BSAI Alaska plaice habitat suitability. Acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success of Alaska plaice. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse contributions to BSAI Alaska plaice habitat suitability. In general, when the Aleutian Low is strong and corresponding water temperatures are high, flatfish recruitment is favored.

- **Cumulative Effects.** A cumulative effect for BSAI Alaska plaice change in habitat suitability is identified, and is rated as insignificant. The combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the BSAI Alaska plaice stock to maintain itself at or above the MSST is jeopardized.

See Table 4.5-17 for a summary of the cumulative effects on BSAI Alaska plaice under PA.1 and PA.2.

BSAI Other Flatfish – Direct/Indirect Effects of PA.1 and PA.2

Total and Spawning Biomass

Estimates of total and spawning biomass are not available for these species.

Fishing Mortality

The catch of BSAI other flatfish in 2002 was estimated to be 2,600 mt. Model projections of future catch are shown in Table H.4-51 of Appendix H. Under PA.1, model projections indicate that the catch is expected to decrease from the 2002 value to 2,100 mt in 2003 and then increase to 2,300 mt in 2007 (14 percent decrease from 2002). The 2003-2007 average catch is 2,200 mt. The other flatfish fishery is likely to be limited by Pacific halibut PSC limits which are expected to decrease by 0-10 percent in the BSAI under PA.1 Under PA.2, model projects indicate that the catch is expected to decrease from a 2002 value of 2,600 mt to a 2006 value of 1,900 mt, and then increase to 2,100 mt through 2007. The 2003-2007 average projected catch is 1,900 mt. The other flatfish fishery is likely to be limited by Pacific halibut PSC limits which are expected to decrease by 0-20 percent in the BSAI under PA.2.

There is a danger within stock complexes to fish one species disproportionately to the other and create localized depletions. As part of PA.2, the Observer Program would continue with improvements. These improvements include the enhancement of training programs that would increase the number of species identified by observers. Observer uncertainty estimates for target species data would also be developed. Criteria for the 'splitting and lumping' of stock complexes and procedures to account for uncertainty when establishing ABC values would be developed, implemented and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future changes in Tier designation for BSAI other flatfish.

Given th low exploitation rates under PA.1 and PA.2, these FMPs are likely to have insignificant effects of the BSAI other flatfish species through mortality.

Spatial/Temporal Concentration of Fishing Mortality

It is unknown what spatial/temporal characteristics of the annual BSAI other flatfish harvest would be affected under PA.1 since it is unknown what MPA efficacy methodology would be developed under this FMP. Bycatch management would include closing hot-spot areas which could disperse fishing locations in both time and space. As mentioned above, the other flatfish fishery may also be restricted temporally due to reductions in PSC limits. Existing closures would remain under this preferred alternative bookend.

The other flatfish fishery may be restricted by Pacific halibut PSC limits, which are projected to be reduced by 0-20 percent in the BSAI under PA.2. This, in combination with the evaluation of inseason bycatch closures (for hotspot areas), could temporally and spatially restrict the fishery. However, the effects of these measures on the spatial and temporal characteristics of the stock complex is unknown.

Status Determination

The available information for flatfish species in the deep water complex requires that they are classified into either the Tier 4 or Tier 5 management category. As a result, no MSSTs are defined for these species. Therefore, it is not possible to determine their status.

Under PA.1 and PA.2, the ABC must be set below the OFL. Under PA.1, the OY range is specified to be between 1.4 and 2 million mt in the BSAI. In the BSAI, if the sum of TAC exceeds 2 million mt, then the TAC must be adjusted down. This means that the TAC, ABC and OFL values may all be reduced in the future for BSAI other flatfish under this preferred alternative bookend (same as FMP 1 and FMP 3.1). Under PA.2, OY caps would be recalculated for relevancy under existing environmental conditions and knowledge of stock levels. Ecosystem indicators would be developed and integrated into the TAC-setting system under this preferred alternative bookend and may affect catch limits in the future, as well.

Age and Size Composition

Age and size composition estimates are not available for these species.

Sex Ratio

The sex ratios of the species in the BSAI other flatfish category are assumed to be 50:50. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this preferred alternative bookend.

Current closure areas would remain under this preferred alternative bookend, including the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing

MPAs would be developed. These measures may help reduce adverse impacts to important flatfish habitat where overlap occurs.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the Bering Sea and Aleutian Islands as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas. EFH and HAPC identification, designation, and assessment would continue and mitigation measures instituted as needed. These measures may help reduce adverse impacts to BSAI flatfish habitat where overlap occurs, although, as stated above, impacts to flatfish habitat suitability are unknown.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 on other flatfish would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1 and PA.2. The direct forage fishery ban would continue under PA.1 and PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects on BSAI other flatfish under PA.1 and PA.2.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI other flatfish is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects have not been identified for BSAI other flatfish mortality.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are the same as those described for BSAI Alaska plaice under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI other flatfish, and is rated as insignificant. Fishing mortality rates for projected years are well below the other flatfish OFL. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of changes in biomass level is rated as unknown since the MSST for this stock is not possible to be determined.

- **Persistent Past Effects.** Past effects have not been identified for the BSAI other flatfish change in biomass level effect indicator.

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are the same as those described for BSAI Alaska plaice under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI other flatfish, but the effect is unknown. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

<u>Spatial/Temporal Concentration of Catch</u>
  - Change in Genetic Structure of Population
  - Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the spatial/temporal concentration of catch is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects identified for the spatial/temporal characteristics are the same as those described for BSAI Alaska plaice under PA.1 and PA.2.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the spatial/temporal characteristics are the same as those described for BSAI Alaska plaice under these bookends.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the other flatfish catch; however, this effect is unknown since it is not possible to determine the MSST. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in prey availability for the BSAI other flatfish is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** The effects on change in prey availability are the same as those described for BSAI Alaska plaice under PA.1 and PA.2.

- **Reasonably Foreseeable Future External Effects.** The effects on change in prey availability are the same as those described for BSAI Alaska plaice under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is possible for change in prey availability; however, this effect is unknown since it is not possible to determine the MSST. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the BSAI other flatfish is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects identified for the habitat suitability of BSAI other flatfish are the same as those described for BSAI Alaska plaice under PA.1 and PA.2.

- **Reasonably Foreseeable Future External Effects.** Future external effects identified for habitat suitability are the same as those described for BSAI Alaska plaice under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is possible for BSAI other flatfish habitat suitability; however, this effect is unknown. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

See Table 4.5-18 for a summary of the cumulative effects on BSAI other flatfish under PA.1 and PA.2.

GOA Rex Sole – Direct/Indirect Effects of PA.1 and PA.2

Total and Spawning Biomass

Estimates of total and spawning biomass are not available for this species.

Fishing Mortality

The catch of GOA rex sole in 2002 was estimated to be 3,000 mt. Model projections of future catch are shown in Table H.4-67 of Appendix H. Under PA.1, model projections indicate that the catch is expected to increase to 3,300 mt for each year 2003-2007. The 2003-2007 average value is 3,300 mt. Under PA.2, model projects indicate that catch is expected to decrease to 3,042 mt in 2007, with a 2003-2007 average of 3,068 mt. Rex sole catch may be limited in the GOA due to Pacific halibut PSC limits which are projected to be reduced by 0-20 percent under PA.2.

Spatial/Temporal Concentration of Fishing Mortality

It is unknown what spatial/temporal characteristics of the annual GOA rex sole harvest would be affected under PA.1 since it is unknown what MPA efficacy methodology would be developed under this FMP. Bycatch management would include closing hot-spot areas which could disperse fishing locations in both time and space.

Pacific halibut PSC limit reductions, in combination with the development of inseason bycatch closures, could actually spatially and temporally restrict the fishery, under PA.2 (see FMP 3.2 map [Figure 4.2-5] described in Section 4.2); however, the effects are unknown. Procedures to account for uncertainty when establishing ABC values would be developed, implemented and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future change in tier designation for GOA rex sole.

Status Determination

The available information for GOA rex sole requires that they are classified into the Tier 5 management category. As a result, no MSSTs are defined for this species. Therefore, it is not possible to determine their status. Under PA.1 and PA.2, the ABC must be set below the OFL. Under PA.1, the OY range for the GOA will be established between 116,000 and 800,000 mt and ecosystem indicators will be developed and used as part of the TAC-setting process. Under PA.2, OY caps would be revisited in light of existing environmental conditions and knowledge of stock levels. These measures may affect the catch limits for rex sole in the future under PA.1 and PA.2.

Age and Size Composition

Age and size composition estimates are not available for this species.

Sex Ratio

The sex ratio of rex sole in the GOA is assumed to be 50:50. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under these FMPs.

Current closure areas will remain under PA.1, including the eastern GOA trawl closure. A methodology for developing and adopting MPAs will be established and the program for identifying and designating EFH and HAPC will continue.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the GOA as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and pollock bottom trawling would be banned in the entire GOA. EFH and HAPC identification, designation, and assessment would continue and mitigation measures would be instituted as needed. These measures may help reduce adverse impacts to GOA rex sole habitat where overlap occurs, although, as stated above, impacts to rex sole habitat suitability are unknown.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 on rex sole would be governed by a complex web of indirect interactions which are currently difficult to quantify. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1 or PA.2. The directed forage fish ban will continue under this preferred alternative.

See Table 4.9-1 for a summary of the direct/indirect effects on GOA rex sole under PA.1 and PA.2.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA rex sole is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Large removals of rex sole by the past foreign, JV, and domestic fisheries have been identified as having had a negative persistent past effect on GOA rex sole stocks (see Section 3.5.1.10).

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause rex sole mortality. Climate changes and regime shifts are not considered to be contributing factors since the change in water temperatures would not likely be of sufficient magnitude to result in mortality of rex sole. Also the State of Alaska scallop fishery is not considered a contributing factor since it is not expected to contribute to direct mortality of rex sole.

- **Cumulative Effects.** A cumulative effect is identified for mortality of GOA rex sole, and is rated as insignificant. Fishing mortality rates for projected years are well below the rex sole OFL. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of changes in biomass level is rated as unknown since the MSST for this stock is not possible to be determined.

- **Persistent Past Effects.** Large removals of rex sole by past foreign, JV, and domestic fisheries have been identified as having had a negative persistent past effect on GOA rex sole stocks (see Section 3.5.1.10).

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause rex sole mortality. Climate changes and regime shifts have also been identified as having an indirect potentially beneficial or adverse effect on the rex sole biomass level. When the Aleutian Low is strong and water temperatures warm, flatfish recruitment is favored, likewise when the Aleutian Low is weak and the temperatures cooler, recruitment tends to be weak. The State of Alaska Scallop Fishery is not considered to be a contributing factor since it is not expected to contribute to direct mortality of rex sole. For more information on climate changes and regime shifts see Sections 3.5.1.10 and 3.10.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of GOA rex sole, but the effect is unknown. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the spatial/temporal concentration of catch is unknown since it is not possible to determine MSST.

- **Persistent Past Effects**. Past effects are not identified for genetic structure of the population; however, climate changes and regime shifts are identified as having persistent past effects on the reproductive success of the GOA rex sole stock (see Sections 3.5.1.10 and 3.10).

- **Reasonably Foreseeable Future External Effects**. Future external effects on the genetic structure of rex sole include the potentially adverse effects of marine pollution since an acute and/or chronic pollution event could alter the genetic structure of the population by causing localized mortality. Neither the State of Alaska scallop fishery nor climate changes and regime shifts are considered to be contributing factors to the change in genetic structure of rex sole stocks. These events are not expected to cause localized depletions that would alter the genetic sub-population structure of rex sole stock. Change in reproductive success of rex sole due to climate changes and regime shifts are identified as having a potentially beneficial or adverse effect. Marine pollution has been identified as a potentially adverse effect since acute and/or chronic pollution events could also the reproductive success of GOA rex sole. Again, the State of Alaska scallop fishery is not a contributing factor since the scallop fishery is not expected to contribute to rex sole removals.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the rex sole catch; however, this effect is unknown since it is not possible to determine MSST. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

Change in Prey Availability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in prey availability for the GOA rex sole is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Climate changes and regime shifts have been identified as having had affected the prey availability of the GOA rex sole stock. The actual effect of climate changes and regime shifts on rex sole prey availability is unknown, but could have had a potential positive or negative effect (see Sections 3.5.1.10 and 3.10).

- **Reasonably Foreseeable Future External Effects**. Future external effects of climate changes and regime shifts on the GOA rex sole stock are potentially beneficial or adverse. When the Aleutian Low is strong and water temperatures warm, flatfish recruitment is favored, likewise when the Aleutian Low is weak and water temperatures cooler, flatfish recruitment is reduced. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to maintain current population levels. The State of Alaska scallop fishery has been identified as having a potentially adverse effect on rex sole prey availability since the habitat disturbances caused by dredging could influence the availability of benthic prey.

- **Cumulative Effects.** A cumulative effect is possible for the change in prey availability; however, this effect is unknown since it is not possible to determine the MSST. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the GOA rex sole is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects identified for GOA rex sole include climate changes and regime shifts. The actual effects of climate changes and regime shifts on habitat suitability are unknown, but could have a potentially beneficial or adverse effect. Habitat disturbances caused by the past foreign, JV, and domestic fisheries have also been identified as having persistent past effects on the GOA rex sole stock. See Sections 3.5.1.10 and 3.10). regarding the past fisheries and climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA rex sole stock are potentially beneficial or adverse. When the Aleutian Low is strong and water temperatures warm, flatfish recruitment is favored, likewise when the Aleutian Low is weak and water temperatures cooler, flatfish recruitment is reduced. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. The State of Alaska scallop fishery is identified as having potentially adverse effects on rex sole habitat suitability that may cause changes in the spawning or rearing success of the stock.

- **Cumulative Effects.** A cumulative effect is identified for GOA rex sole habitat suitability; however, this effect is unknown. The combined effect of internal removals and removals due to reasonably foreseeable future external events may or may not jeopardize the capacity of the stock to maintain current population levels.

See Table 4.5-19 for a summary of the cumulative effects on GOA rex sole under PA.1 and PA.2.

4.9.1.11 Pacific Ocean Perch

Pacific ocean perch (*Sebastes alutus*) are managed under Tier 3 in the BSAI and GOA.

BSAI Pacific Ocean Perch – Direct/Indirect Effects of PA.1 and PA.2

Total Biomass

Total biomass of BSAI Pacific ocean perch at the start of 2003 is estimated to be 374,000 mt. Model projections of future total BSAI Pacific ocean perch biomass are shown in Table H.4-53 of Appendix H.

Under PA.1, model projections indicate that BSAI Pacific ocean perch biomass is expected to increase to a value of 392,000 mt in 2007 with a 2003-2007 average value of 383,000 mt. Under PA.2, model projections indicate that BSAI Pacific ocean perch biomass is expected to increase to a value of 402,000 mt in 2007, with a 2003-2007 average value of 388,000 mt.

Spawning Biomass

Spawning biomass of BSAI Pacific ocean perch at the start of 2003 is estimated to be 135,500 mt. Model projections of future total BSAI Pacific ocean perch biomass are shown in Table H.4-53 of Appendix H. Under PA.1, model projections indicate that BSAI Pacific ocean perch biomass is expected to increase to a value of 137,500 mt in 2007, with a 2003-2007 average value of 136,200 mt. Under PA.2, model projections indicate that BSAI Pacific ocean perch biomass is expected to increase to a value of 142,300 mt in 2007, with a 2003-2007 average value of 138,600 mt.

Fishing Mortality

Under PA.1, the projected fishing mortality imposed on the BSAI Pacific ocean perch stock is 0.033 in 2003, decreasing to 0.029 in 2005, and increasing 0.035 in 2007, with an average from 2003-2007 of 0.032 (Table H.4-53 of Appendix H).

Under PA.2, the projected fishing mortality imposed on the BSAI Pacific ocean perch stock is approximately 0.023 in each year from 2003 to 2007. The proportion of spawner biomass per recruit conserved under this fishing mortality rate is 60 percent (Table H.4-53 of Appendix H).

Spatial/Temporal Concentration of Fishing Mortality

Under PA.1, a projected average of 10,600 mt of BSAI Pacific ocean perch are caught annually from 2003 to 2007, with about half of the harvest occurring in the eastern Aleutian Islands. The harvest in this area occurs largely from the directed fishery, although the Atka mackerel fishery is projected to harvest approximately 1,000 mt annually from 2003-2007.

As with PA.1, the eastern Aleutians Islands contributes the largest proportion of the BSAI Pacific ocean perch catch. The average annual projected catch from 2003-2007 was 7,830 mt, of which approximately half is expected to occur in the eastern Aleutian Islands. The directed Pacific ocean perch fishery accounted entirely for the Pacific ocean perch harvest in this area in 2003 and 2004, but from 2005-2006 the Atka mackerel fishery was projected to harvest approximately 1,000 mt of Pacific ocean perch annually from this region. A series of no-take reserves is also specified under PA.2, but comparison with the recent spatial distribution of the fishery indicates that substantial areas would remain open for Pacific ocean perch fisheries. The Pacific halibut PSC limits, which are projected to be reduced by 0-20 percent under this FMP, could restrict the Pacific ocean perch fishery if large amounts of bycatch were to occur.

Status Determination

Under PA.1 and PA.2, the ABC is set lower than the OFL, creating a buffer between these two harvest regulations. Model projections of future catches of BSAI Pacific ocean perch are below ABC and OFL levels from 2003 to 2008. The projected spawning stock biomass is projected to be greater than the B_{MSY} ($B_{35\%}$)

level of 120,200 mt in each year of the projection, so BSAI Pacific ocean perch are above the MSST level under PA.1 and PA.2. Under PA.1, the BSAI OY is specified between 1.4 and 2.0 million mt. This means that if the sum of the TACs in the BSAI exceeds 2.0 million mt, TACs must be reduced. However, under PA.2, OY caps would be revisited for relevance under existing environmental conditions and stock levels. Ecosystem indicators will also be built into the TAC-setting process under these preferred alternative bookend. These measures could affect the future catch limits of BSAI Pacific ocean perch.

Age and Size Composition

Under PA.1, the mean age of the BSAI Pacific ocean perch stock in 2008, as computed in model projections (Table H.4-53 of Appendix H), is 10.37 years. Under PA.2, the mean age of the BSAI Pacific ocean perch stock in 2008, as computed in model projections (Table H.4-53 of Appendix H), is 10.53 years. This compares with a mean age in the equilibrium unfished stock of 14.01 years.

Sex Ratio

The sex ratio of BSAI Pacific ocean perch is assumed to be 50:50. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change under this PA.1 or PA.2.

Current closure areas would remain under this preferred alternative bookend, including the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. These measures may help reduce adverse impacts to important Pacific ocean perch habitat where overlap occurs.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the Bering Sea and Aleutian Islands as MPAs or redesignating current closure areas as fishery- or gear-specific. A management area in the Aleutian Islands would be developed to protect coral and live bottom habitats and the EFH and HAPC identification and mitigation process would also be continued under PA.2. These measures could help to reduce the adverse impacts to BSAI Pacific ocean perch habitat where overlap occurs.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that trophic interactions would undergo significant qualitative change under PA.1 or PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects of PA.1 and PA.2 on BSAI Pacific ocean perch.

Cumulative Effects Analysis of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI Pacific ocean perch stock is insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** The past foreign, JV, and domestic fisheries are identified as having had negative effects on the BSAI Pacific ocean perch stock. Large removals of Pacific ocean perch occurred in the past and there appears to be a lingering effect on the BSAI populations (see Section 3.5.1.11).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fishery is not expected to contribute to BSAI Pacific ocean perch mortality since no bycatch is expected in this fishery. Marine pollution is identified as a potentially adverse contributor since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not expected to contribute to Pacific ocean perch mortality.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI Pacific ocean perch, and it is rated as insignificant. Pacific ocean perch are fished at less than the OFL. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the BSAI Pacific ocean perch stock is expected to be insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** The past foreign, JV, and domestic fisheries are identified as having had negative effects on the BSAI Pacific ocean perch stock. Large removals of Pacific ocean perch occurred in the past and there appears to be a lingering effect on the BSAI populations (see Section 3.5.1.11).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fishery is not expected to contribute significantly to BSAI Pacific ocean perch mortality since no bycatch is expected in this fishery. Therefore, the IPHC longline fishery is not expected to cause significant changes in biomass levels. Marine pollution is identified as a potentially adverse contributor since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are identified as beneficial or adverse contributors to Pacific ocean perch change in biomass levels as a function of reproductive success.

- **Cumulative Effects.** A cumulative effect for the change in biomass is identified and rated as insignificant. The combination of internal and external factors is not expected to sufficiently reduce the Pacific ocean perch biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Impacts of the spatial and temporal changes should have an insignificant effect on the genetic structure and reproductive success of the BSAI Pacific ocean perch population.

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure. However, there are lingering past effects due to climate changes and regime shifts (see Section 3.5.1.11).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fishery is not expected to contribute to changes in genetic structure or reproductive success of BSAI Pacific ocean perch since no bycatch of BSAI Pacific ocean perch is expected in this fishery. Marine pollution is identified as a potentially adverse contributor since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are identified as potentially beneficial or adverse contributors to reproductive success since changes in climate can affect prey availability and/or habitat suitability which in turn can affect recruitment. Generally, changes in climate changes that lead to increased advection of the Alaska current are believed to increase euphausiid production, a major prey item of BSAI Pacific ocean perch. Climate changes and regime shifts are not considered contributors to changes in genetic structure.

- **Cumulative Effects.** A cumulative effect is identified for the spatial/temporal concentration, and is rated as insignificant. The combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** PA.1 and PA.2 would have insignificant effects on Pacific ocean perch prey availability.

- **Persistent Past Effects.** Past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on Pacific ocean perch prey species (see Section 3.5.1.11).

- **Reasonably Foreseeable Future External Effects.** Future external effects of climate changes and regime shifts on Pacific ocean perch prey species are identified as potential beneficial or adverse contributors. In general, it is believed that climate changes and regime shifts that lead to the increased advection of the Alaska current also increase production of euphausiids, a major prey item of BSAI Pacific ocean perch. Marine pollution has also been identified as a reasonably foreseeable external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** A cumulative effect identified for prey availability is rated as insignificant. The combination of internal and external removals of prey is not expected to decrease prey availability such that the Pacific ocean perch stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** PA.1 and PA.2 would have an insignificant effect on Pacific ocean perch habitat suitability.

- **Persistent Past Effects.** Past effects on habitat suitability identified for BSAI Pacific ocean perch stocks include past foreign, JV, and domestic fisheries, IPHC longline fisheries, climate changes and regime shifts (see Section 3.5.1.11). Intense bottom trawling on Pacific ocean perch habitat in the past fisheries likely disrupted spawning and/or rearing habitats in areas of the BSAI. It is possible that some of these areas have not recovered from the intense efforts. The IPHC longline fisheries are also identified as having negative effects on Pacific ocean perch habitat, although these fishing gear impacts are considered to be less significant than those associated with trawl gear (see Section 3.6 for additional information on the effects of trawling on benthic habitat). Climate changes and regime shifts have had both positive and negative effects on Pacific ocean perch habitat.

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fishery is identified as having an adverse effect on Pacific ocean perch habitat through fishing gear impacts. As stated above, these impacts are expected to be of lesser magnitude than those effects associated with trawl gear. Impacts on habitat from climate changes and regime shifts on the BSAI Pacific ocean perch stock are identified as potentially beneficial or adverse contributors, although the magnitude and direction of the change in relation to strong and weak Aleutian Low systems are unknown. Marine pollution has also been identified as a potentially adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for habitat suitability and is rated as insignificant. The combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the Pacific ocean perch stock to sustain itself at or above MSST is jeopardized.

See Table 4.5-20 for a summary of the cumulative effects on BSAI Pacific ocean perch under PA.1 and PA.2.

GOA Pacific Ocean Perch – Direct/Indirect Effects of PA.1 and PA.2

Total Biomass

Total biomass of GOA Pacific ocean perch at the start of 2003 is estimated to be 338,000 mt. Model projections of future total GOA Pacific ocean perch biomass are shown in Table H.4-77 of Appendix H. Under PA.1, model projections indicate that GOA Pacific ocean perch biomass is expected to increase to a value of 361,000 mt in 2007 with a 2003-2007 average value of 349,000 mt. Under PA.2, model projections indicate that GOA Pacific ocean perch biomass is expected to increase to a value of 376,000 mt in 2007 with a 2003-2007 average value of 358,000 mt.

Spawning Biomass

Spawning biomass of GOA Pacific ocean perch at the start of 2003 is estimated to be 112,700 mt. Model projections of future total GOA Pacific ocean perch biomass are shown in Table H.4-77 of Appendix H. Under PA.1, model projections indicate that GOA Pacific ocean perch biomass is expected to increase to a value of 115,500 mt in 2007, with a 2003-2007 average value of 113,200 mt. Under PA.2, model projections indicate that GOA Pacific ocean perch biomass is expected to increase to a value of 122,500 mt in 2007, with a 2003-2007 average value of 117,300 mt.

Fishing Mortality

Bycatch model results for PA.1 show catches comparable to FMP 1 for GOA Pacific ocean perch and therefore appear reasonable. Average fishing mortality during the years 2003 - 2007 is expected to be less than F_{OFL} (0.060) (Table H.4-77 of Appendix H).

PA.2 requires that appropriate harvest strategies be developed for rockfish. If these strategies were to use F_{60} as the basis for determining ABCs, then the catch of GOA Pacific ocean perch would be reduced because they are included in the slope rockfish assemblage. Under PA.2 the PSC limits for Pacific halibut could also be reduced by 0-10 percent. If the GOA Pacific ocean perch are caught in bottom trawl gear with a high bycatch of Pacific halibut, then a reduction in Pacific halibut bycatch could also reduce catch of GOA Pacific ocean perch. Bycatch model results using F_{60} as a harvest strategy for PA.2 show catches reduced from FMP 1 for GOA Pacific ocean perch and therefore, appear reasonable. Average fishing mortality during the years 2003-2008 is expected to be less than F_{OFL} (0.060) (Table H.4-77 of Appendix H).

Spatial/Temporal Concentration of Fishing Mortality

The effects that PA.1 has on the spatial and temporal concentration of Pacific ocean perch catch depends on the decisions made by NPFMC. The spatial distribution of catch would not be affected by proposed closures, and the apportionment of catch among management areas should provide some protection against localized depletion. Concentrating fishery effort into a short season would likely continue unless NPFMC implemented some “rights-based” management scheme.

The effects of PA.2 on the spatial and temporal concentration of Pacific ocean perch catch depends on the decisions made by NPFMC. The spatial distribution of catch would not be affected by proposed closures and apportionment of catch among management areas should provide some protection against localized depletion (see FMP 3.2 map [Figure 4.2-5] which illustrates the closures, similar to those proposed for PA.2; FMP 3.2 map is discussed in Section 4.2). The implementation of fishery rationalization should also spread out the fishery in time and space. PA.2 may also potentially have a large effect on the spatial concentration of Pacific ocean perch catch if 20 percent of the GOA is set aside as no-take reserves or as MPAs. Pacific ocean perch catches are taken in directed fisheries where the effort is highly localized and concentrated in slope areas. Much of this effort occurs in proposed closed areas. Therefore, if the proposed MPAs are closed to all bottom trawling, the spatial concentration of fishing effort would likely shift from the closure areas to the remaining open areas. The effect of shifting effort away from the closed areas is unclear.

Under PA.2 the spatial and temporal concentration of fishing effort may also be affected by Pacific halibut bycatch considerations if they substantially change the distribution of fishing effort.

Status Determination

Under PA.1 and PA.2, the projected 2003 biomass of 112,700 mt under PA.1, and 113,500 mt under PA.2, is greater than $B_{35\%}$ and consequently the stock is projected to be above its MSST and not projected to be in an overfished condition. The projected 2005 biomass of 116,700 mt is greater than $B_{35\%}$ and consequently the stock is not projected to be approaching an overfished condition.

Age and Size Composition

Under PA.1 and PA.2, the age composition of GOA Pacific ocean perch may be changed under fishing pressure as in FMP 1. Size composition of GOA Pacific ocean perch might change in proportion to the change in age composition. Age and size composition could also change if Pacific halibut bycatch considerations substantially change the distribution of fishing effort. The projected average age at the end of 2007 for GOA Pacific ocean perch is 10.61 years under PA.1 and 10.85 years under PA.2, compared to a projected unfished population age of 14.33 years (Table H.4-77 of Appendix H).

Sex Ratio

No information is available to suggest that the sex ratio would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Under PA.1 damage to epifauna by bottom trawls may negatively impact juvenile Pacific ocean perch habitat. PA.1 may also positively affect habitat for GOA Pacific ocean perch because it maintains the eastern GOA closure to trawling. This provides a de facto no-take zone or refugium for Pacific ocean perch in this area and provides protection from the potential effects of trawling on adult and or juvenile rockfish habitat.

Under PA.2, bottom trawl damage to epifauna would likely be reduced due to less fishing pressure and would likely result in less impact to juvenile Pacific ocean perch habitat. PA.2 may also have a positive effect on the habitat of GOA Pacific ocean perch because it maintains the eastern GOA closure to trawling and proposes to set aside 0-20 percent of the GOA as no-take reserves or as marine protected areas (MPAs). If the proposed MPAs are closed to all bottom trawling, then additional refuges for Pacific ocean perch and/or protection of juvenile rockfish habitat from the potential effects of trawling could be provided in these zones.

Predation-Mediated Impacts

There is insufficient information to conclude that existing trophic interactions would undergo significant qualitative change under PA.1 and PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects of PA.1 and PA.2 on GOA Pacific ocean perch.

Cumulative Effects Analysis of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA Pacific ocean perch stock is insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects on mortality are the same as those described for GOA Pacific ocean perch under PA.1 and PA.2.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are the same as those described for BSAI Pacific ocean perch under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect identified for mortality of GOA Pacific ocean perch is rated as insignificant. Pacific ocean perch are fished below the OFL. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the GOA Pacific ocean perch stock is expected to be insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects on the change in biomass are the same as those described for BSAI Pacific ocean perch under PA.1 and PA.2.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in biomass are the same as those described for BSAI Pacific ocean perch under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect for change in biomass is identified and is rated as insignificant. The combination of internal and external factors is not expected to sufficiently reduce the Pacific ocean perch biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch
– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Impacts of the spatial and temporal changes should have an insignificant effect on the genetic structure and reproductive success of the population.

- **Persistent Past Effects.** Past effects on the spatial and temporal characteristics of GOA Pacific ocean perch are the same as those described for BSAI Pacific ocean perch under PA.1 and PA.2.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the spatial and temporal characteristics of GOA Pacific ocean perch are the same as those described for BSAI Pacific ocean perch under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is identified for the spatial/temporal concentration of GOA Pacific ocean perch, and is rated as insignificant. The combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects.** PA.1 and PA.2 would have insignificant effects on Pacific ocean perch prey availability.

- **Persistent Past Effects**. Past effects on the change in prey availability of GOA Pacific ocean perch are the same as those described for BSAI Pacific ocean perch under PA.1 and PA.2.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in prey availability of GOA Pacific ocean perch are the same as those described for BSAI Pacific ocean perch under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is identified for prey availability, and is rated as insignificant. The combination of internal and external removals of prey is not expected to decrease prey availability such that the Pacific ocean perch stock is unable to sustain itself at or above MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** PA.1 and PA.2 would have insignificant effects on GOA Pacific ocean perch habitat suitability.

- **Persistent Past Effects.** Past effects on the change in habitat suitability of GOA Pacific ocean perch are the same as those described for BSAI Pacific ocean perch under PA.1 and PA.2.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in habitat suitability of GOA Pacific ocean perch are the same as those described for BSAI Pacific ocean perch under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect identified for habitat suitability is rated as insignificant. The combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the Pacific ocean perch stock to sustain itself at or above MSST is jeopardized.

See Table 4.5-21 for a summary of the cumulative effects on GOA Pacific ocean perch under PA.1 and PA.2.

4.9.1.12 Thornyhead Rockfish

GOA thornyhead rockfish are described in more detail in Section 3.5.1.12 of this Programmatic SEIS. Until recently, thornyhead rockfish is managed as its own stock under the GOA Groundfish FMP under the Tier 3 management category, thus MSSTs are defined for these species. Beginning in 2004, thornyhead rockfish will be managed under Tier 5; however, for the purposes of this analysis, thornyhead rockfish were modeled as a Tier 3 species.

Direct/Indirect Effects of PA.1 and PA.2

Total Biomass

Total (ages 5 through 55+) biomass of GOA thornyheads at the beginning of 2002 is estimated to be 54,000 mt. Model projections of future total GOA biomasses are shown in Table H.4-78 of Appendix H. Under PA.1, model projections indicate that total GOA biomass is expected to remain at 54,000 mt until 2003, then slowly increase to 55,000 mt by 2006, with a 2003-2007 average value of 55,000 mt. Under PA.2, model projections indicate that total GOA biomass is expected to remain at 54,000 mt in 2003, then slowly increase to 57,000 mt by 2007, with a 2003-2007 average value of 56,000 mt.

Spawning Biomass

Spawning biomass of female GOA thornyheads at the start of 2002 is estimated to be 23,500 mt. Model projections of future GOA spawning biomasses are shown in Table H.4-78 of Appendix H. Under PA.1, model projections indicate that GOA spawning biomass is expected to increase to 23,600 mt by 2003, then slowly increase to 24,300 mt by 2007, with a 2002-2007 average value of 23,900 mt. Under PA.2, model projections indicate that GOA spawning biomass is expected to increase to 23,600 mt by 2004, and continue increasing to 25,200 mt by 2007, with a 2002-2007 average value of 24,400 mt.

Fishing Mortality

The average fishing mortality imposed on the GOA thornyhead stock in 2002 is projected to be 0.032 under current management. Under PA.1, fishing mortality is projected to decrease to 0.025 in 2003 and further decrease to 0.020 in 2007. PA.2 appropriate harvest strategies are to be developed for rockfish. Should these strategies use F_{60} as the harvest rule, then fishing mortality is projected to decrease to 0.013 in 2003 and further decrease to 0.012 in 2007. These values are well below the F_{MSY} proxy value of 0.102 which is the rate associated with the OFL (Table H.4-78 of Appendix H).

Spatial/Temporal Concentration of Fishing Mortality

Thornyhead catch is approximately evenly divided between longliners and trawlers under status quo management. There is nothing about PA.1 or PA.2 that is expected to change this. Longline catches are spatially dispersed along the continental shelf break throughout the GOA (Figure 4.5-1), and temporally dispersed due to the nature of the IFQ sablefish fishery. For example, longline thornyhead catches in 2000 occurred year-round, with peaks in April and September, that did not exceed 60 mt per week. Trawler catch has been more concentrated in time, with some catches of 20-40 mt per week occurring in late spring, with a single large peak of 160 mt per week in July of 2000, coinciding with the rockfish trawl fishery.

Between 1997 and 1999, thornyhead trawl catches appear to have become more concentrated in space (Figure 4.5-2). According to surveys, during 1997-1999, the distribution of thornyheads did not appear to change (Figure 4.5-3). This apparent concentration may be the indirect result of changes in the trawl fisheries for deepwater flatfish and rockfish since thornyheads are not a primary target of trawl fisheries. However, it should be noted that the overall catch of thornyheads is low relative to both the estimated biomass and the ABC, such that this apparent concentration of catch is unlikely to have any negative population effects.

Status Determination

The GOA thornyhead stock is not currently overfished. At 23,500 mt, spawning stock biomass is expected to remain well above both the $B_{35\%}$ level (14,681 mt) and the $B_{40\%}$ level (16,045 mt) during the year 2002 and will remain above $B_{40\%}$ in all projection years under PA.1 and PA.2. Under PA.1 and PA.2, the ABC must be set below the OFL and the GOA OY cap has been set between 116,000 and 800,000 mt. Ecosystem considerations will be implemented into the TAC-setting process under this bookend, which may result in changes to catch limits in the future.

Age and Size Composition

Under PA.1, the mean age of the GOA thornyhead stock in 2007, as computed in model projections (Table H.4-78 of Appendix H), is 10.15 years. Under PA.2, the mean age of the GOA thornyhead stock in 2007, as computed in model projections (Table H.4-78 of Appendix H), is 10.35 years. This compares with a mean age in the equilibrium unfished GOA stock of 12.67 years.

Sex Ratio

The sex ratio of GOA thornyheads is assumed to be 50:50. No information is available to suggest that this would change under PA.1 and PA.2.

Habitat-Mediated Impacts

Under PA.1, all current management measures would be maintained. The level of habitat disturbance under PA.1 (and FMP 1) does not appear to affect the sustainability of thornyheads either through changes in the genetic structure of the population or changes in reproductive success, as measured by the ability of the stock to maintain itself above its MSST. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this FMPs.

Under PA.2, all current management measures would be maintained. Furthermore, an Aleutian Islands management area would be established to protect coral and live bottom habitats. Pollock bottom trawling would be prohibited throughout the entire GOA and 0-20 percent of the GOA would be established as MPAs and no-take reserves. EFH and HAPC programs that identify, designate and implement mitigation measures would continue under PA.2. The level of habitat disturbance under FMP 1 (and PA.2) does not appear to affect the sustainability of thornyheads either through changes in the genetic structure of the population or changes in reproductive success, as measured by the ability of the stock to maintain itself above its MSST. Information is insufficient to conclude whether or not existing habitat-mediated impacts would undergo significant qualitative change during the next 5 years under this FMP.

Predation-Mediated Impacts

In the GOA, shortspine thornyheads prey on benthic invertebrates; according to the AFSC food habits database, much of their diet in the 1990s has been composed of shrimp. Thornyheads are rare in the diets of other groundfish, birds, or marine mammals in the GOA according to the present limited information. Therefore, the effects of status quo federal groundfish fisheries on trophic interactions involving GOA thornyheads are expected to be minor. The current levels and distribution of groundfish harvest do not appear to impact prey availability for thornyheads such that it affects the sustainability of the stock as measured by the ability of the stock to maintain itself above its MSST. Information is insufficient to conclude that existing trophic interactions would undergo significant qualitative change during the next 5 years under PA.1 and PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects of PA.1 and PA.2 on GOA thornyhead rockfish.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA thornyhead rockfish is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects include past foreign, JV, and domestic groundfish fisheries. The removals of thornyhead rockfish that occurred in these fisheries have had a lingering negative effect on the populations (see Section 3.5.1.12 for more information.

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause thornyhead rockfish mortality. Climate changes and regime shifts are not considered contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of thornyhead rockfish. The IPHC longline fishery is identified as a potentially adverse contributor to thornyhead rockfish mortality since they are caught as bycatch in this fishery. However, the State of Alaska shrimp fishery is not considered a contributing factor since thornyhead rockfish bycatch is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is identified for mortality of GOA thornyhead rockfish and is rated as insignificant. Fishing mortality at projected levels is well below the OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass Level

- **Direct/Indirect Effects.** PA.1 and PA.2 are expected to have insignificant effects on these stocks.

- **Persistent Past Effects.** Past effects include past foreign, JV, and domestic groundfish fisheries. Past removals by these fisheries have had a lingering negative effect on the GOA thornyhead rockfish populations (see Section 3.5.1.12 for more information.

- **Reasonably Foreseeable Future External Effects.** Future external effects on change in biomass level are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause thornyhead rockfish mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the thornyhead rockfish biomass level. A strong Aleutian Low and high water temperatures tend to favor recruitment whereas a weak Aleutian Low and cooler water temperatures tend to result in weak recruitment. For more information on climate changes and regime shifts, please see Sections 3.5.1.12 and 3.10. The IPHC longline fishery is identified as a potentially adverse contributor to the thornyhead rockfish biomass level since they are caught as bycatch in this fishery. The State of Alaska shrimp fishery is not considered to be a contributing factor since thornyhead rockfish bycatch is not expected in this fishery.

- **Cumulative Effects.** A cumulative effect is identified for the change in biomass level of GOA thornyhead rockfish and is rated as insignificant. The spawning biomass is above the B_{MSY} value for all years. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock to sustain itself above the MSST.

Spatial/Temporal Concentration of Catch

- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the spatial/temporal concentration of catch is considered insignificant for the stock.

- **Persistent Past Effects.** Past effects are not identified for the change in genetic structure of the GOA thornyhead rockfish. Climate changes and regime shifts have been identified as having a persistent past effect on the reproductive success of GOA thornyhead rockfish. Climate changes and regime shifts and corresponding water temperature variation could affect prey availability and habitat suitability, which in combination could affect the reproductive success of the thornyhead rockfish stock.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of thornyhead rockfish include contributions from climate changes and regime shifts which may be potentially beneficial or adverse. Marine pollution has also been identified as having a potentially adverse effect since acute and/or chronic pollution events could alter the genetic structure and/or the reproductive success of GOA thornyhead rockfish. The IPHC longline fishery removals of thornyheads could be sufficiently concentrated as to alter the genetic structure and reproductive success of GOA thornyhead rockfish populations and are therefore identified as potentially adverse contributors. The State of Alaska shrimp fishery is not considered to be a contributing factor since bycatch of thornyhead rockfish is not expected in this fishery.

- **Cumulative Effects.** A cumulative effect is identified for the spatial/temporal concentration of the thornyhead rockfish catch, and is ranked as insignificant. The spatial and temporal distribution of thornyhead rockfish catch is not expected to change significantly. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above the MSST is jeopardized.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in prey availability for the GOA thornyhead rockfish is expected to be insignificant.

- **Persistent Past Effects.** Past effects include climate changes and regime shifts. Climate changes and regime shifts and corresponding water temperature variation do affect the availability of some prey species (i.e. shrimp); however, this has not been confirmed by scientific studies in the GOA.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA thornyhead rockfish stock may be potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST. The IPHC longline fishery is not considered to be a contributing factor since bycatch of GOA thornyhead rockfish prey species is not expected to occur in this fishery. The State of Alaska shrimp fishery is identified as a potentially adverse contributor to prey availability since removal of shrimp, the main prey species of GOA thornyhead rockfish, occurs in this fishery.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability, and is considered insignificant. The combination of internal and external removals of prey is not expected to jeopardize the ability of the stock to sustain itself above the MSST.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the GOA thornyhead rockfish is ranked as insignificant.

- **Persistent Past Effects.** Past effects identified for GOA thornyhead rockfish include climate changes and regime shifts.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the GOA thornyhead rockfish stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. The IPHC longline fishery has been identified as a potential adverse contributor to GOA thornyhead rockfish habitat suitability. See Section 3.6 for information on the impacts of fishery gear on EFH. The State of Alaska shrimp fishery is not considered to be a contributing factor since habitat degradation by the shrimp fishery gear is not expected to occur.

- **Cumulative Effects.** A cumulative effect is identified for GOA thornyhead rockfish habitat suitability, and is considered insignificant. The combination of internal and external habitat disturbances is not expected to lead to a detectable change in spawning or rearing success such that the ability of the thornyhead rockfish stock to sustain itself at or above the MSST is jeopardized.

See Table 4.5-22 for a summary of the cumulative effects on GOA thornyhead rockfish under PA.1 and PA.2.

4.9.1.13 Rockfish

Rockfish are considered in more detail in Section 3.5.1.13.

BSAI Northern Rockfish

Until recently, BSAI northern rockfish were a part of the BSAI red rockfish assemblage and evaluated under Tier 5. As of 2004, northern rockfish will be evaluated under Tier 3 with their own age-structured model, and the red rockfish group will no longer exist. However, for the purposes of this analysis, BSAI northern rockfish were modeled as a Tier 5 species.

Direct/Indirect Effects of PA.1 and PA.2

Total and Spawning Biomass

Reliable estimates of total and spawning biomass are not available for this species.

Fishing Mortality

The catch of BSAI northern rockfish in 2003 was estimated as 4,600 mt. Projected catches from 2003-2007 are shown in Table H.4-56 of Appendix H. Under PA.1, model projections indicate that the catch is expected to increase to 6,390 mt in 2003, then decrease to 5,510 mt in 2007. The 2003-2007 average catch is 5,790 mt. The northern rockfish fisheries may be limited by Pacific halibut PSC limits which are projected to decrease between 0-10 percent under PA.1. Under PA.2, appropriate harvest strategies for rockfish are to be developed. Should these strategies use F_{60}, then the projected catch is expected to decrease to 2,942 mt in 2003 and then increase through 2007 to 3,717 mt. The 2003-2007 average catch is 3,442 mt. The northern rockfish fisheries may be limited by Pacific halibut PSC limits which are projected to decrease between 0-20 percent under PA.2.

Given the low levels of exploitation under PA.1 and PA.2, these FMPs are expected to have insignificant effects on BSAI northern rockfish through mortality.

Spatial/Temporal Concentration of Fishing Mortality

Model projections indicate that the average harvest of 5,790 mt from 2003-2007 occurs largely in the eastern Aleutian Islands (approximately 55 percent), with 1,200 mt (22 percent) occurring in the central Aleutian Islands and 1,100 mt (19 percent) coming from the western Aleutian Islands. The harvest of northern rockfish in the each of these areas is taken largely in the Atka mackerel fishery. As stated above, the northern rockfish fisheries may be limited by Pacific halibut PSC limits under PA.1.

BSAI northern rockfish catch may be limited due to Pacific halibut PSC limits which are projected to be reduced by 0-25 percent under PA.2. Procedures to account for uncertainty when establishing ABC values would be developed, implemented and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future change in tier designation for BSAI rockfish.

Status Determination

The catch rates are below the ABC and OFL values for all years. The MSST for northern rockfish cannot be determined. Under PA.1, the BSAI OY cap is established between 1.4 and 2.0 million mt. Under PA.2, OY caps would be revisited for relevancy with existing environmental conditions and knowledge of stock status. If the sum of the TACs for the BSAI target fish exceeds 2.0 million mt, than TACs must be reduced. As part of PA.1 and PA.2, ecosystem indicators would be implemented into the TAC setting process.

Age and Size Composition and Sex Ratio

Age and size composition estimates are not available for this species. The sex ratio of BSAI northern rockfish is assumed to be 50:50. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change under PA.1 or PA.2.

Current closure areas would remain under this preferred alternative bookend, including the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. These measures may help reduce adverse impacts to important northern rockfish habitat where overlap occurs.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the Bering Sea and Aleutian Islands as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and an Aleutian Islands management area would be established to protect live bottom and coral habitat. EFH and HAPC identification, designation, and assessment would continue and mitigation measures would be instituted as needed. These measures may help reduce adverse impacts to BSAI rockfish habitat where overlap occurs, although, as stated above, impacts to rockfish habitat suitability are unknown.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that trophic interactions would undergo significant qualitative change under PA.1 or PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects on BSAI northern rockfish under PA.1 and PA.2.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI northern rockfish is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Due to large harvest rates and the longevity of rockfish, past foreign, JV, and domestic fisheries have been identified as having had a negative persistent past effect on BSAI northern rockfish (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause northern rockfish mortality. Climate changes and regime shifts are not considered to be contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of northern rockfish. The IPHC longline fishery is not considered a contributing factor since bycatch of BSAI northern rockfish is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI northern rockfish, and is rated as insignificant. Fishing mortality at projected levels is well below OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of changes in biomass level is rated as unknown since the MSST for this stock cannot be determined.

- **Persistent Past Effects.** Due to large harvest rates and the longevity of rockfish, past foreign, JV, and domestic fisheries have been identified as having had a negative persistent past effect on BSAI northern rockfish (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects**. Future external effects on the change in biomass level are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause northern rockfish mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the northern rockfish biomass level; however, it is unknown whether warmer water temperatures will favor or reduce recruitment. For more information on climate changes and regime shifts see Sections 3.5.1.13 and 3.10. The IPHC longline fishery is not considered to be a contributing factor since bycatch of BSAI northern rockfish species is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI northern rockfish, but the effect is unknown. It is unknown whether the combined effect of internal and external removals is likely to jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the spatial/temporal concentration of catch is unknown since it is not possible to determine the MSST.

- **Persistent Past Effects.** Past effects are not identified for the change in genetic structure of BSAI northern rockfish. Climate changes and regime shifts are identified as having a potentially beneficial/negative effect on BSAI northern rockfish (see Sections 3.5.1.13 and 3.10).

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success of northern rockfish due to climate changes and regime shifts are potentially beneficial or adverse. However, climate changes and regime shifts are not expected to be sufficient to alter the genetic sub-population structure of northern rockfish. Marine pollution has been identified as a potentially adverse effect since acute and/or chronic pollution events could alter the genetic sub-population structure and/or the reproductive success of BSAI northern rockfish. The IPHC longline fishery is not considered to be a contributing factor to the genetic structure and reproductive success of the other rockfish species since bycatch of this species is not expected to occur in this fishery.

- **Cumulative Effects**. A cumulative effect is possible for the spatial/temporal concentration of the northern rockfish catch; however, this effect is unknown since it is not possible to determine the MSST.

Change in Prey Availability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in prey availability for the BSAI northern rockfish is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Climate changes and regime shifts have been identified as persistent past effects for the change in prey availability of the BSAI northern rockfish stock. The actual effect of climate changes and regime shifts on northern rockfish prey availability is unknown, but could have had a potentially positive or negative effect (see Sections 3.5.1.13 and 3.10).

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI northern rockfish stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to maintain current population levels. The IPHC longline fishery is not considered to be a contributing factor since it is unlikely that bycatch of northern rockfish prey species occurs in this fishery see Section 3.5.1.13 for more information on the trophic interactions of BSAI northern rockfish species.

- **Cumulative Effects.** A cumulative effect is possible for change in prey availability; however, this effect is unknown since it is not possible to determine the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the BSAI northern rockfish is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects identified for BSAI northern rockfish include climate changes and regime shifts. The actual effects of climate changes and regime shifts on habitat suitability are unknown, but could have a potentially beneficial or adverse effect. The past foreign, JV, and domestic groundfish fisheries are identified as having a past adverse effect on habitat suitability, largely due to the intense bottom trawling that has occurred in northern rockfish species habitat. The IPHC longline fishery has also been identified as having had an adverse effect on northern rockfish species habitat suitability, possibly having disrupted northern rockfish species spawning and/or rearing habitats. See Section 3.5.1.13 for more information on the past events that have effected northern rockfish habitat suitability.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI northern rockfish stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. The IPHC longline fisheries have also been identified as having a potentially adverse effect on the northern rockfish habitat suitability. These fisheries are expected to continue into the future and could disrupt northern rockfish species spawning and/or rearing habitats.

- **Cumulative Effects.** A cumulative effect is possible for the change in habitat suitability; however, the effect is unknown since the MSST is unable to be determined. It is unknown whether the combined effects will make the northern rockfish species vulnerable to spawning and rearing habitat disturbances due to fishing gear.

See Table 4.5-23 for a summary of the cumulative effects on BSAI northern rockfish under PA.1 and PA.2.

BSAI Shortraker/Rougheye Rockfish – Direct/Indirect Effects of PA.1 and PA.2

Total and Spawning Biomass

Reliable estimates of total and spawning biomass are not available for these stocks.

Fishing Mortality

The catch of BSAI shortraker/rougheye rockfish in 2003 was estimated as 570 mt. Projected catches from 2003-2007 are shown in Table H.4-57 of Appendix H. Under PA.1, model projections indicate that the catch is expected to range between 700 and 900 mt from 2003-2007, with an average of 800 mt. As stated above, the shortraker/rougheye rockfish fishery may be limited by Pacific halibut PSC limits. PA.2 requires that appropriate harvest strategies be developed for rockfish. Should these strategies use F_{60} to determine ABCs, then the projected catch is expected to decrease to 419 mt through 2007 with a 2003-2007 average catch is 419 mt. The rockfish fisheries may be limited by Pacific halibut PSC limits which are projected to decrease between 0-20 percent under PA.2.

Given the low levels of exploitation under PA.1 and PA.2, these FMPs are expected to have insignificant effects on BSAI shortraker/rougheye rockfish through mortality.

Spatial/Temporal Concentration of Fishing Mortality

Model projections indicate that the average harvest of 800 mt from 2003-2007 is relatively evenly spread among the three Aleutian Islands subareas, with between 26 percent and 32 percent of the harvest occurring in each subarea. The harvest in the western and eastern Aleutian Islands occurs largely in the Pacific ocean perch trawl fishery, whereas the harvest in the central Aleutian Islands occurs largely in the Pacific cod longline fishery. The shortraker/rougheye rockfish fishery may be limited by Pacific halibut PSC limits which are expected to decrease by 0-10 percent under PA.1.

BSAI shortraker/rougheye rockfish catch may be limited due to Pacific halibut PSC limits which are projected to be reduced by 0-25 percent under PA.2. Procedures to account for uncertainty when establishing ABC values would be developed, implemented and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future change in tier designation for BSAI rockfish.

Status Determination

The catch rates are below the ABC and OFL values for all years. The MSST for this stock cannot be determined. Under PA.1, the BSAI OY cap is established between 1.4 and 2.0 million mt. If the sum of the TACs for the BSAI target fish exceeds 2.0 million mt, than TACs must be reduced. Under PA.2, calculations of OY caps would be revisited for relevance with existing environmental conditions and knowledge of stock status. As part of PA.1 and PA.2, ecosystem indicators would be implemented into the TAC setting process.

Age and Size Composition and Sex Ratio

Age and size composition estimates are not available for these species. The sex ratio of BSAI shortraker/rougheye rockfish is assumed to be 50:50. No information is available to suggest that this would change under PA.1 or PA.2.

Habitat-Mediated Impacts

Any habitat-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that existing habitat-mediated impacts would undergo significant qualitative change under PA.1 or PA.2.

Current closure areas would remain under PA.1, including the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. These measures may help reduce adverse impacts to important shortraker/rougheye rockfish habitat where overlap occurs.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the Bering Sea and Aleutian Islands as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and an Aleutian

Islands management area would be established to protect live bottom and coral habitat. EFH and HAPC identification, designation, and assessment would continue and mitigation measures would be instituted as needed. These measures may help reduce adverse impacts to BSAI rockfish habitat where overlap occurs, although, as stated above, impacts to rockfish habitat suitability are unknown.

Predation-Mediated Impacts

As with habitat-mediated impacts, any predation-mediated impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that trophic interactions would undergo significant qualitative change under PA.1 or PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects on BSAI shortraker/rougheye rockfish under PA.1 and PA.2.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI shortraker/rougheye rockfish is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Due to large harvest rates and the longevity of rockfish, past foreign, JV, and domestic fisheries have been identified as having had a negative persistent past effect on BSAI shortraker/rougheye rockfish (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause shortraker/rougheye rockfish mortality. Climate changes and regime shifts are not considered to be contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of shortraker/rougheye rockfish. The IPHC longline fishery and the State of Alaska shrimp fishery are not considered to be contributing factors since bycatch of BSAI shortraker/rougheye rockfish is not expected to occur in these fisheries.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI shortraker/rougheye rockfish, and is rated as insignificant. Fishing mortality at projected levels is well below OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the fishery on biomass level is rated as unknown since the MSST for this stock cannot be determined.

- **Persistent Past Effects.** Due to large harvest rates and the longevity of rockfish, past foreign, JV, and domestic fisheries have been identified as having had a negative persistent past effect on BSAI shortraker/rougheye rockfish (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in biomass level are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause shortraker/rougheye rockfish mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the shortraker/rougheye rockfish biomass level; however, it is unknown whether warmer water temperatures will favor or reduce recruitment. For more information on climate changes and regime shifts see Sections 3.5.1.13 and 3.10. The IPHC longline fishery and the State of Alaska shrimp fishery are not considered to be contributing factors since bycatch of BSAI shortraker/rougheye rockfish species is not expected to occur in these fisheries.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI shortraker/rougheye rockfish, but the effect is unknown. It is unknown whether the combined effect of internal and external removals is likely to jeopardize the capacity of the stock to maintain current population levels.

<u>Spatial/Temporal Concentration of Catch</u>

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the spatial/temporal concentration of catch is unknown since it is not possible to determine the MSST.

- **Persistent Past Effects.** Past effects are not identified for the change in genetic structure of BSAI shortraker/rougheye rockfish. Climate changes and regime shifts are identified as having a potentially beneficial/negative effect on BSAI shortraker/rougheye rockfish (see Sections 3.5.1.13 and 3.10).

- **Reasonably Foreseeable Future External Effects**. Future external effects on the reproductive success of shortraker/ rougheye rockfish due to climate changes and regime shifts are potentially beneficial or adverse. However, climate changes and regime shifts are not expected to be sufficient to alter the genetic sub-population structure of shortraker/rougheye rockfish. Marine pollution has been identified as a potentially adverse effect since acute and/or chronic pollution events could alter the genetic sub-population structure and/or the reproductive success of BSAI shortraker/rougheye rockfish. The IPHC longline fishery and State of Alaska shrimp fishery are not considered to be contributing factors to the genetic structure and reproductive success of the other rockfish species since bycatch of this species is not expected to occur in these fisheries.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the shortraker/rougheye rockfish catch; however, this effect is unknown since is not possible to determine the MSST.

Change in Prey Availability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in prey availability for the BSAI shortraker/rougheye rockfish is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Climate changes and regime shifts have been identified as persistent past effects for the change in prey availability of the BSAI shortraker/rougheye rockfish stock. The actual effect of climate changes and regime shifts on shortraker/rougheye rockfish prey availability is unknown, but could have had a potential positive or negative effect (see Sections 3.5.1.13 and 3.10).

- **Reasonable Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI shortraker/rougheye rockfish stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to maintain current population levels. The IPHC longline fishery is not considered a contributing factor since it is unlikely that bycatch of shortraker/rougheye rockfish prey species occurs in this fishery. The State of Alaska shrimp fishery is identified as a potentially adverse contributor to BSAI shortraker/rougheye prey availability since shrimp is on e of the main prey species of rougheye rockfish. See Section 3.5.1.13 for more information on the trophic interactions of BSAI shortraker/rougheye rockfish species.

- **Cumulative Effects.** A cumulative effect is identified for change in prey availability; however, this effect is unknown since it is not possible to determine the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the BSAI shortraker/rougheye rockfish is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects identified for BSAI shortraker/rougheye rockfish include climate changes and regime shifts. The actual effects of climate changes and regime shifts on habitat suitability are unknown, but could have a potentially beneficial or adverse effect. The past foreign, JV, and domestic groundfish fisheries are identified as having a past adverse effect on habitat suitability, largely due to the intense bottom trawling that has occurred in shortraker/rougheye rockfish species habitat. The IPHC longline fishery has also been identified as having had an adverse effect on shortraker/ rougheye rockfish species habitat suitability, possibly having disrupted shortraker/rougheye rockfish species spawning and/or rearing habitats. The State of Alaska shrimp fishery is not considered a contributing factor to shortraker/rougheye rockfish habitat suitability since habitat degradation by shrimp fishery gear is not expected to occur. See Section 3.5.1.13 for more information on the past events that have effected shortraker/rougheye rockfish habitat suitability.

- **Reasonably Foreseeable Future External Effects.** Future external effects of the climate changes and regime shifts on the BSAI shortraker/rougheye rockfish stock are potentially beneficial or adverse. Marine pollution has also been identified as a potentially adverse effect since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. The IPHC longline fisheries have also been identified as having a potentially adverse effect on the shortraker/rougheye rockfish habitat suitability. These fisheries are expected to continue into the future and could disrupt shortraker/rougheye rockfish species spawning and/or rearing habitats.

- **Cumulative Effects.** A cumulative effect is possible for the change in habitat suitability; however, this effect is unknown since the MSST is unable to be determined. It is unknown whether the combined effects will make the shortraker/rougheye rockfish species vulnerable to spawning and rearing habitat disturbances due to fishing gear.

See Table 4.5-24 for a summary of the cumulative effects on BSAI shortraker/rougheye rockfish under PA.1 and PA.2.

BSAI Other Rockfish – Direct/Indirect Effects of PA.1 and PA.2

Total and Spawning Biomass

Reliable estimates of total and spawning biomass are not available for these species.

Fishing Mortality

Under PA.1, the projected catch of Aleutian Islands other rockfish in 2003 to 2007 ranged from 200 mt to 300 mt, with and average of 260 mt. The projected harvest of EBS other rockfish from 2003 to 2007 was about 100 mt in each year. Projected catches from 2003-2007 are shown in Tables H.4-54 and H.4-55 of Appendix H. Under PA.2, appropriate harvest strategies for rockfish are to be developed. Should these strategies use F_{60} as the harvest rule, then the projected catch of EBS other rockfish is expected to decrease to 72 mt in 2003 and continue to decrease through 2007 to 66 mt. The 2003-2007 average catch is 69 mt. The projected catch of Aleutian Islands other rockfish is expected to decrease to 151 mt in 2003 and continue to decrease through 2007 to 130 mt. The 2003-2007 average catch is 140 mt. These projections suggest that direct fishing mortality on other rockfish stocks will be very low relative to the OFL and that such harvest levels will not present any significant impact to the species ability to maintain current population levels. Other rockfish fisheries may be limited by Pacific halibut PSC limits which are expected to decrease by 0-10 percent under PA.1. The rockfish fisheries may be limited by Pacific halibut PSC limits which are projected to decrease between 0-20 percent under PA.2.

Spatial/Temporal Concentration of Fishing Mortality

In the Aleutian Islands, 89 percent of the average harvest of 300 mt occurs in the cental and western Aleutian Islands, taken largely in the Atka mackerel and Pacific cod trawl fisheries and the Pacific cod and sablefish longline fisheries. In the EBS, the average catch of 100 mt is taken largely in the Pacific cod and Greenland turbot bottom trawl fisheries and the sablefish and Greenland turbot longline fisheries. No significant changes are expected in the spatial and temporal concentration of catch as a result of reduced other rockfish TACs.

BSAI rockfish catch may be limited due to Pacific halibut PSC limits which are projected to be reduced by 0-25 percent under PA.2. Procedures to account of uncertainty when establishing ABC values would be developed, implemented, and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future change in tier designation for BSAI rockfish.

Status Determination

The fishing mortality rate is below the ABC and OFL for all years. The MSST is unable to be determined. Under PA.1, the BSAI OY cap is established between 1.4 and 2.0 million mt. If the sum of the TACs for the BSAI target fish exceeds 2.0 million mt, than TACs must be reduced. Under PA.2, OY caps would be recalculated in light of existing environmental conditions and current knowledge of stock levels. As part of PA.1 and PA.2, ecosystem indicators would be implemented into the TAC setting process.

Age and Size Composition and Sex Ratio

Age and size composition estimates are not available for these species. Estimated sex ratios are not available for these species.

Habitat-Mediated Impacts

Any habitat related impacts of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude whether existing habitat conditions would undergo any significant change under PA.1 or PA.2.

Current closure areas would remain under PA.1, including the ban on bottom trawling for pollock in the BSAI as described under FMP 1. Definitions and methodology for establishing MPAs would be developed. These measures may help reduce adverse impacts to important rockfish habitat where overlap occurs.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the Bering Sea and Aleutian Islands as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and an Aleutian Islands management area would be established to protect live bottom and coral habitat. EFH and HAPC identification, designation, and assessment would continue and mitigation measures would be instituted as needed. These measures may help reduce adverse impacts to BSAI rockfish habitat where overlap occurs, although, as stated above, impacts to rockfish habitat suitability are unknown.

Predation-Mediated Impacts

As with habitat suitability impacts, any effect on predator-prey relationships of PA.1 and PA.2 would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude whether trophic interactions would undergo any significant change as a result of the PA.1 or PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects on Aleutian Islands and EBS other rockfish under PA.1 and PA.2.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the BSAI other rockfish is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects on mortality are the same as those considered for BSAI shortraker/rougheye rockfish under bookends.

- **Reasonably Foreseeable Future External Effects**. Future external effects on mortality are the same as those considered for BSAI shortraker/rougheye rockfish under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI other rockfish, and is rated as insignificant. Fishing mortality at projected levels is below OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of changes in biomass level is unknown since the MSST for this stock cannot be determined.

- **Persistent Past Effects.** Past effects on the change in biomass level are the same as those indicated for BSAI shortraker/rougheye rockfish under PA.1 and PA.2.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in biomass level are the same as those indicated for BSAI shortraker/rougheye rockfish under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI other rockfish, but is the effect is unknown. It is unknown whether the combined effect of internal external and external removals is likely to jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch
- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the spatial/temporal concentration of catch is rated as unknown.

- **Persistent Past Effects.** Past effects are not identified for spatial/temporal characteristics of BSAI other rockfish catch.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the reproductive success and genetic structure of other rockfish are the same as those considered for BSAI shortraker/rougheye rockfish under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is possible for the spatial/temporal concentration of the other rockfish catch, but this effect is unknown since it is not possible to calculate the MSST. However, the spatial and temporal concentration of the fishery is not expected to change significantly.

Change in Prey Availability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in prey availability for the BSAI other rockfish is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects on the change in prey availability are the same as those described for BSAI shortraker/rougheye rockfish under PA.1 and PA.2.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in prey availability are the same as those described for BSAI shortraker/rougheye rockfish under PA.1 and PA.2.

- **Cumulative Effects.** A cumulative effect is identified for the change in prey availability; however, this effect is unknown since it is not possible to determine the MSST.

Change in Habitat Suitability

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the change in habitat suitability for the BSAI other rockfish is unknown since it is not possible to determine MSST.

- **Persistent Past Effects.** Past effects on the change in habitat suitability are the same as those considered for BSAI shortraker/rougheye rockfish under PA.1 and PA.2.

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in habitat suitability are the same as those considered for BSAI shortraker/rougheye rockfish under PA.1 and PA.2.

- **Cumulative Effects.** The cumulative effect of habitat suitability is unknown. It is unknown whether the combined effect will make the other rockfish species vulnerable to spawning and rearing habitat disturbances due to fishing gear.

See Table 4.5-25 for a summary of the cumulative effects on BSAI other rockfish under PA.1 and PA.2.

GOA Northern Rockfish – Direct/Indirect Effects of PA.1 and PA.2

Total Biomass

Total biomass of GOA northern rockfish at the start of 2003 is estimated to be 112,000 mt. Model projections of future total GOA northern rockfish biomass are shown in Table H.4-76 of Appendix H. Under PA.1, model projections indicate that GOA northern rockfish biomass is expected to decrease to a value of 101,000 mt in 2007, with a 2003-2007 average value of 104,000 mt. Under PA.2, model projections indicate that GOA northern rockfish biomass is expected to decrease to a value of 103,000 mt in 2007, with a 2003-2007 average value of 105,000 mt.

Spawning Biomass

Spawning biomass of GOA northern rockfish at the start of 2003 is estimated to be 42,700 mt. Model projections of future total BSAI flathead sole biomass are shown in Table H.4-76 of Appendix H. Under PA.1, model projections indicate that BSAI flathead sole biomass is expected to decrease to a value of 37,600 mt in 2007, with a 2003-2007 average value of 40,200 mt. Under PA.2, model projections indicate that BSAI flathead sole biomass is expected to decrease to a value of 38,400 mt in 2007, with a 2003-2007 average value of 40,700 mt.

Fishing Mortality

Under PA.1 the PSC limits for Pacific halibut are reduced by ten percent. If the GOA northern rockfish are caught in bottom trawl gear with a high bycatch of Pacific halibut, then a reduction in Pacific halibut bycatch could reduce catch of GOA northern rockfish as well. Average fishing mortality during the years 2003 - 2008 is expected to be less than F_{OFL} (0.066) (Table H.4-76 of Appendix H).

PA.2 requires that appropriate harvest strategies be developed for rockfish. If these strategies were to use F_{60} as the basis for determining ABCs, then catch of GOA northern rockfish would be reduced. Under PA.2 the PSC limits for Pacific halibut are also reduced by 30 percent. If the GOA northern rockfish are caught in bottom trawl gear with a high bycatch of Pacific halibut, then a reduction in Pacific halibut bycatch could reduce catch of GOA northern rockfish as well. Average fishing mortality during the years 2003-2008 is expected to be less than F_{OFL} (0.066) (Table H.4-76 of Appendix H).

Spatial/Temporal Concentration of Fishing Mortality

The effects that PA.1 and PA.2 has on the spatial and temporal concentration of northern rockfish catch depends on the decisions made by NPFMC. The spatial distribution of catch would not be affected by proposed closures, and apportionment of catch among management areas should provide some protection against localized depletion. Concentrating fishery effort into a short season would likely continue unless NPFMC implemented some rights-based management scheme. Under PA.1 and PA.2 the spatial and temporal concentration of fishing effort may also be affected by Pacific halibut bycatch considerations if they substantially change the distribution of fishing effort. Under PA.1, the potential for localized depletion of the stock exists if fishing occurs year after year on localized aggregations of northern rockfish.

Under PA.2, the implementation of fishery rationalization should also spread the fishery out in time and space. PA.2 may also potentially have a large effect on the spatial concentration of northern rockfish catch if the maximum proposal of 20 percent of the GOA is set aside as no-take reserves or as MPAs. Northern rockfish catches are taken in directed fisheries where the effort is highly localized and concentrated in slope areas. Much of this effort occurs in proposed closed areas. Therefore, if the proposed MPAs are closed to all bottom trawling, the spatial concentration of fishing effort would likely shift from the closure areas to remaining open areas. The effect of shifting effort away from the closed areas is unclear, but since fishing effort is highly localized the spatial distribution of catch is likely to change.

Status Determination

Under PA.1 and PA.2, the projected 2003 biomass of 42,700 mt is greater than $B_{35\%}$ and consequently the stock is projected to be above its MSST and not projected to be in an overfished condition. The projected 2005 biomass of 40,400 mt under PA.1, and 40,800 mt under PA.2, is greater than $B_{35\%}$ and consequently the stock is not projected to be approaching an overfished condition. The ABC must be set below the OFL under both bookends. As part of PA.1, the GOA OY cap is established between 116,000 and 800,000 mt. However, under PA.2, OY caps would be recalculated for relevancy under existing environmental conditions and knowledge of stock levels.

Age and Size Composition and Sex Ratio

Under PA.1 and PA.2, the age composition of GOA northern rockfish may be affected by fishing mortality as in FMP 1. Size composition of GOA northern rockfish might change in proportion to the change in age composition. Age and size composition could also change if Pacific halibut bycatch considerations substantially change the distribution of fishing effort. No information is available to suggest that sex ratio would change under PA.1.

Habitat-Mediated Impacts

Under PA.1, damage to epifauna by bottom trawls may negatively impact juvenile northern rockfish habitat. Existing closures would remain under PA.1, including the eastern GOA trawl closure. EFH and HAPC identification and designation programs would also be continued. NPFMC and NOAA Fisheries would also develop a methodology for establishing MPAs.

Under PA.2 damage to epifauna by bottom trawls would likely be reduced under less fishing pressure and result in less impact on juvenile northern rockfish habitat. PA.2 may also have a positive effect on the habitat of GOA northern rockfish because it proposes to set aside 0-20 percent of the GOA as no-take reserves or as MPAs. If these MPAs are closed to all bottom trawling, then they may serve as refugia for northern rockfish allowing for increased survival of larger and older fish that produce significantly more eggs and larvae to replenish the GOA population. If these MPAs are closed to all bottom trawling, then they would also provide protection from the potential effects of trawling on juvenile rockfish habitat in these areas. The proposed ban on GOA pollock bottom trawling is likely to have a beneficial effect on juvenile rockfish habitat.

Predation-Mediated Impacts

There is insufficient information to conclude that existing trophic interactions would undergo significant qualitative change under PA.1 or PA.2.

See Table 4.9-1 for the summary of direct/indirect effects of GOA northern rockfish under PA.1 and PA.2.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA northern rockfish stock is insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects of the past foreign fisheries are identified for the GOA northern rockfish stock. Large removals of northern rockfish occurred in the past and there appears to be a lingering effect on the GOA northern rockfish populations (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fishery has not been identified as a contributing factor since bycatch is this fishery has already been accounted for by domestic groundfish management. Marine pollution is identified as having a potentially adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are not considered contributors to northern rockfish mortality.

- **Cumulative Effects.** A cumulative effect is identified for mortality of GOA northern rockfish, and is rated as insignificant. Northern rockfish are fished at less than the OFL. The combined effect of internal removals and removals due to reasonably foreseeable external events is unlikely to jeopardize the capacity of the stock to produce MSY on a continuing basis.

Change in Biomass

- **Direct/Indirect Effects.** Change in biomass of the GOA northern rockfish stock is expected to be insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Past effects of the past foreign fisheries are identified for the GOA northern rockfish stock. Large removals of northern rockfish occurred in the past and there appears to be a lingering effect on the GOA northern rockfish populations (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** Bycatch in the IPHC longline fishery has already been accounted for by domestic groundfish management. Marine pollution is identified as having a potentially adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are identified as having beneficial or adverse contributions to northern rockfish change in biomass levels as a function of change in reproductive success.

- **Cumulative Effects.** A cumulative effect for the change in biomass is identified as insignificant. The combination of internal and external factors is not expected to sufficiently reduce the northern rockfish biomass such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Spatial/Temporal Concentration of Catch

- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects**. Impacts of the spatial and temporal characteristics of GOA northern rockfish should have an insignificant effect on the genetic structure and reproductive success of the population.

- **Persistent Past Effects.** Past effects are not identified for change in genetic structure . However, there are lingering past effects due to climate changes and regime shifts (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** As noted above, the IPHC longline fishery has already been accounted for by domestic groundfish management and is not expected to contribute to changes in genetic structure or reproductive success of northern rockfish. Marine pollution is identified as having a potentially adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock to produce MSY on a continuing basis is jeopardized. Climate changes and regime shifts are identified as potentially beneficial or adverse contributor to reproductive success since changes in climate can effect prey availability and/or habitat suitability which in turn can effect recruitment. The magnitude and direction of the change in reproductive success with water temperatures is currently unknown. Climate changes and regime shifts are not considered to be contributors to change in genetic structure.

- **Cumulative Effects.** A cumulative effect is identified for the spatial/temporal characteristics of GOA northern rockfish, and is rated as insignificant. The combination of internal and external factors is not expected to sufficiently alter the genetic structure or the reproductive success of the population such that the ability of the stock to maintain itself at or above MSST is jeopardized.

Change in Prey Availability

- **Direct/Indirect Effects**. PA.1 and PA.2 would have an insignificant effect on northern rockfish prey availability.

- **Persistent Past Effects.** Past climate changes and regime shifts are likely to have had lingering effects (both beneficial and adverse) on northern rockfish prey species (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fishery has not been identified as a contributing factor since northern rockfish prey species bycatch is not expected to occur. Climate changes and regime shifts are identified as having potentially beneficial or adverse contributions on prey availability, although the magnitude and the direction of change in relation to strong and weak Aleutian Low systems are unknown. Marine pollution has also been identified as a reasonably foreseeable external contributing factor since acute and/or chronic pollution events could reduce prey availability or prey quality and thus jeopardize the stock's ability to sustain itself above its MSST.

- **Cumulative Effects.** A cumulative effect is identified for prey availability, and is rated as insignificant. The combination of internal and external removals of prey is not expected to decrease prey availability such that the northern rockfish stock is unable to sustain itself at or above MSST.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects**. PA.1 and PA.2 would have an insignificant effect on northern rockfish habitat suitability.

- **Persistent Past Effects.** Past effects on habitat suitability identified for GOA northern rockfish stocks include past foreign, JV, and domestic fisheries, IPHC longline fishery and climate changes and regime shifts (see Section 3.5.1.13). Intense bottom trawling on northern rockfish habitat in the past fisheries likely disrupted spawning and/or rearing habitats in areas of the GOA. It is possible that some of these areas have not recovered from the intense efforts. The IPHC longline fisheries have also been identified as having negative effects on northern rockfish habitat, although these effects are not expected to have been as intense as those effects associated with trawl gear. See Section 3.6 for additional information on the effects of trawling on benthic habitat). Climate changes and regime shifts have had both positive and negative effects on northern rockfish habitat.

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fishery has been identified as an adverse contributing factor since the fishery gear could disrupt spawning and/or rearing habitats. Although, as stated above, the impacts associated with longline gear are not as significant as those associated with trawl gear. Impacts on habitat from climate changes and regime shifts on the GOA northern rockfish stock are identified as potentially beneficial or adverse contributors, although the magnitude and direction of the change in relation to strong and weak Aleutian Low systems are unknown. Marine pollution has also been identified as a potentially adverse contributing factor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success.

- **Cumulative Effects.** A cumulative effect is identified for habitat suitability, and is rated as insignificant. The combination of internal and external habitat disturbance factors is not expected to lead to a detectable change in spawning or rearing success such that the ability of the northern rockfish stock to sustain itself at or above MSST is jeopardized.

See Table 4.5-26 for a summary of the cumulative effects on GOA northern rockfish under PA.1 and PA.2.

GOA Shortraker/Rougheye Rockfish – Direct/Indirect Effects of PA.1 and PA.2

Total and Spawning Biomass

No projections are possible for these two parameters, as shortraker/rougheye are classified as Tier 4 or Tier 5 species, with insufficient information to compute either parameter.

Fishing Mortality

PA.1 is more precautionary in its approach than FMPs 1, 2.1, and 2.2. However, for most measures in regards to shortraker/rougheye it remains very similar to FMP 1 and the baseline situation. One would therefore expect the catch projections for shortraker/rougheye in this bookend would be very similar to those in FMP 1. The projections, however, are consistently higher for PA.1, which does not appear reasonable (Table H.4-75 of Appendix H). Under PA.1, these projections indicate an increase from the 2002 value of 1,300 mt to 1,418 mt in 2003, and then decrease to 1,231 mt in 2007. The 2003-2007 average projected catch is 1,272 mt. PA.2 requires that appropriate harvest strategies be developed for rockfish. If those strategies were to use F_{60} to determine ABCs, then projections indicate a decrease in catch to 679 mt through 2005, and an increase through 2007 to 776. The 2003-2007 average projected catch under PA.2 is 724 mt.

There is a danger within stock complexes to fish one species disproportionately to the other and create localized depletions. As part of PA.2, the Observer Program would continue with improvements. These improvements include the enhancement of training programs that would increase the number of species identified by observers. Observer uncertainty estimates for target species data would also be developed. Criteria for the 'splitting and lumping' of stock complexes and procedures to account for uncertainty when establishing ABC values would be developed, implemented and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future change in tier designation for GOA rockfish.

Given the low levels of exploitation under PA.1 and PA.2, these FMPs are expected to have insignificant effects on GOA shortraker/rougheye rockfish through mortality.

Spatial/Temporal Concentration of Fishing Mortality

Whether PA.1 would have substantial effects on the spatial or temporal concentration of shortraker/rougheye catch would somewhat depend on decisions made by NPFMC after the bookend was implemented. ABCs would still be geographically apportioned amongst management areas, which would continue to provide some protection against localized depletion of the resource. IFQs and fishing cooperatives may be established as needed, but since specific recommendations concerning such rights-based management are not included in the FMP, it is difficult to evaluate how they would impact shortraker/rougheye. If NPFMC decided to not establish IFQs and/or cooperatives for trawlers, the shortraker/rougheye trawl catch would continue to be concentrated into relatively short open seasons. Similar to the baseline and FMP 1, this would increase the risk of possible overfishing because of the difficulty of managing a short, compressed fishery.

PA.2 would have a large effect on the spatial and temporal concentration of GOA rockfish catch compared to what has occurred in past years and what is proposed in FMP 1, FMP 2.1, FMP 2.2, and FMP 3.1. The spatial distribution of the catch would change substantially because PA.2 sets aside 0-20 percent of the GOA as either no-take reserves or as MPAs. As in the other FMPs, ABCs would still be geographically apportioned amongst management areas, which would continue to provide some protection against localized depletion of the resource. The rockfish fishery may be restricted by Pacific halibut PSC limits, which are projected to be reduced by 0-10 percent in the GOA under PA.2. Hence, if PA.2 were adopted, an indirect effect might be to reduce catches of rockfish if means were not found to control or prevent Pacific halibut bycatch. However, the effects of these measures on the spatial and temporal characteristics of the stock complex is unknown.

PA.2 would also have an important temporal effect on rockfish trawl fisheries, as all these fisheries would become "rationalized" through the establishment of IFQs or cooperatives. The existence of IFQs or fishing cooperatives would mean rockfish trawl fishermen would no longer have to compete with each other to catch fish during a short-duration open fishery. The so-called race for fish would be a thing of the past, and the trawl fisheries could extend over a longer time period. This would allow better management oversight of the trawl fishery and reduce the risk of over-harvesting slope rockfish.

Status Determination

The catch rates are below the ABC and OFL values. The MSST cannot be determined. As part of PA.1 and PA.2, the GOA OY cap is established between 116,000 and 800,000 mt. Under PA.2, OY caps would be reconsidered under existing environmental conditions and knowledge of stock levels. The ABC must be set below the OFL under these FMPs. A measure in PA.2 that would affect catch of rockfish is that procedures to account for uncertainty would be incorporated into ABC determinations. These uncertainty corrections would also act to reduce ABC and result in a further decrease in catches of rockfish, thereby providing even greater protection against overfishing.

Age and Size Composition and Sex Ratio

No projections are possible for these two parameters, as shortraker/rougheye are classified as Tier 4 or Tier 5 species, with insufficient information to compute either parameter. There is no information on the sex ratio of shortraker/rougheye, although sex ratio for many other species of *Sebastes* has been reported to be approximately 50:50. How the sex ratio may be affected by PA.1 or PA.2 is unknown.

Habitat-Mediated Impacts

Similar to FMP 1 and the baseline situation in past years, PA.1 may impact habitat for shortraker/rougheye because it closes the eastern GOA to trawling. This closure prevents damage to the benthic environment in the eastern GOA because bottom trawls cannot be used. Although little is known about the habitat preferences of shortraker/rougheye, an undamaged benthic habitat may benefit these species. For example, observations from a manned submersible in the eastern GOA have found shortraker and/or rougheye rockfish associated with boulders along steep slopes (Krieger and Ito 1999) and with colonies of Primnoa coral (Krieger and Wing 2002). The eastern GOA trawl closure presumably causes a reduction in the alteration or destruction of these habitats, which may have a positive effect on shortraker/rougheye in this region.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the GOA as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and pollock bottom trawling would be banned in the entire GOA. EFH and HAPC identification, designation, and assessment would continue and mitigation would be measures instituted as needed. These measures may provide substantial habitat benefits to GOA rockfish.

Predation-Mediated Impacts

Pacific cod, and to a lesser extent walleye, pollock are species that are known to prey on shrimp, a major prey item of rougheye rockfish, so any changes in their abundance as a result of PA.1 and PA.2 hypothetically could affect the food supply of shortraker/rougheye. To protect Steller sea lions, PA.1 has two measures that could reduce the catch and increase the abundance of Pacific cod and walleye pollock: fishing closures around sea lion rookeries, and a $B_{20\%}$ fishing rule for two species. Under PA.2, catch projections for walleye pollock indicate catches would be reduced compared to FMP 1, FMP 2.1, FMP 2.2, and FMP 3.1, and abundance of walleye pollock would somewhat increase. However, whether a change in abundance of Pacific cod or walleye pollock would actually affect the food supply for shortraker/rougheye is unknown, as there is no quantitative information on trophic interactions between all these species. Moreover, shortraker and rougheye rockfish reside in deeper depths than Pacific cod or walleye pollock, so they may not be competing for the same spatial aggregations of food.

The direct/indirect effects of PA.1 and PA.2 on shortraker/rougheye in the GOA are summarized in Table 4.9-1.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA shortraker/rougheye rockfish is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Due to large harvest rates and the longevity of rockfish, past foreign, JV, and domestic fisheries have been identified as having had a negative persistent past effect on GOA shortraker/rougheye rockfish stocks (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause shortraker/rougheye rockfish mortality. Climate changes and regime shifts are not considered contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of shortraker/rougheye rockfish. The IPHC longline fishery and State of Alaska shrimp fishery are not considered contributing factors since bycatch of rockfish species is not expected to occur in these fisheries.

- **Cumulative Effects.** A cumulative effect is identified for mortality of GOA shortraker/rougheye rockfish, and is rated as insignificant. Fishing mortality at projected levels is well below OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of changes in biomass level is unknown since the MSST for this stock cannot be determined.

- **Persistent Past Effects.** Due to large harvest rates and the longevity of rockfish, past foreign, JV, and domestic fisheries have been identified as having had a negative persistent past effect on GOA shortraker/rougheye rockfish stocks (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** Future external effects on the change in biomass level are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause shortraker/rougheye rockfish mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the shortraker/rougheye rockfish biomass level; however, it is unknown whether warmer water temperatures will favor or reduce recruitment. For more information on climate changes and regime shifts see Sections 3.5.1.13 and 3.10. The IPHC longline fishery and State of Alaska shrimp are not considered contributing factors to GOA slope rockfish biomass level since bycatch is not expected to occur in these fisheries.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of GOA shortraker/rougheye rockfish, but the effect is unknown. It is unknown whether the combined effect of internal and external removals is likely to jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch
   – Change in Genetic Structure of Population
   – Change in Reproductive Success

- **Direct/Indirect Effects.** The spatial/ temporal characteristics of GOA shortraker/rougheye rockfish under PA.1 and PA.2 are unknown.

- **Persistent Past Effects.** No persistent past effects have been identified for the change in genetic structure of GOA shortraker/rougheye rockfish; however, climate changes and regime shifts have been identified as having had potential positive or negative effects on shortraker/rougheye rockfish reproductive success. Climate changes and regime shifts influence prey availability and habitat suitability which in combination effect reproductive success (see Sections 3.5.1.13 and 3.10).

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as a potentially adverse contributor to GOA shortraker/rougheye rockfish genetic structure and reproductive success since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment. Climate changes and regime shifts are not considered contributing factors to genetic structure; however, could affect reproductive success by driving changes in prey availability and habitat suitability. The IPHC longline fishery and the State of Alaska shrimp fishery are not considered contributing factors to the change in genetic structure and reproductive success of GOA shortraker/rougheye rockfish since bycatch in these fisheries is unlikely to occur.

- **Cumulative Effects.** A cumulative effect for the spatial and temporal characteristics of the GOA shortraker/rougheye rockfish complex is possible; however, the effect is unknown. It is unknown whether the combined effect of internal and external removals will occur in a localized manner such that it will lead to a detectable reduction in genetic diversity and reproductive success of the GOA shortraker/rougheye rockfish complex.

Change in Prey Availability

- **Direct/Indirect Effects.** The change in prey availability under PA.1 and PA.2 is unknown.

- **Persistent Past Effects.** Climate changes and regime shifts have been identified as having had positive or negative effects on shortraker/rougheye rockfish prey availability (see Sections 3.5.1.13 and 3.10).

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as a potentially adverse contributor to shortraker/rougheye rockfish prey availability since acute and/or chronic pollution events could reduce prey availability or prey quality such that the ability of the stock complex to maintain itself at current population levels is jeopardized. Climate changes and regimes shifts are identified as potentially beneficial or adverse contributors to prey availability (see Sections 3.5.1.13 and 3.10). The IPHC longline fishery is not considered contributing factor to shortraker/rougheye rockfish prey availability since bycatch of shortraker/rougheye rockfish prey species is not expected to occur in this fishery. The State of Alaska shrimp fishery is identified as a potential adverse contributor to shortraker/rougheye rockfish prey availability since shrimp is a main prey item of rougheye rockfish.

- **Cumulative Effects.** A cumulative effect is possible for the change in prey availability of the GOA shortraker/rougheye rockfish; however, the effect is unknown due to lack of scientific information.

Change in Habitat Suitability

- **Direct/Indirect Effects.** The change in habitat suitability is determined to be unknown under PA.1 and PA.2.

- **Persistent Past Effects.** Past foreign, JV, and domestic groundfish fisheries, and the IPHC longline fisheries have been identified as having past persistent negative effects on GOA shortraker/rougheye rockfish habitat due to the impacts caused by fishery gear. Climate changes and regime shifts have also been identified as having past positive or negative effects on GOA shortraker/rougheye rockfish habitat suitability (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** Marine pollution has been identified as a potentially adverse contributor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. Climate changes and regime shifts could make a potentially beneficial or adverse contribution to shortraker/rougheye rockfish habitat suitability (see Sections 3.5.1.13 and 3.10). The IPHC longline fishery has been identified as a potentially adverse contributor to shortraker/rougheye rockfish habitat suitability due to impacts from fishery gear. The State of Alaska shrimp fishery is not considered contributing factor since habitat degradation from shrimp fishery gear is not expected to occur (see Section 3.6).

- **Cumulative Effects.** Although a cumulative effect is possible for habitat suitability of GOA shortraker/rougheye rockfish, the effect is currently unknown due to lack of scientific information.

See Table 4.5-27 for a summary of the cumulative effects on GOA shortraker/rougheye rockfish under PA.1 and PA.2.

GOA Slope Rockfish – Direct/Indirect Effects of PA.1 and PA.2

The average exploitable biomass for the other slope rockfish groups are placed in Tier 5 where ABC is determined by F = 0.75M. Sharpchin are assessed under Tier 4 where OFL is calculated by F = M.

Total and Spawning Biomass

No projections are possible for these two parameters, as slope rockfish species are classified as Tier 4 or Tier 5 fish, with insufficient information to compute either parameter.

Fishing Mortality

PA.1 is more precautionary in its approach than FMPs 1, 2.1, and 2.2. However, for most measures in regards to slope rockfish it remains very similar to the baseline FMP 1. For example, the eastern GOA trawl closure is retained in this bookend, which means most of the GOA population of slope rockfish will not be vulnerable to fishing. The model projections for PA.1, however, show ABCs much less than those for FMP 1, whereas the catches for PA.1 are slightly higher than those for FMP 1. Therefore, the model results do not seem plausible (Table H.4-72 of Appendix H). Under PA.1, these projections indicate an increase from the 2002 value of 572 mt to 980 mt in 2004, and then decrease to 944 mt in 2007. The 2003-2007 average projected catch is 960 mt. PA.2 requires that appropriate harvest strategies be developed for rockfish. Should F_{60} be used as a harvest rule, then projections indicate an increase in catch to 712 mt in 2003, a decrease through 2005 to 672 mt, and then an increase through 2007 at 745 mt. The 2003-2007 average projected catch under PA.2 is 705 mt.

There is a danger within stock complexes to fish one species disproportionately to the other and create localized depletions. As part of PA.2, the Observer Program would continue with improvements. These improvements include the enhancement of training programs that would increase the number of species identified by observers. Observer uncertainty estimates for target species data would also be developed. Criteria for the ‘splitting and lumping’ of stock complexes and procedures to account for uncertainty when establishing ABC values would be developed, implemented and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future change in tier designation for GOA rockfish.

Given the low levels of exploitation under PA.1 and PA.2, these FMPs are expected to have insignificant effects on GOA slope rockfish through mortality.

Spatial/Temporal Concentration of Fishing Mortality

The main spatial effect of PA.1 on slope rockfish would be caused by the bookend's retention of the eastern GOA trawl closure, which would mean most of the GOA population of slope rockfish would not be vulnerable to fishing. If this bookend was implemented, the only slope rockfish catch would be taken by trawl west of the closure area and by longline mostly in the eastern GOA. There have been no studies to determine stock structure for any species of slope rockfish, and it is unknown if subpopulations exist. However, because most of the biomass of slope rockfish occurs in the eastern GOA, localized depletion is unlikely under this FMP. Whether this bookend would have much effect on the temporal concentration of slope rockfish catch would depend on decisions made by NPFMC after the bookend was implemented. PA.1 states that IFQs and fishing cooperatives may be established as needed, but since specific recommendations concerning such rights-based management are not included in the FMP, it is difficult to evaluate how they would impact slope rockfish. If NPFMC decided to not establish IFQs and/or cooperatives for rockfish trawlers, most of the slope rockfish catch could continue to be concentrated into a relatively short open season. Similar to the baseline and FMP 1, this would increase the risk of possible overfishing because of the difficulty of managing a short, compressed fishery.

PA.2 would have a large effect on the spatial and temporal concentration of GOA rockfish catch compared to what has occurred in past years and what is proposed in FMP 1, FMP 2.1, FMP 2.2, and FMP 3.1. The spatial distribution of the catch would change substantially because PA.2 sets aside 0-20 percent of the GOA as either no-take reserves or as MPAs. As in the other FMPs, ABCs would still be geographically apportioned amongst management areas, which would continue to provide some protection against localized depletion of the resource. The rockfish fishery may be restricted by Pacific halibut PSC limits, which are projected to b reduced by 0-10 percent in the GOA under PA.2. Hence, if PA.2 were adopted, an indirect effect might be to reduce catches of rockfish if means were not found to control or prevent Pacific halibut bycatch. However, the effects of these measures on the spatial and temporal characteristics of the stock complex is unknown.

PA.2 would also have an important temporal effect on rockfish trawl fisheries, as all these fisheries would become "rationalized" through the establishment of IFQs or cooperatives. The existence of IFQs or fishing cooperatives would mean rockfish trawl fishermen would no longer have to compete with each other to catch fish during a short-duration open fishery. The so-called race for fish would be a thing of the past, and the trawl fisheries could extend over a longer time period. This would allow better management oversight of the trawl fishery and reduce the risk of over-harvesting slope rockfish.

Status Determination

No projections are possible for the fishing mortality rate or MSST, as slope rockfish species are classified as Tier 4 or Tier 5 fish, with insufficient information to compute either parameter. As part of PA.1, the GOA OY cap is established between 116,000 and 800,000 mt. The ABC must be set below the OFL under PA.1. PA.2 revisits the OY caps to determine relevancy to current environmental conditions and knowledge of current stock levels. This would result in a decreased catch for rockfish and greatly reduce any risk of overfishing these species. One other measure in PA.2 that would affect catch of rockfish is that procedures to account for uncertainty would be incorporated into ABC determinations. These uncertainty corrections would also act to reduce ABC and result in a further decrease in catches of rockfish, thereby providing even greater protection against overfishing.

Age and Size Composition and Sex Ratio

Age and size composition estimates are not available for these species. There is no information on the sex ratio of slope rockfish, although sex ratio for many other species of *Sebastes* has been reported to be approximately 50:50. How the sex ratio may be affected by PA.1 or PA.2 is unknown.

Habitat-Mediated Impacts

Similar to FMP 1 and the baseline situation in past years, PA.1 greatly impacts habitat for slope rockfish because it closes the eastern GOA to trawling. This creates a de facto no-take zone or refuge for slope rockfish in this area, as trawls are generally the only effective gear for capturing most of these species. Nearly all the biomass of slope rockfish is found in the eastern GOA, which means the trawl closure in this region protects most of the GOA population from any fishing pressure.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the GOA as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and pollock bottom trawling would be banned in the entire GOA. EFH and HAPC identification, designation, and assessment would continue and mitigation would be measures instituted as needed. These measures may provide substantial habitat benefits to GOA rockfish.

Predation-Mediated Impacts

No studies have been done in Alaska to determine the food habits for any of the slope rockfish species. Many of the abundant species, such as sharpchin, harlequin, and redstripe rockfish, are relatively small in size and may be plankton-feeders, but this is conjecture. There is also no documentation of predation on slope rockfish, although larger fishes such as Pacific halibut that are known to prey on other rockfish presumably also prey on slope rockfish. Because of this lack of information, the effect of PA.1 and PA.2 on predator-prey relationships for slope rockfish is unknown.

The direct/indirect effects of PA.1 and PA.2 on slope rockfish in the GOA are summarized in Table 4.9-1.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of fishing mortality on the GOA other slope rockfish is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Due to large harvest rates and the longevity of rockfish, past foreign, JV, and domestic fisheries and State of Alaska groundfish fisheries have been identified as having had a negative persistent past effect on GOA other slope rockfish stocks (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** Future external effects on mortality are indicated due to the potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause other slope rockfish mortality. Climate changes and regime shifts are not considered to be contributing factors since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of other slope rockfish. The State of Alaska groundfish fisheries is also not considered a contributing factor since catch and bycatch of slope rockfish species is already accounted for by the domestic groundfish fishery management. In addition, the IPHC longline fishery is not considered a contributing factor since bycatch of slope rockfish species is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect identified for mortality of GOA other slope rockfish is rated as insignificant. Fishing mortality at projected levels is well below OFL for this stock. The combined effect of internal removals and removals due to reasonably foreseeable future external events is unlikely to jeopardize the capacity of the stock maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of changes in biomass level is unknown since the MSST for this stock cannot be determined.

- **Persistent Past Effects.** Due to large harvest rates and the longevity of rockfish, past foreign, JV, and domestic fisheries have been identified as having had a negative persistent past effect on GOA other slope rockfish stocks (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effect.** Future external effects on the change in biomass level are indicated due to potentially adverse effects of marine pollution since acute and/or chronic pollution events could cause other slope rockfish mortality. Climate changes and regime shifts have also been identified as having potentially beneficial or adverse effects on the other slope rockfish biomass level; however, it is unknown whether warmer water temperatures will favor or reduce recruitment. For more information on climate changes and regime shifts see Sections 3.5.1.13 and 3.10. The State of Alaska groundfish fisheries are not considered contributing factors to GOA slope rockfish biomass level. Although catch and bycatch do occur in these fisheries, the removals are already accounted for by the domestic groundfish fishery management.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of GOA other slope rockfish, but the effect is unknown. It is unknown whether the combined effect of internal and external removals is likely to jeopardize the capacity of the stock to maintain current population levels.

Spatial/Temporal Concentration of Catch
- – Change in Genetic Structure of Population
- – Change in Reproductive Success

- **Direct/Indirect Effects.** The spatial/temporal characteristics of GOA slope rockfish under PA.1 and PA.2 are unknown.

- **Persistent Past Effects.** No persistent past effects have been identified for the change in genetic structure of GOA slope rockfish; however, climate changes and regime shifts have been identified as having had potential positive or negative effects on slope rockfish reproductive success. Climate changes and regime shifts influence prey availability and habitat suitability which in combination effect reproductive success (see Sections 3.5.1.13 and 3.10).

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as a potentially adverse contributor to GOA slope rockfish genetic structure and reproductive success since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment. Climate changes and regime shifts are not considered contributing factors to genetic structure; however, could affect reproductive success by driving changes in prey availability and habitat suitability. The State of Alaska groundfish fishery is not considered a contributing factor to the change in genetic structure and reproductive success of GOA slope rockfish. Although catch and bycatch of slope rockfish species occurs in these fisheries, they are not expected to contribute to localized depletion such that it leads to a detectable reduction in genetic diversity or reproductive success. The IPHC longline fishery is also not considered a contributing factor since bycatch of slope rockfish species is not expected to occur in this fishery.

- **Cumulative Effects.** A cumulative effect for the spatial and temporal characteristics of the GOA slope rockfish complex is possible; however, the effect is unknown. It is unknown whether the combined effect of internal and external removals will occur in a localized manner such that it will lead to a detectable reduction in genetic diversity and reproductive success of the GOA slope rockfish complex.

<u>Change in Prey Availability</u>

- **Direct/Indirect Effects.** The change in prey availability under PA.1 and PA.2 is unknown.

- **Persistent Past Effects.** Climate changes and regime shifts have been identified as having had positive or negative effects on slope rockfish prey availability (see Sections 3.5.1.13 and 3.10).

- **Reasonably Foreseeable Future External Effects.** Marine pollution is identified as a potentially adverse contributor to slope rockfish prey availability since acute and/or chronic pollution events could reduce prey availability or prey quality such that the ability of the stock complex to maintain itself at current population levels is jeopardized. Climate changes and regimes shifts are identified as potentially beneficial or adverse contributors to prey availability (see Sections 3.5.1.13 and 3.10). The State of Alaska groundfish fishery and the IPHC longline fishery are not considered contributing factors to slope rockfish prey availability since bycatch of slope rockfish prey species is not expected to occur in these fisheries.

- **Cumulative Effects.** A cumulative effect is possible for the change in prey availability of the GOA slope rockfish; however, the effect is unknown due to lack of scientific information.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** The change in habitat suitability is determined to be unknown under PA.1 and PA.2.

- **Persistent Past Effects.** Past foreign, JV, and domestic groundfish fisheries, State of Alaska groundfish fisheries and the IPHC longline fisheries have been identified as having past persistent negative effects on GOA slope rockfish habitat due to the impacts caused by fishery gear. Climate changes and regime shifts have also been identified as having past positive or negative effects on GOA slope rockfish habitat suitability (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** Marine pollution has been identified as a potentially adverse contributor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. Climate changes and regime shifts could have a potentially beneficial or adverse contribution on slope rockfish habitat suitability (see Sections 3.5.1.13 and 3.10). The State of Alaska groundfish fishery and the IPHC longline fishery have been identified as potentially adverse contributors to slope rockfish habitat suitability due to impacts from fishery gear (see Section 3.6).

- **Cumulative Effects.** Although a cumulative effect is possible for habitat suitability of GOA slope rockfish, the effect is currently unknown due to lack of scientific information.

See Table 4.5-27 for a summary of the cumulative effects on GOA slope rockfish under PA.1 and PA.2.

GOA Pelagic Shelf Rockfish – Direct/Indirect Effects of PA.1 and PA.2

<u>Total and Spawning Biomass</u>

No projections are possible for these two parameters, as PSR species are classified as Tier 4 or Tier 5 fish. Until recently, an age-structured model had not been finalized for dusky rockfish. As of 2004, dusky rockfish will be evaluated under Tier 3; however, for the purposes of this analysis, dusky rockfish were modeled under Tier 4.

<u>Fishing Mortality</u>

PA.1 is more precautionary in its approach than FMPs 1, 2.1, and 2.2. However, for most measures in regards to PSR it remains very similar to FMP 1 and the baseline situation. One measure in PA.1 that could affect catch of PSR is that PSC limits for Pacific halibut are reduced 0-10 percent. In at least one instance in recent years, the PSR fishery has been closed early with substantial TAC remaining so that excessive bycatch of halibut would be prevented. Hence, if PA.1 were adopted, an indirect effect might be to reduce catches of PSR if means were not found to control or prevent Pacific halibut bycatch. The model projections for PA.1 show catches about 25 percent less than those for FMP 1, which may be plausible given the reduced PSC limits for Pacific halibut (Table H.4-73 of Appendix H).

Under PA.1, these projections indicate a decrease from the 2002 value of 3,318 mt to 1,657 mt through 2007. The 2003-2007 average projected catch is 1,735 mt. PA.2 requires that appropriate harvest strategies be developed for rockfish. If those strategies were to use F_{60} to determine ABCs, then projections indicate a decrease to 1,086 mt through 2005, and an increase through 2007 to 1,372 mt. The 2003-2007 average projected catch under PA.2 is 1,222 mt.

There is a danger within stock complexes to fish one species disproportionately to the other and create localized depletions. As part of PA.2, the Observer Program would continue with improvements. These improvements include the enhancement of training programs that would increase the number of species identified by observers. Observer uncertainty estimates for target species data would also be developed. Criteria for the 'splitting and lumping' of stock complexes and procedures to account for uncertainty when establishing ABC values would be developed, implemented and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future change in tier designation for GOA rockfish.

Given the low levels of exploitation under PA.1 and PA.2, these FMPs are expected to have insignificant effects on GOA PSR through mortality.

Spatial/Temporal Concentration of Fishing Mortality

Whether PA.1 would have substantial effects on the spatial or temporal concentration of PSR catch would somewhat depend on decisions made by NPFMC after the bookend was implemented. ABCs would still be geographically apportioned amongst management areas, which would continue to provide some protection against localized depletion of the resource. IFQs and fishing cooperatives may be established as needed, but since specific recommendations concerning such rights-based management are not included in the FMP, it is difficult to evaluate how they would impact PSR. If NPFMC decided to not establish IFQs and/or cooperatives for rockfish trawlers, the PSR fishery could continue to be concentrated into a relatively short open season. Similar to the baseline, this would increase the risk of possible overfishing because of the difficulty of managing a short, compressed fishery.

PA.2 would have a large effect on the spatial and temporal concentration of GOA rockfish catch compared to what has occurred in past years and what is proposed in FMP 1, FMP 2.1, FMP 2.2, and FMP 3.1. The spatial distribution of the catch would change substantially because PA.2 sets aside 0-20 percent of the GOA as either no-take reserves or as MPAs. As in the other FMPs, ABCs would still be geographically apportioned amongst management areas, which would continue to provide some protection against localized depletion of the resource. The rockfish fishery may be restricted by Pacific halibut PSC limits, which are projected to be reduced by 0-10 percent in the GOA under PA.2. Hence, if PA.2 were adopted, an indirect effect might be to reduce catches of rockfish if means were not found to control or prevent Pacific halibut bycatch. However, the effects of these measures on the spatial and temporal characteristics of the stock complex are unknown.

PA.2 would also have an important temporal effect on rockfish trawl fisheries, as all these fisheries would become "rationalized" through the establishment of IFQs or cooperatives. The existence of IFQs or fishing cooperatives would mean rockfish trawl fishermen would no longer have to compete with each other to catch fish during a short-duration open fishery. The so-called race for fish would be a thing of the past, and the trawl fisheries could extend over a longer time period. This would allow better management oversight of the trawl fishery and reduce the risk of over-harvesting slope rockfish.

Status Determination

The catch rates are below the ABC and OFL values. The MSST cannot be determined for this stock. One measure in PA.2 that would affect catch of rockfish is that procedures to account for uncertainty would be incorporated into ABC determinations. These uncertainty corrections would also act to reduce ABC and result in a further decrease in catches of rockfish, thereby providing even greater protection against overfishing.

Age and Size Composition and Sex Ratio

No projections are possible for these two parameters, as PSR species are classified as Tier 4 or Tier 5 fish and an age-structured model has not been finalized for dusky rockfish. There is no information on the sex ratio of PSR, although sex ratio for many other species of *Sebastes* has been reported to be approximately 50:50. How the sex ratio may be affected by PA.1 or PA.1 is unknown.

Habitat-Mediated Impacts

Similar to FMP 1 and the baseline situation in past years, PA.1 impacts habitat for PSR because it retains the eastern GOA trawl closure. This creates a de facto no-take zone or refuge for PSR in this area, as trawls are generally the only effective gear for capturing these species. Although biomass estimates from trawl surveys indicate that the trawl closure area in the eastern GOA only contains about 10-15 percent of the GOA biomass of dusky biomass, this is still large enough that it may provide enhanced protection to the dusky rockfish resource. Use of refugia as a conservation measure could be particularly effective for rockfish species, as most are generally believed to be sedentary in nature and not undergo extensive migrations. The closed areas may allow increased survival of larger and older fish that produce significantly more eggs and larvae to replenish the GOA population. The trawl closure also prevents damage to the benthic environment in the eastern GOA because bottom trawls cannot be used. Although little is known about the habitat preferences of PSR, an undamaged benthic habitat likely provides a benefit to these species. For example, observations from manned submersibles in the eastern GOA have found adult dusky rockfish associated with colonies of Primnoa coral (Krieger and Wing 2002) and with large vase-type sponges. Prevention of possible damage by bottom trawls to these living substrates may increase the amount of protective cover available to dusky rockfish to escape predation and thus have a positive impact on the stocks. Juvenile dusky rockfish may also be associated with epifauna such as corals or sponges that provide structural relief on the bottom. If so, reducing the damage to this epifauna by bottom trawls may increase survival of juvenile fish.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the GOA as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and pollock bottom trawling would be banned in the entire GOA. EFH and HAPC identification, designation, and assessment would continue and mitigation measures would be instituted as needed. These measures may provide substantial habitat benefits to GOA rockfish.

Predation-Mediated Impacts

The major prey of dusky rockfish appears to be euphausiids, based on the limited food information available for this species (Yang 1993). Euphausiids are also the major prey of walleye pollock, which means dusky rockfish and walleye pollock may be competing for the same food resource. Thus, any measures in PA.1 that affect the commercial catch of walleye pollock could have a subsequent indirect effect on dusky rockfish by increasing or decreasing the amount of euphausiids available to dusky rockfish. To protect Steller sea lions, PA.1 (similar to FMP 1 and the baseline situation in past years) has two measures that may reduce catch of walleye pollock: fishing closures around sea lion rookeries, and a $B_{20\%}$ fishing rule for walleye pollock. Catch projections for walleye pollock in PA.2 indicate catches would be reduced compared to FMP 1, FMP 2.1, FMP 2.2, and FMP 3.1., and abundance of walleye pollock would somewhat increase. Hypothetically, these measures could increase the abundance of walleye pollock, resulting in the consumption of more euphausiids and having an adverse effect on the food supply for dusky rockfish. How adverse this effect would really be, however, is unknown, as there is little or no quantitative information on trophic interactions between dusky rockfish and walleye pollock or data on whether they even feed on the same spatial aggregations of euphausiids.

The direct/indirect effects of PA.1 and PA.2 on PSR in the GOA are summarized in Table 4.9-1.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects.** The effect of the fisheries on the mortality of the GOA PSR complex is insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Removals by past foreign, JV, and domestic fisheries are identified as having a lingering negative effect on the GOA PSR population (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** The State of Alaska shrimp fishery is not considered to be a contributing factor to GOA PSR mortality since no bycatch is expected in this fishery. Marine pollution is identified as a potentially adverse contributor to GOA PSR mortality since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock complex to maintain current population levels is jeopardized. Climate changes and regime shifts are not considered to be contributors to PSR mortality.

- **Cumulative Effects**. A cumulative effect identified for mortality of GOA PSR is rated as insignificant. PSR are expected to be fished at levels below the OFL. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to maintain current population levels.

Change in Biomass

- **Direct/Indirect Effects.** The effect of fisheries on the biomass level under PA.1 and PA.2 is unknown since the MSST cannot be determined.

- **Persistent Past Effects.** Removals by past foreign, JV, and domestic fisheries are identified as having a lingering negative effect on the GOA DSR population (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** The State of Alaska shrimp and fishery is not considered a contributing factor to GOA PSR biomass levels since no bycatch is expected in this fishery. Marine pollution is identified as a potentially adverse contributor to GOA PSR mortality since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the capacity of the stock complex to maintain current population levels is jeopardized. Climate changes and regime shifts are not considered contributors to PSR mortality.

- **Cumulative Effects.** A cumulative effect is identified for change in biomass; however, the effect is unknown since total and spawning biomass levels and MSST are currently unavailable.

Spatial/Temporal Concentration of Catch

- Change in Genetic Structure of Population
- Change in Reproductive Success

- **Direct/Indirect Effects.** The effect of the fisheries on the spatial/temporal characteristics of GOA PSR under PA.1 and PA.2 is unknown.

- **Persistent Past Effects**. No persistent past effects have been identified for the change in genetic structure of GOA PSR; however, climate changes and regime shifts have been identified as having had potentiallyy positive or negative effects on PSR reproductive success. Climate changes and regime shifts influence prey availability and habitat suitability which in combination affect reproductive success (see Sections 3.5.1.13 and 3.10).

- **Reasonably Foreseeable Future External Effects.** The State of Alaska shrimp and fishery is not considered a contributing factor to GOA PSR genetic structure and reproductive success since no bycatch is expected in this fishery to occur. Marine pollution is identified as a potentially adverse contributor to GOA PSR genetic structure and reproductive success since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment. Climate changes and regime shifts are not considered contributing factors to genetic structure; however, they could affect reproductive success by driving changes in prey availability and habitat suitability.

- **Cumulative Effects.** A cumulative effect of the spatial and temporal characteristics of the GOA PSR complex is possible; however, the effect is unknown.

Change in Prey Availability

- **Direct/Indirect Effects.** The change in prey availability of GOA PSR under PA.1 and PA.2 is unknown.

- **Persistent Past Effects.** Climate changes and regime shifts have been identified as having had positive or negative effects on PSR prey availability (see Sections 3.5.1.13 and 3.10).

- **Reasonably Foreseeable Future External Effects.** The State of Alaska shrimp fishery has been identified as a potentially adverse contributor to GOA PSR prey availability. The catch of shrimp in the shrimp fishery is expected to continue in the future. Marine pollution is identified as a potentially adverse contributor to PSR prey availability since acute and/or chronic pollution events could reduce prey availability or prey quality such that the ability of the stock complex to maintain itself at current population levels is jeopardized. Climate changes and regimes shifts are identified as potentially beneficial or adverse contributors to prey availability (see Sections 3.5.1.13 and 3.10).

- **Cumulative Effects.** A cumulative effect is possible for the change in prey availability of the GOA PSR; however, the effect is unknown due to lack of scientific information.

Change in Habitat Suitability

- **Direct/Indirect Effects.** The change in habitat suitability of GOA PSR under PA.1 and PA.2 is unknown.

- **Persistent Past Effects.** Past foreign, JV, and domestic groundfish fisheries have been identified as having past persisting negative effects on GOA PSR habitat due to the impacts caused by fishery gear. Climate changes and regime shifts have also been identified as having past positive or negative effects on GOA PSR habitat suitability (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** The State of Alaska shrimp fishery is not considered a contributing factor to GOA PSR habitat suitability since the gear associated with this fishery is not expected to cause a significant impact to the benthic habitat (see Sections 3.5.1.13 and 3.6). Marine pollution has been identified as a potentially adverse contributor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. Climate changes and regime shifts could have a potentially beneficial or adverse contribution on DSR habitat suitability (see Sections 3.5.1.13 and 3.10).

- **Cumulative Effects.** Although a cumulative effect is possible for habitat suitability of GOA PSR, the effect is currently unknown due to lack of scientific information.

See Table 4.5-29 for a summary of the cumulative effects on PSR under PA.1 and PA.2.

GOA Demersal Shelf Rockfish – Direct/Indirect Effects of PA.1 and PA.2

Total and Spawning Biomass

Reliable total and spawning biomass statistics are not available for DSR species.

Fishing Mortality

Projected catch of DSR species under PA.1 is expected to increase from the 2002 value of 182 mt to 350 mt in 2003, and is then expected to remain relatively steady throughout 2007. The 2003-2007 average projected catch is 316 mt. PA.2 requires that appropriate harvest strategies be developed for rockfish. If these strategies were to use F_{60}, then projected catch would increase from the 2002 value to 227 mt in 2003, and also remains relatively steady throughout 2007. The 2003-2007 average projected catch under PA.2 is 231 mt.

Under PA.1, there would be few effects on DSR species in the short-term, and overall this management plan would be similar to the FMP 1. As described previously for FMP 1, DSR species are managed conservatively to reduce the risk of overfishing this assemblage. The 2003 OFL has been set at 540 mt (NPFMC 2002a). The 2003 TAC was set equal to the ABC, or 390 mt; so management of DSR in the eastern GOA already complies with this PA.1 requirement. Over the long-term, this FMP would initiate the collection of scientific information necessary to specify a MSST for DSR. Currently DSR fall into Tier 4 and no MSST threshold exists for this species assemblage. Obtaining the information necessary to elevate DSR into a higher Tier and specifying MSST would certainly benefit DSR species and provide opportunities for refining management measures to more fully achieve policy objectives.

DSR species are taken in a small directed fishery with hook and line gear and as bycatch in the halibut longline fishery. Reported catch of DSR has been relatively constant over the last 5 years with landings ranging from 226 mt to 363 mt in large part due to very conservative management practices (Table H.4-74 of Appendix H). Estimated bycatch mortality of DSR in the halibut fishery has ranged about 130 mt to 355 mt annually. A DSR bycatch limit (10 percent) is established during the halibut season to limit mortality of DSR in this fishery. ADF&G requires full retention of DSR in state waters and NPFMC has also recently approved a management measure that requires full retention of DSR species. Once approved by NOAA Fisheries, the measure will improve catch statistics and reduce discards and waste. These measures would continue in PA.1.

There is a danger within stock complexes to fish one species disproportionately to the other and create localized depletions. As part of PA.2, the Observer Program would continue with improvements. These improvements include the enhancement of training programs that would increase the number of species identified by observers. Observer uncertainty estimates for target species data would also be developed. Criteria for the 'splitting and lumping' of stock complexes and procedures to account for uncertainty when establishing ABC values would be developed, implemented and updated as necessary under PA.2. Moreover, the collection of biological information necessary to designate spawning stock biomass estimates would be improved, possibly leading to a future changes in Tier designation for GOA rockfish.

Under PA.1 and PA.2, we expect both the TAC and reported landings to remain stable at present levels. A more precautionary management policy will likely have no significant impact on the ability of DSR to sustain current population levels. Fishing mortality will remain below the OFL under PA.1 and PA.2. Therefore, PA.1 and PA.2 are expected to have insignificant effects on DSR species through mortality.

Spatial/Temporal Concentration of Fishing Mortality

Although management of this assemblage has been conservative, and overall the population appears stable, a decline in the density estimates in the Fairweather Grounds under PA.1 may be an indication that localized overfishing is occurring (O'Connell *et al.* 2002). The TAC for the eastern GOA is partitioned by management district based on biomass density and known habitat. The current harvest strategy indicates that two percent of the exploitable biomass is taken per year and that this level of exploitation is sustainable. However, fishing effort on the Fairweather Grounds appears to be concentrated in areas of best habitat and high density and it may be that local overfishing occurs. The question is whether such potential for localized overfishing would continue under PA.1. The answer is that it could, but the probability is reduced due to the likelihood that TAC will be adjusted downward as better information is obtained on DSR bycatch. Improved scientific information on DSR species would result in improved management that could lead to catch restrictions or other measures designed to prevent localized overfishing. It is presumed that a more precautionary management policy would provide benefits to DSR. As a result, we conclude that PA.1 would generate no significantly adverse impact on DSR stocks.

PA.2 would have a large effect on the spatial and temporal concentration of GOA rockfish catch compared to what has occurred in past years and what is proposed in FMP 1, FMP 2.1, FMP 2.2, and FMP 3.1. The spatial distribution of the catch would change substantially because PA.2 sets aside 0-20 percent of the GOA as either no-take reserves or as MPAs. As in the other FMPs, ABCs would still be geographically apportioned amongst management areas, which would continue to provide some protection against localized depletion of the resource. The rockfish fishery may be restricted by Pacific halibut PSC limits, which are projected to be reduced by 0-10 percent in the GOA under PA.2. Hence, if PA.2 were adopted, an indirect effect might be to reduce catches of rockfish if means were not found to control or prevent Pacific halibut bycatch. However, the effects of these measures on the spatial and temporal characteristics of the stock complex is unknown.

PA.2 would also have an important temporal effect on rockfish trawl fisheries, as all these fisheries would become "rationalized" through the establishment of IFQs or cooperatives. The existence of IFQs or fishing cooperatives would mean rockfish trawl fishermen would no longer have to compete with each other to catch fish during a short-duration open fishery. The so-called race for fish would be a thing of the past, and the trawl fisheries could extend over a longer time period. This would allow better management oversight of the trawl fishery and reduce the risk of over-harvesting slope rockfish.

Status Determination

The MSST cannot be determined for this stock complex. One measure in PA.2 that would affect catch of rockfish is that procedures to account for uncertainty would be incorporated into ABC determinations. These uncertainty corrections would also act to reduce ABC and result in a further decrease in catches of rockfish, thereby providing even greater protection against overfishing. Continual reduction of TAC in the DSR fishery would be beneficial and likely place DSR as a bycatch-only fishery under PA.2.

Age and Size Composition and Sex Ratio

Age and size composition data is not available for GOA demersal shelf rockfish species. The sex ratio of GOA demersal shelf rockfish species is unknown.

Habitat-Mediated Impacts

Any habitat suitability impacts of PA.1 and PA.2, such as adverse effects to spawning habitat, nursery grounds, benthic structures, as a result of fishing, would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient at the present time to conclude that existing habitat suitability indices would undergo any significant change under PA.1. However, PA.1 would initiate a federal MPA program and it is likely that certain areas of the eastern GOA would be candidates for MPA designation. Such a program, by design, could mitigate adverse effects of fishing by protecting areas important to DSR species.

Under PA.2, NOAA Fisheries and NPFMC would consider adopting 0-20 percent of the GOA as MPAs and no-take reserves. Existing closure areas would be reviewed to see if these areas already qualify as MPAs or may be redesignated as gear- or fishery-specific areas and pollock bottom trawling would be banned in the entire GOA. EFH and HAPC identification, designation, and assessment would continue and mitigation measures instituted as needed. These measures may provide substantial habitat benefits to GOA rockfish.

Predation-Mediated Impacts

As with habitat suitability indices, any effects to predator-prey relationships of PA.1 and PA.2 management would be governed by a complex web of direct and indirect interactions that are difficult to quantify. Information is insufficient to conclude that predator-prey relationships would undergo any significant change under PA.1 or PA.2.

See Table 4.9-1 for a summary of the direct/indirect effects on DSR under PA.1 and PA.2.

Cumulative Effects of PA.1 and PA.2

Mortality

- **Direct/Indirect Effects**. The effect of fishing mortality on the GOA DSR complex is insignificant under PA.1 and PA.2.

- **Persistent Past Effects.** Removals by past foreign, JV, and domestic fisheries are identified as having a lingering negative effect on the GOA DSR population (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** The State of Alaska herring, shrimp and groundfish fisheries and the IPHC longline fishery are not considered to be contributing factors to GOA DSR mortality since catch/bycatch in these fisheries is already accounted for by the domestic fishery management levels or bycatch is not expected to occur. Marine pollution is identified as a potentially adverse contributor to GOA DSR mortality since acute and/or chronic pollution events, if large enough in scale, could cause mortality to the point that the capacity of the stock complex to maintain current population levels is jeopardized. Climate changes and regime shifts are not considered to be contributors to DSR mortality.

- **Cumulative Effects.** A cumulative effect is identified for mortality of GOA DSR and is rated as insignificant. DSR are expected to be fished at levels below the OFL. The combined effect of internal removals and removals due to reasonably foreseeable external events is not expected to jeopardize the capacity of the stock to maintain current population levels.

Change in Biomass

- **Direct/Indirect Effects.** The effect of the fisheries on the change in biomass level under PA.1 and PA.2 is unknown.

- **Persistent Past Effects.** Removals by past foreign, JV, and domestic fisheries are identified as having a lingering negative effect on the GOA DSR population (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** The State of Alaska herring, shrimp and groundfish fisheries and the IPHC longline fishery are not considered to be contributing factors to GOA DSR biomass levels since catch/bycatch in these fisheries is already accounted for by the domestic fishery management levels or bycatch is not expected to occur. Marine pollution is identified as a potentially adverse contributor to GOA DSR mortality since acute and/or chronic pollution events, if large enough in scale, could impact biomass to the point that the capacity of the stock complex to maintain current population levels is jeopardized. Climate changes and regime shifts are not considered contributors to DSR mortality.

- **Cumulative Effects.** A cumulative effect is identified for change in biomass; however, the effect is unknown since total and spawning biomass levels are currently unavailable.

Spatial/Temporal Concentration of Catch

– Change in Genetic Structure of Population
– Change in Reproductive Success

- **Direct/Indirect Effects.** The effect of the fisheries on the spatial/temporal characteristics of GOA DSR under PA.1 and PA.2 is unknown.

- **Persistent Past Effects.** No persistent past effects have been identified for the change in genetic structure of GOA DSR; however, climate changes and regime shifts have been identified as having had potentially positive or negative effects on DSR reproductive success. Climate changes and regime shifts influence prey availability and habitat suitability which in combination affect reproductive success (see Sections 3.5.1.13 and 3.10).

- **Reasonably Foreseeable Future External Effects.** The State of Alaska herring, shrimp and groundfish fisheries and IPHC longline fisheries are not considered to be contributing factors to GOA DSR genetic structure and reproductive success. Catch/bycatch of these fisheries is already accounted for by the domestic groundfish management or is not expected to occur (as in the case of the State of Alaska herring and shrimp fisheries). Marine pollution is identified as a potentially adverse contributor to GOA DSR genetic structure and reproductive success since acute and/or chronic pollution events, depending on their location and magnitude, could alter the genetic structure of the population through localized mortality events, and also could result in reduced recruitment. Climate changes and regime shifts are not considered contributing factors to genetic structure; however, could affect reproductive success by driving changes in prey availability and habitat suitability.

- **Cumulative Effects.** A cumulative effect of the spatial and temporal characteristics of the GOA DSR complex is possible; however, the effect is unknown.

Change in Prey Availability

- **Direct/Indirect Effects.** The effect of the fisheries on the change in prey availability of GOA DSR under PA.1 and PA.2 is unknown.

- **Persistent Past Effects.** Climate changes and regime shifts have been identified as having had positive or negative effects on DSR prey availability (see Sections 3.5.1.13 and 3.10).

- **Reasonably Foreseeable Future External Effects.** The State of Alaska herring and shrimp fisheries have been identified as potentially adverse contributors to GOA DSR prey availability. Catch of herring in the herring fishery and the catch of shrimp in the shrimp fishery are expected to continue in the future. The State of Alaska groundfish fishery and the IPHC longline fishery are not considered to be contributing factors to GOA DSR prey availability since bycatch of DSR prey species in not expected to occur. Marine pollution is identified as a potentially adverse contributor to DSR prey availability since acute and/or chronic pollution events could reduce prey availability or prey quality such that the ability of the stock complex to maintain itself at current population levels is jeopardized. Climate changes and regimes shifts are identified as potentially beneficial or adverse contributors to prey availability (see Sections 3.5.1.13 and 3.10).

- **Cumulative Effects.** A cumulative effect is possible for the change in prey availability of the GOA DSR; however, the effect is unknown due to lack of scientific information.

<u>Change in Habitat Suitability</u>

- **Direct/Indirect Effects.** The effect of the fisheries on the change in habitat suitability of GOA DSR under PA.1 and PA.2 is unknown.

- **Persistent Past Effects.** Past foreign, JV, and domestic groundfish fisheries and the IPHC longline fisheries have been identified as having past persisting negative effects on GOA DSR habitat due to the impacts caused by fishery gear. Climate changes and regime shifts have also been identified as having past positive or negative effects on GOA DSR habitat suitability (see Section 3.5.1.13).

- **Reasonably Foreseeable Future External Effects.** The State of Alaska herring and shrimp fisheries are not considered to be contributing factors to GOA DSR habitat suitability since the gear associated with these fisheries is not expected to cause a significant impact to the benthic habitat. The State of Alaska groundfish fisheries and the IPHC longline fisheries are identified as potential adverse contributors to DSR habitat suitability. See Sections 3.5.1.13 and 3.6 for more information on the effects of fishery gear on EFH. Marine pollution has been identified as a potentially adverse contributor since acute and/or chronic pollution events could cause habitat degradation and may cause changes in spawning or rearing success. Climate changes and regime shifts could have a potentially beneficial or adverse contribution to DSR habitat suitability (see Sections 3.5.1.13 and 3.10).

- **Cumulative Effects.** Although a cumulative effect is possible for habitat suitability of GOA DSR, the effect is currently unknown due to lack of scientific information.

See Table 4.5-30 for a summary of the cumulative effects on DSR under PA.1 and PA.2.

4.9.2 Prohibited Species Preferred Alternative Analysis

4.9.2.1 Pacific Halibut

Pacific halibut are managed by the IPHC. Halibut bycatch in federal groundfish fisheries is controlled by the use of PSC limits. IPHC accounts for all removals of halibut, including bycatch in other fisheries, when setting quotas for the directed longline fishery. Thus, changes in bycatch (increase or decrease) are reflected in changes to quotas set for the directed fishery.

Direct/Indirect Effects PA.1 and PA.2 – Pacific Halibut

Direct and indirect effects for Pacific halibut include mortality, and changes in reproductive success and prey availability. These effects, which are associated with changes in catch, are considered insignificant because annual quota setting processes implemented by the IPHC account for all removals of halibut including bycatch in other fisheries. Thus, if changes to the baseline condition of the stock occur, they are reflected in the quotas set for the directed fishery. Halibut spawn in deep waters of the continental slope in midwinter where they are not significantly affected by any fishery. Halibut are opportunistic predators with a wide range of prey species and no significant change to prey structure is expected as a result of either PA. No evidence of fishery impact to habitat of halibut has been shown, so this effect will not be considered in the cumulative effects analysis that follows. A summary of these effects is shown in Table 4.9-2.

Under PA.1, current halibut PSC caps would be retained with the possibility of future reduction in the BSAI of 0 to 10 percent). Estimated halibut bycatch mortality under PA.1 in the BSAI and GOA combined would decrease slightly from currently observed rates. This decrease would enable a corresponding increase in halibut catch by the IPHC directed fishery. Total removals would continue to be limited by the IPHC to protect the halibut resource.

Under PA.2, current halibut PSC caps in the BSAI would be reduced between 0 and 20 percent with the possibility of also reducing GOA PSC limits by zero to ten percent. Reductions in halibut are assumed to occur as a result of bycatch reduction incentives implemented as part of the rationalization of the groundfish fisheries. Estimated bycatch mortality in the BSAI and GOA would decrease, as noted in PA.1, thus enabling directed IPHC fisheries to increase halibut catch rates. Total removals would continue to be limited by the IPHC. In addition, PA.2 proposes the development of inseason closure areas in the GOA once PSC limits have been reached. This measure may provide for additional protection of the halibut resource in areas characterized with significant halibut bycatch.

Cumulative Effects Analysis PA.1 and PA.2 – Pacific Halibut

A summary of the cumulative effects analysis associated with PA.1 and PA.2 is shown in Table 4.5-31. For further information on persistent past effects included in this analysis, see Section 3.5.2.1 of this Programmatic SEIS.

<u>Mortality</u>

- **Direct/Indirect Effects.** The potential effect of fishing mortality on BSAI and GOA Pacific halibut is insignificant under PA.1 and PA.2 because current management of halibut by the IPHC accounts for all removals of halibut including bycatch in other fisheries when setting quotas for the directed fishery. Thus, if changes to the baseline condition of the stock occur, quotas set by the IPHC for the directed fishery will be adjusted accordingly.

- **Persistent Past Effects.** No persistent past effects of mortality on Pacific halibut have been identified. It is inferred that halibut bycatch in past fisheries was accounted for under the IPHC management process that is still in effect today.

- **Reasonably Foreseeable Future External Effects.** The directed longline fishery for Pacific halibut remains in effect, but is closely managed by the IPHC. Although state-managed fisheries may incidentally catch halibut, the IPHC provides for all removals, including bycatch in other fisheries, when setting quotas for the directed longline fishery. Thus, changes in halibut bycatch (increase or decrease) are reflected in changes to quotas set for the directed fishery. The directed longline fishery and other state-managed fisheries are not considered contributing factors to changes in halibut mortality. Long-term climate changes and regime shifts are not considered contributing factors, as they are not expected to result in direct mortality.

- **Cumulative Effects.** The combined effects of mortality on Pacific halibut resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are considered insignificant for PA.1 and PA.2.

Change in Reproductive Success

- **Direct/Indirect Effects.** The potential effect of changes in reproductive success on BSAI and GOA Pacific halibut is insignificant under PA.1 and PA.2. Halibut spawn in deep waters of the continental slope in midwinter where they are not significantly affected by any fishery. No significant change from the baseline condition is expected as a result of PA.1 and PA.2.

- **Persistent Past Effects.** No persistent past effects of changes in reproductive success on Pacific halibut have been identified. Currently, halibut stocks are considered healthy and stable.

- **Reasonably Foreseeable Future External Effects.** Halibut spawn in deep waters of the continental slope in midwinter where they are not significantly affected by any fishery. The directed longline fishery and other state-managed fisheries are not considered contributing factors to changes in reproductive success for halibut. Long-term climate change and regime shifts could have impacts to the reproductive success of Pacific halibut depending on the direction of the shift. It has been shown that warm trends favor recruitment while cool trends weaken recruitment in most fish species; however, the effects of this type of large scale event on halibut cannot be determined at this time.

- **Cumulative Effects.** The combined effects of changes in reproductive success on Pacific halibut resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are considered insignificant for PA.1 and PA.2.

Change in Prey Availability

- **Direct/Indirect Effects.** The potential effect of changes in prey availability on BSAI and GOA Pacific halibut is insignificant under PA.1 and PA.2. Halibut are opportunistic predators with a wide range of prey species and no significant change to prey structure is expected as a result of PA.1 and PA.2.

- **Persistent Past Effects.** No persistent past effects impacting prey availability of halibut have been identified.

- **Reasonably Foreseeable Future External Effects.** Halibut are opportunistic predators with a wide range of prey species. An increase in prey competition between Pacific halibut and fisheries catch is not expected. Thus, the directed longline fishery and other state-managed fisheries are not considered contributing factors to changes in prey availability for halibut. Long-term climate changes and regime shifts could have impacts on certain prey species of Pacific halibut depending on the direction of the shift. It has been shown that warm trends favor recruitment while cool trends weaken recruitment in most fish species; however, the effects of this type of large scale event on the prey structure of halibut cannot be determined at this time.

- **Cumulative Effects.** The combined effects of changes in prey availability on Pacific halibut resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are considered insignificant for PA.1 and PA.2.

4.9.2.2 Pacific Salmon or Steelhead Trout

Pacific salmon are managed by ADF&G, which also manages the salmon sport fisheries and permitted subsistence harvesting, to ensure that escapement goals are met for the spawning population in order to maintain sustained yields from the stock as a whole. Annual harvest levels are responsive to fluctuations in run sizes.

For reasons discussed in Section 4.5.2.2, ESA-listed Pacific Northwest chinook salmon and steelhead trout were not specifically considered in this cumulative effects analysis.

Management of Alaskan salmon stocks is challenging due to the lack of precise information on total returns and the inability to predict future returns to most rivers or tributaries with any degree of certainty. In most cases, total return and escapement are not known. As a result of this lack of information, estimates of significant impacts of bycatch on various runs are unreliable. Another factor to consider in salmon management is the Alaska subsistence preference law. This law requires that commercial, recreational, and personal use fisheries be restricted before subsistence use fisheries. Therefore, management of all fisheries for these stocks in state waters incorporates conservative measures.

A summary of assumptions included in the impact analysis of the proposed FMPs is presented in Section 4.5.2.2.

The cumulative effects analyses were based on two groupings of Alaska salmon in the BSAI and GOA: chinook salmon and other salmon.

Direct/Indirect Effects PA.1 and PA.2 – Chinook and Other Salmon

Direct and indirect effects for chinook salmon and other salmon in the BSAI and GOA include mortality, changes in spawning habitat, prey availability, genetic structure of population, and reproductive success. A summary of these effects is shown in Table 4.9-2.

PA.1 would maintain current PSC limits for salmon in the BSAI with the possibility for reducing them by zero to ten percent in the future. In the GOA, it is proposed that PSC limits, or other appropriate measures, be established for salmon, as well as identifying salmon savings areas to improve management of salmon stocks residing in this region. Under PA.2, BSAI PSC limits for salmon may be further reduced (0 to 20 percent) while considering reduction in GOA PSC limits by zero to ten percent. PA.2 also proposes the development of in-season closures in the GOA to ensure that once PSC limits have been reached, fishing does not continue within that region. These proposed measures may provide additional protection to Alaska salmon stocks, particularly in years of poor runs.

BSAI Chinook Salmon

Under PA.1, chinook salmon bycatch in the BSAI varies, with an average of approximately 25,000 fish over the five-year projection period. Assuming that 58 to 70 percent of BSAI chinook salmon bycatch may be of western Alaska origin, the bycatch of western Alaska chinook salmon stocks could range from 14,500 to 17,500 fish during the next 6 years. This harvest represents approximately four to six percent of the average western Alaska commercial and subsistence harvest of approximately 300,000 chinook salmon from 1998 through 2000. Such bycatch levels, which are not detectable in natal streams, would have little or no effect on commercial or subsistence harvests and escapement, and are not expected to significantly impact the sustainability of the stock.

Under PA.2, chinook salmon bycatch in the BSAI varies, with an average of about 20,000 fish over the five-year projection period. In keeping consistent with the assumption in PA.1, the bycatch of western Alaska chinook salmon stocks could range from 11,600 to 14,000 fish during the next six years. This harvest represents approximately three to five percent of the average western Alaska commercial and subsistence harvest of approximately 300,000 chinook salmon from 1998 through 2000. Reductions in BSAI chinook salmon are assumed to occur as a result of bycatch reduction incentives implemented as part of the rationalization of the groundfish fisheries. PA.2 results in a reduction in western Alaska chinook salmon catches; however, such bycatch levels may not be detectable in natal streams, may not exert significant effects on commercial or subsistence harvests or escapement, and may not impact the sustainability of the stock as a whole.

BSAI Other Salmon

Under PA.1, bycatch of other salmon in the BSAI varies averaging 65,000 fish over the projection period. Assuming that 96 percent of other salmon bycatch is chum salmon and 19 percent may be of western Alaska origin, the resulting bycatch of western Alaska chum salmon stocks would be about 12,000 fish over the next 6 years. This harvest represents approximately one percent of the average western Alaska commercial and subsistence harvest of approximately 1,100,000 chum salmon from 1998 through 2000. It is presumed that these bycatch levels are not detectable in natal streams, would have no detectable effect on commercial or subsistence harvests and escapement, and would not significantly impact the sustainability of the stock.

Under PA.2, bycatch of other salmon in the BSAI varies, averaging 54,000 fish over the projection period. Maintaining the distribution assumptions noted in PA.1, the bycatch of western Alaska chum salmon stocks would be approximately 10,000 fish during the next six years. This harvest represents less than one percent of the average western Alaska commercial and subsistence harvest of approximately 1,100,000 chum salmon from 1998 through 2000. Reductions in BSAI other salmon are assumed to occur as a result of bycatch reduction incentives implemented as part of the rationalization of the groundfish fisheries. PA.2 results in bycatch reductions for western Alaska chum salmon catches. However, such bycatch levels may not be detectable in natal streams, may not exert significant effects on commercial or subsistence harvests, or escapement, or significantly impact the sustainability of the stock.

GOA Chinook Salmon

Under PA.1, predicted chinook salmon bycatch in the GOA initially decreases and then gradually increases over the 5-year projection period, reaching similar levels to those observed today (approximately 21,000 fish). Assuming that 58 percent of GOA chinook salmon bycatch is of western Alaska origin, bycatch of western Alaska chinook salmon would average approximately 12,000 fish during the next 6 years. This harvest represents approximately four percent of the average western Alaska commercial and subsistence harvest of approximately 300,000 chinook salmon from 1998 through 2000. PA.1 results in reductions of annual western Alaska chinook salmon catch; however, these bycatch levels may not be detectable in natal streams, or exert effects on commercial or subsistence harvests and escapement resulting in significant impacts to sustainability of the stock.

Under PA.2, chinook salmon bycatch in the GOA varies, but remains below those catch rates currently observed (21,000 fish). Thus, chinook salmon bycatch of western Alaska origin is predicted at less than 7,000 fish over the 5-year projection period. This harvest represents less than one percent of the average western Alaska commercial and subsistence harvest of approximately 300,000 chinook salmon from 1998 through 2000. PA.2 results in a reduction in western Alaska chinook salmon catch. Reductions in GOA chinook salmon are assumed to occur as a result of bycatch reduction incentives implemented as part of the rationalization of the groundfish fisheries. However, significance of these reductions on escapement, commercial or subsistence harvests, and sustainability of the stocks is difficult to determine.

GOA Other Salmon

Under PA.1, bycatch of other salmon in the GOA varies, averaging about 5,000 fish over the 5-year projection period. Assuming that 56 percent of this other salmon bycatch is chum salmon, bycatch would consist of approximately 3,000 chum salmon. The proportion of these fish from western Alaska is unknown. Assuming that all of these fish were from western Alaska, this harvest represents less than one percent of the average western Alaska commercial and subsistence harvest of approximately 1,100,000 chum salmon from 1998 through 2000. PA.1 reduces western Alaska chum salmon catches. Reductions in GOA other salmon are assumed to occur as a result of bycatch reduction incentives implemented as part of the rationalization of the groundfish fisheries. However, the significance of these reductions to escapement, commercial or subsistence harvests, and sustainability of the stock cannot be determined.

Under PA.2, bycatch of other salmon in the GOA varies, but remains similar to those trends noted above for PA.1.

Cumulative Effects Analysis PA.1 – BSAI and GOA Chinook and Other Salmon

A summary of the cumulative effects analysis associated with PA.1 is shown in Tables 4.9-2. For further information on persistent past effects included in this analysis, see Section 3.5.2.2 of this Programmatic SEIS.

Mortality

- **Direct/Indirect Effects.** The potential effect of fishing mortality on BSAI and GOA chinook and other salmon is considered insignificant under PA.1.

- **Persistent Past Effects.** Past foreign fisheries in Japan and Russia are associated with direct catch and bycatch of salmon in the BSAI and GOA. Bilateral agreements between the U.S. and these countries attempted to reduce gear conflicts between State of Alaska salmon fisheries, and foreign fisheries while allocating salmon resources to the State of Alaska fisheries. These bilateral agreements were considered marginal management measures for protection of salmon stocks. Before 1959, salmon fisheries in Alaska were managed federally. The State of Alaska took over salmon management after statehood in 1959. However, the domestic fleet continued to grow during the years to follow and by the 1970s, the state initiated a limited entry system upon the realization that salmon stocks were being overfished. Persistent past effects of mortality on Alaskan salmon stocks exist and are associated with past foreign, JV, and domestic groundfish fisheries.

- **Reasonably Foreseeable Future External Effects.** State of Alaska commercial and subsistence fisheries exert effects on mortality of western Alaska chinook and other salmon populations. The magnitude of this effect cannot be determined; however, current stock status indicates that salmon runs in western Alaska are depressed. Taking this stock condition into consideration, impacts of catch and bycatch by state fisheries could hinder recovery of depressed stocks and are considered a potential adverse contribution to the population as a whole. State of Alaska commercial, subsistence, and sport fisheries also impact salmon populations other than western Alaska chinook. Land management practices heavily influence the condition of watersheds used by spawning salmon, but are not considered contributing factors in direct mortality of salmon. State of Alaska hatchery enhancement programs initiated in the GOA potentially counteract the effects of mortality on salmon stocks. In addition, long-term climate changes and regime shift are not expected to result in direct mortality of salmon.

- **Cumulative Effects.** Given the poor stock status of salmon runs in western Alaska, the combined effects of mortality on BSAI and GOA chinook, and BSAI other salmon resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are considered conditionally significant adverse for PA.1. Combined bycatch potential in the BSAI and GOA under this FMP could impede the successful recovery of depressed stocks and impact sustainability of the stock as a whole. The combined effects of mortality on GOA other salmon resulting from internal bycatch and future events are considered insignificant under PA.1.

Change in Prey Availability

- **Direct/Indirect Effects**. The potential effects of PA.1 on prey availability for BSAI and GOA chinook and other salmon are unknown. A relationship between fisheries bycatch of salmon prey and salmon prey availability has not been defined.

- **Persistent Past Effects.** It has not been determined if past effects are currently impacting prey availability for BSAI and GOA chinook and other salmon.

- **Reasonably Foreseeable Future External Effects.** In both the BSAI and GOA, a relationship between State of Alaska commercial, subsistence, and GOA sport fisheries bycatch of salmon prey and salmon prey availability has not been defined, and potential effects are unknown. Land management practices are not considered contributing factors in salmon prey availability of salmon, as it is not likely that they would impact the marine environment in which salmon forage. State of Alaska hatchery enhancement programs occur in GOA, but do not include prey species of salmon. Long-term climate changes and regime shifts could have impacts on certain prey species of Pacific salmon in the BSAI and GOA depending on the direction of the shift. It has been shown that warm trends favor recruitment while cool trends weaken recruitment in most fish species. However, the effects of this type of large scale event on the prey structure of salmon cannot be determined at this time.

- **Cumulative Effects.** The combined effects of potential changes in prey availability for BSAI and GOA chinook and other salmon resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown under PA.1.

<u>Change in Genetic Structure of Population</u>

- **Direct/Indirect Effects.** The potential effects of PA.1 on genetic structure of salmon populations in the BSAI and GOA are unknown.

- **Persistent Past Effects.** It has not been determined if past effects may be impacting the genetic structure of the BSAI and GOA chinook and other salmon populations.

- **Reasonably Foreseeable Future External Effects.** In both the BSAI and GOA, salmon bycatch composition has not been determined, so potential effects of State of Alaska commercial, subsistence, and sport fisheries on genetic structure of salmon populations are unknown. For reasons stated above, land management practices, long-term climate changes, and regime shifts are not considered contributing factors to changes in the BSAI and GOA salmon populations. State of Alaska hatchery enhancement programs in the GOA focus on building certain salmon stocks, but because actual stock composition for all species of salmon is unknown, the potential effects of this program on genetic structure of salmon populations in the GOA are not known.

- **Cumulative Effects.** Due to the uncertainty of current stock composition for chinook and other salmon in the BSAI and GOA, the combined effects of changes in genetic structure on salmon populations in Alaska resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown under PA.1.

<u>Change in Reproductive Success</u>

- **Direct/Indirect Effects.** The potential effects of PA.1 on reproductive success for BSAI and GOA chinook and other salmon cannot be determined.

- **Persistent Past Effects.** Given the poor stock status of salmon runs in western Alaska it may be inferred that reproductive success has been impacted in certain populations of the BSAI region. Successful reproduction of salmon depends on spawning adults' ability to reach intended spawning habitat. Persistent past effects of mortality on salmon stocks exist, and it is likely that reproductive success of these stocks has suffered as a result. Stocks in GOA are currently considered stable, so it is inferred that any past effects on the population have been mitigated over time.

- **Reasonably Foreseeable Future External Effects.** State of Alaska commercial and subsistence fisheries catch of western Alaska chinook and other salmon populations could cause potential adverse impacts to reproductive success of these already depressed stocks. Successful reproduction of salmon relies on spawning adults' ability to reach destined spawning habitat. The direct take of these fish would prevent their return to spawning grounds. Considering the condition of this depressed stock, impacts of catch and bycatch by State of Alaska fisheries could hinder its recovery, and are therefore considered a potential adverse contribution to the population as a whole. GOA other salmon stocks are considered stable, so potential effects of State of Alaska commercial, subsistence, and sport fisheries on reproductive success of this stock are considered insignificant for this population. Degradation of watersheds used by spawning salmon, resulting from poor land management practices, could significantly impact the reproductive success of BSAI salmon stocks. Thus, these practices are considered potential adverse contributions to possible changes in reproductive success of this population. Hatchery enhancement programs in GOA may help to restore depressed stocks and maintain stable stocks in Alaska, and are considered potentially beneficial to the reproductive success of salmon.

Long-term climate changes and regime shifts could have impacts on the reproductive success of Pacific salmon in the BSAI and GOA depending on the direction of the shift. It has been shown that warm trends favor recruitment while cool trends weaken recruitment in most fish species; however, the effects of this type of large scale event on reproductive success of BSAI and GOA salmon cannot be determined at this time.

- **Cumulative Effects.** Successful reproduction of salmon relies on spawning adults' ability to reach destined spawning habitat. Given the poor stock status of salmon runs in western Alaska, and the combined bycatch potential in the BSAI and GOA fisheries, the sustainability of BSAI and GOA chinook, and BSAI other salmon stocks could be impacted. Thus, fisheries catch may remove spawning adults destined for spawning grounds, and potential combined effects from internal and external events are considered conditionally significant adverse to the reproductive success of BSAI and GOA chinook and BSAI other salmon. Although current stock status of GOA chinook and other salmon is stable, combined effects of changes in reproductive success in Alaskan salmon populations resulting from internal bycatch and future external events (both human controlled and natural) cannot be determined for GOA other salmon stocks under PA.1.

Cumulative Effects Analysis PA.2 – BSAI and GOA Chinook and Other Salmon

A summary of the cumulative effects analysis associated with PA.2 is shown in Table 4.9-2. For further information on persistent past effects included in this analysis, see Section 3.5.2.2 of this Programmatic SEIS.

<u>Mortality</u>

- **Direct/Indirect Effects.** The potential effect of fishing mortality on BSAI and GOA chinook and other salmon is considered insignificant under PA.2.

- **Persistent Past Effects.** Past foreign fisheries in Japan and Russia are associated with direct catch and bycatch of salmon in the BSAI and GOA. U.S. bilateral agreements between the U.S. and these countries attempted to reduce gear conflicts between State of Alaska salmon fisheries and foreign fisheries while allocating salmon resources to the State of Alaska fisheries. These bilateral agreements were considered marginal management measures for protection of salmon stocks. Before 1959, salmon fisheries in Alaska were managed federally. The State of Alaska took over salmon management after statehood in 1959. However, the domestic fleet continued to grow during the years to follow and by the 1970s, the state initiated a limited entry system upon the realization that salmon stocks were being overfished. Persistent past effects of mortality on Alaskan salmon stocks exist and are associated with past foreign, JV, and domestic groundfish fisheries.

- **Reasonably Foreseeable Future External Effects**. External effects on Alaskan salmon populations differ between the BSAI and GOA and will be discussed independently for each region.

  In the BSAI, State of Alaska commercial and subsistence fisheries exert effects on mortality of chinook and other salmon populations. The magnitude of this effect cannot be determined; however, current stock status indicates that salmon runs in western Alaska are depressed. In considering this stock condition, impacts of catch and bycatch by State of Alaska fisheries could hinder recovery of depressed stocks, and are considered a potential adverse contribution to the population as a whole. In the GOA, State of Alaska commercial, subsistence, and sport fisheries exert effects on mortality of other salmon populations due to their stability. Land management practices heavily influence the condition of watersheds used by spawning salmon, but are not considered contributing factors in direct mortality of salmon. State of Alaska commercial enhancement programs were initiated in the GOA and have a potential beneficial contribution to effects of mortality on salmon stocks. In addition, long-term climate changes and regime shifts are not expected to result in direct mortality of salmon.

  In the GOA, State of Alaska commercial, subsistence, and sport fisheries exert effects on mortality of chinook and other salmon populations. However, they are not expected to impact salmon stocks in this region under PA.2. As mentioned in the BSAI above, land management practices are an important factor influencing spawning habitat of salmon, but are not considered contributing factors in direct mortality of salmon in the GOA. State of Alaska commercial enhancement programs were initiated in the GOA and have a potential beneficial contribution to effects of mortality on salmon stocks. Long-term climate changes and regime shifts are not expected to result in direct mortality of salmon.

- **Cumulative Effects.** Given the poor stock status of salmon runs in western Alaska, the combined effects of mortality on the BSAI and GOA chinook and BSAI other salmon resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are considered conditionally significant adverse for PA.2. Combined bycatch potential of the BSAI and GOA under this FMP could impede on the successful recovery of depressed stocks in the BSAI and impact sustainability of the stock as a whole. The combined effects of mortality on GOA other salmon resulting from bycatch and future events are considered insignificant under PA.2.

Change in Prey Availability

- **Direct/Indirect Effects**. The potential effects of PA.2 on prey availability for BSAI and GOA and other salmon are unknown. A relationship between fisheries bycatch of salmon prey and salmon prey availability has not been defined.

- **Persistent Past Effects.** It has not been determined if past effects are currently impacting prey availability for BSAI and GOA chinook and other salmon.

- **Reasonably Foreseeable Future External Effects.** In both the BSAI and GOA, a relationship between State of Alaska commercial, subsistence, and GOA sport fisheries bycatch of prey and salmon prey availability has not been defined, and potential effects are unknown. Land management practices are not considered contributing factors in prey availability of salmon, as it is not likely that they would impact the marine environment in which salmon forage. Long-term climate changes and regime shifts could have impacts on certain prey species of Pacific salmon in the BSAI and GOA depending on the direction of the shift. It has been shown that warm trends favor recruitment, while cool trends weaken recruitment in most fish species. However, the effects of this type of large scale event on the prey structure of salmon cannot be determined at this time. State of Alaska hatchery enhancement programs that occur in the GOA do not include prey species of salmon.

- **Cumulative Effects.** The combined effects of potential changes in prey availability for BSAI and GOA chinook and other salmon resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown under PA.2.

Change in Genetic Structure of Population

- **Direct/Indirect Effects.** The potential effects of PA.2 on genetic structure of salmon populations in the BSAI and GOA are unknown.

- **Persistent Past Effects.** It has not been determined if past effects may be impacting the genetic structure of the BSAI and GOA chinook and other salmon populations.

- **Reasonably Foreseeable Future External Effects**. In both the BSAI and GOA, salmon bycatch composition has not been determined, so potential effects of State of Alaska commercial and subsistence fisheries on genetic structure of salmon populations are unknown. Significant impacts to genetic structure of salmon populations by land management practices are not expected, and are not considered contributing factors to a possible change in baseline condition. Long-term climate changes and regime shifts are not expected to result in direct mortality, which would potentially affect genetic structure of BSAI and GOA chinook and other salmon stocks. State of Alaska hatchery enhancement programs in the GOA focus on building certain salmon stocks, but because actual stock composition for all species of salmon is unknown, the potential effects of this program on genetic structure of salmon populations in the GOA are not known.

- **Cumulative Effects.** Due to the uncertainty of current stock composition for chinook and other salmon in the BSAI and GOA, the combined effects of changes in genetic structure on salmon populations in Alaska resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown under PA.2.

Change in Reproductive Success

- **Direct/Indirect Effects.** The potential effects of PA.2 on reproductive success for BSAI and GOA chinook and other salmon cannot be determined.

- **Persistent Past Effects**. Given the poor stock status of salmon runs in western Alaska it may be inferred that reproductive success has been impacted in certain populations of the BSAI region.

Successful reproduction of salmon depends on spawning adults' ability to reach destined spawning habitat. Persistent past effects of mortality on salmon stocks exist, and it is likely that reproductive success of these stocks has suffered as a result. Stocks in the GOA are currently considered stable so it is inferred that any past effects on the population have been mitigated over time.

- **Reasonably Foreseeable Future External Effects.** External effects on Alaskan salmon populations differ between BSAI and GOA and will be discussed independently for each region.

  In the BSAI, State of Alaska commercial and subsistence fisheries catch of chinook and other salmon populations could cause potential adverse impacts to reproductive success of these already depressed stocks. Successful reproduction of salmon relies on spawning adults' ability to reach destined spawning habitat. The direct take of these fish would prevent their return to spawning grounds. In considering this depressed stock condition, impacts of catch and bycatch by State of Alaska fisheries could hinder recovery of depressed stocks and are considered a potential adverse contribution to the population as a whole. Degradation of watersheds used by spawning salmon, and caused by poor land management practices, could significantly impact the reproductive success of BSAI salmon stocks. Thus, these practices are considered potential adverse contributions to possible changes in reproductive success of this population.

  Salmon stocks in the GOA are considered stable, so potential effects of State of Alaska commercial, subsistence, and sport fisheries on reproductive success of this stock are considered insignificant for this population. For reasons stated above, land management practices are considered as potential adverse contributions to the reproductive success of the GOA salmon stocks. Hatchery enhancement programs in GOA may help to restore depressed stocks and maintain stable stocks in Alaska and are considered potentially beneficial to the reproductive success of salmon.

  Long-term climate changes and regime shifts could have impacts on the reproductive success of Pacific salmon in the BSAI and GOA depending on the direction of the shift. It has been shown that warm trends favor recruitment while cool trends weaken recruitment in most fish species. However, the effects of this type of large scale event on reproductive success of BSAI and GOA salmon cannot be determined at this time.

- **Cumulative Effects.** Successful reproduction of salmon relies on spawning adults' ability to reach destined spawning habitat. Given the poor stock status of salmon runs in western Alaska and combined bycatch potential of the BSAI and GOA, the sustainability of BSAI and GOA chinook and BSAI other salmon stocks could be impacted. Thus, fisheries catch may remove spawning adults destined for spawning grounds. Potential combined effects from internal and external events is considered conditionally significant adverse to the reproductive success of BSAI and GOA chinook and BSAI other salmon. Although current stock status of GOA chinook and other salmon is stable, combined effects of changes in reproductive success in Alaskan salmon populations resulting from internal catch, internal bycatch, and reasonably foreseeable future external events (both human controlled and natural) cannot be determined for GOA other salmon stocks under PA.2.

4.9.2.3 Pacific Herring

Pacific herring are managed by ADF&G. Harvest policy and allocations among gear (user) groups are established by the Alaska Board of Fisheries. Annual harvest quotas are set by ADF&G under an exploitation rate harvest policy; herring exploitation rates are capped at a maximum level of 20 percent statewide. All directed herring fisheries occur in State of Alaska waters, and are managed by regulatory stocks.

A detailed discussion of the modeling approach used in this analysis is included in Section 4.5.2.3. Given the low herring bycatch levels that are predicted across all proposed FMPs, bycatch removals would not be expected to have significantly different impacts on herring abundance estimates between FMPs.

Direct/Indirect Effects PA.1 and PA.2 – Pacific Herring

Direct and indirect effects for Pacific herring include mortality changes in reproductive success, prey availability, and habitat. These effects, which are associated with changes in catch, are considered insignificant because annual quota setting processes implemented by ADF&G are responsive to fluctuations in herring biomass. A summary of these effects is shown in Table 4.9-2.

Under PA.1, current herring PSC caps would be retained with the possibility of future reduction in the BSAI (0 to 10 percent). Total removals would continue to be limited by ADF&G to protect the herring resource.

Under PA.2, current herring PSC caps in the BSAI would be reduced between 0 and 20 percent with the possibility of also reducing GOA PSC limits by 0 to 10 percent . Total removals would continue to be limited by ADF&G. In addition, PA.2 proposes the development of inseason closure areas in the GOA once PSC limits have been reached. This measure may provide for additional protection of the herring resource in areas characterized with significant herring bycatch.

Cumulative Effects Analysis PA.1 and PA.2 – Pacific Herring

A summary of the cumulative effects analysis associated with PA.1 and PA.2 is shown in Table 4.5-34. For further information on persistent past effects included in this analysis, see Section 3.5.2.3 of this Programmatic SEIS.

<u>Mortality</u>

- **Direct/Indirect Effects**. The potential effect of fishing mortality on BSAI and GOA herring is insignificant under PA.1 and PA.2 because current management of herring by ADF&G is responsive to fluctuations in herring biomass. The herring savings areas reduce herring bycatch potential by triggering closures in years when herring are abundant within fishing grounds.

- **Persistent Past Effects.** Domestic herring fisheries became prominent in the early 1900s, with peak catches occurring in the 1920s and 1930s. Foreign herring harvests became prominent in the BSAI in the late 1950s, with highs in the late 1960s and early 1970s. Overexploitation of herring likely resulted during these years of high catch. By 1980, foreign harvest of herring had been eliminated; however, years of unregulated catch of herring may have had long-term impacts on impacted herring populations long-term. In addition, past federal groundfish fisheries bycatch, combined with the directed State of Alaska fisheries, have exceeded the State of Alaska's herring harvest policy and may still exert lingering effects on current herring populations in the BSAI and GOA.

- **Reasonably Foreseeable Future External Effects.** Directed State of Alaska herring fisheries still occur, but are closely managed by ADF&G. Fishing quotas are based on variable exploitation rates that account for declines in stock and are capped at a maximum rate of 20 percent. State of Alaska subsistence catch is also accounted for in ADF&G herring management plans. These fisheries are not considered contributing factors to changes in herring mortality. Future acute and chronic marine pollution could occur and is considered potentially adverse to herring mortality, especially for those populations that are still recovering from the EVOS in the GOA. Long-term climate changes and regime shifts are not considered contributing factors as they are not expected to result in direct mortality.

- **Cumulative Effects.** ADF&G Pacific herring management plans are responsive to changes in herring biomass. Fishing quotas are based on variable exploitation rates that account for declines in stock and are capped at a maximum rate of 20 percent. Thus, although some persistent past effects may still be present on certain herring populations in the BSAI and GOA, the combined effects of mortality on Pacific herring resulting from bycatch and reasonably foreseeable future external events (both human controlled and natural) are considered insignificant for PA.1 and PA.2.

Change in Reproductive Success

- **Direct/Indirect Effects.** The potential effect of federal groundfish fisheries on reproductive success of BSAI and GOA herring is insignificant under PA.1 and PA.2 because current management of herring by ADF&G is responsive to fluctuations in herring biomass. Thus, if a change in reproductive success occurs, it would most likely be reflected in corresponding changes to biomass, which are incorporated into ADF&G management plans for Pacific herring.

- **Persistent Past Effects**. As discussed in the analysis of cumulative effects on Pacific herring mortality, years of unregulated foreign harvest and past federal groundfish fisheries bycatch that exceeded the State of Alaska's herring harvest policy may still exert lingering effects on current herring populations in the BSAI and GOA. Herring spawning habitat in the GOA (specifically PWS) was contaminated with oil resulting from the EVOS in 1989. It has been found that this type of contamination exposure to adult and larval herring can result in many adverse effects such as: increased rates of egg mortality, larval deformities, and immune system deficiencies. It is presumed that the effects of EVOS still exist, and subsets of herring populations in the GOA are still recovering.

- **Reasonably Foreseeable Future External Effects.** Directed State of Alaska herring fisheries still occur, but are closely managed by the ADF&G. Fishing quotas are based on variable exploitation rates that account for declines in stock. State subsistence fisheries catch is accounted for in ADF&G herring management plans. Thus, these fisheries are not considered contributing factors to changes in herring reproductive success. Future acute and chronic marine pollution could occur and is considered potentially adverse to herring reproductive success, especially for those populations that are still recovering from the EVOS in the GOA. Long-term climate changes and regime shifts could have impacts to the reproductive success of Pacific herring depending on the direction of the shift.

It has been shown that warm trends favor recruitment while cool trends weaken recruitment in most fish species. However, the effects of this type of large scale event on herring cannot be determined at this time.

- **Cumulative Effects.** ADF&G Pacific herring management plans are responsive to changes in herring biomass and fishing quotas are based on variable exploitation rates that account for declines in herring stock. Although certain herring populations in the GOA have been impacted by EVOS, the stock as a whole is considered recovering. Thus, some persistent past effects may still be present on certain herring populations in the BSAI and GOA, but the combined effects on Pacific herring reproductive success resulting from bycatch and future external events (both human controlled and natural) are considered insignificant for PA.1 and PA.2.

Change in Prey Availability

- **Direct/Indirect Effects**. The potential effect of federal groundfish fisheries on prey availability for BSAI and GOA herring is insignificant under PA.1 and PA.2 because current management by ADF&G is responsive to fluctuations in herring biomass regardless of the cause associated with the change. Thus, if a change in prey availability did occur, it would most likely be reflected in corresponding changes to biomass, which are accounted for in ADF&G management plans for Pacific herring.

- **Persistent Past Effects.** No persistent past effects impacting prey availability of herring have been identified.

- **Reasonably Foreseeable Future External Effects**. Pacific herring feed primarily on zooplankton which are not affected by State of Alaska directed herring fisheries or State of Alaska subsistence fisheries. Thus, these fisheries are not considered contributing factors to changes in prey availability for herring. Future acute and chronic marine pollution could occur, but effects on prey such as zooplankton, are unknown. Long-term climate changes and regime shifts could have impacts too many species that contribute to the prey structure of Pacific herring. The nature of these impacts depends on the direction of the climatic shift. It has been shown that warm trends favor recruitment while cool trends weaken recruitment in most fish species. However, the effects of this type of large scale event on herring cannot be determined at this time.

- **Cumulative Effects.** Potential effects of future natural events, such as marine pollution and climatic shifts, on prey availability for Pacific herring are unknown for PA.1 and PA.2.

Change in Habitat

- **Direct/Indirect Effects.** The potential effect of federal groundfish fisheries on habitat of BSAI and GOA herring is insignificant under PA.1 and PA.2 because current management of herring by ADF&G is responsive to fluctuations in herring biomass. Thus, if a change in important habitat occurs, it would most likely be reflected in corresponding changes to biomass, which are accounted for in ADF&G management plans for Pacific herring. The herring savings areas reduce herring bycatch potential and protect important habitat by triggering closures in years when herring are abundant within fishing grounds.

- **Persistent Past Effects.** Herring spawning habitat in the GOA (specifically PWS) was contaminated with oil resulting from the EVOS in 1989. The long-term effects of this event to herring habitat are unknown. It is presumed that the effects of EVOS still exist and subsets of herring populations in the GOA are still recovering.

- **Reasonably Foreseeable Future External Effects.** No evidence of fishery impacts on habitat of herring exists. Thus, fisheries are not considered contributing factors to changes in herring habitat at this time. Future acute and chronic marine pollution could occur and is considered potentially adverse to some herring habitat, especially those that are still recovering from EVOS in the GOA. Long-term climate changes and regime shifts are not expected to significantly change physical habitat of Pacific herring.

- **Cumulative Effects.** Potential impacts of future natural events, such as marine pollution and climatic shifts, in addition to lingering contamination from EVOS on certain habitat of herring in the GOA exist, but effects are not known for PA.1 and PA.2.

4.9.2.4 Crab

Alaska king, bairdi Tanner crab, and opilio Tanner crab (also called snow crab) fisheries are managed by the State of Alaska, with federal oversight and guidelines established in the BSAI king and Tanner crab FMP (NPFMC 1989). Section 4.5.2.4 contains further information on current stock status and management of crab in Alaska.

For cumulative effects analyses, crab stocks in the BSAI and GOA will be placed in the following groups: bairdi Tanner, opilio Tanner (only BSAI), red king, blue king, and golden king.

Direct/Indirect Effects PA.1 and PA.2 – Crab

Direct and indirect effects for all species of crab in the BSAI and GOA include mortality, changes in biomass, reproductive success, prey availability, and habitat. These effects may be attributed to fishing activities (both directed fishing and bycatch), but may also be linked to natural events such as long-term climatic changes and decadal regime shifts. Significance of these effects is based on the likelihood that population-level changes will result from internal events within the groundfish fishery. An effect that is considered insignificant corresponds to a change that is not likely to result in population-level effects on crab or that lies within the range of natural variability for the species.

Under PA.1, all existing closures/restricted areas (i.e., Red King Crab Area and Pribilof Island closures) will be maintained, as will the 2002 Steller sea lion closures. In addition, identification and designation of EFH and HAPC is proposed. Current PSC limits for crab in the BSAI will be maintained under PA.1 with consideration for further reduction by zero to ten percent. PSC limits, or other appropriate measures, will be established for crab in the GOA and based on biomass estimates or other fishery data.

PA.2 includes and builds upon the proposed measures in PA.1. In addition to maintaining existing closure areas, review of these closures to determine if they qualify as MPAs, including no-take reserves, has been suggested. Other proposed measures under PA.2 include: implementation of mitigation measures for EFH and HAPC that show significantly adverse effects from fishing, establishing an Aleutian Islands management area to protect living habitat (often contained in crab habitat), possible modification to Steller sea lion closures (including Aleutian Islands) with designation of critical habitat based on scientific data, and development of inseason closure areas in the GOA triggered by PSC limits being reached. Also proposed under PA.2 is a further reduction in the BSAI crab PSC limits by 0 to 20 percent and GOA limits by zero to ten percent. Expansion of observer coverage based on scientific data and compliance needs for all vessels is also included in PA.2. This observer coverage, along with improved species identification for non-target species, may provide additional protection to crab populations throughout the BSAI and GOA regions and provide for more reliable crab bycatch composition data.

Cumulative Effects Analysis PA.1 and PA.2 – Crab

Summaries of the cumulative effects analyses associated with PA.1 and PA.2 are shown in Table 4.9-2. For further information on persistent past effects included in this analysis, see Section 3.5.2.4 of this Programmatic SEIS.

The foundation of the cumulative effects analysis is the baseline description for each species that includes population status and trends, if known, and the major human and natural influences that have affected the population in the past and that continue up to the present.

For each species, the predicted direct and indirect effects of the groundfish fishery are then analyzed for their contribution to the overall impacts from all sources, including reasonably foreseeable future events resulting from human and natural events external to the fishery. The reasonably foreseeable future events also include other U.S. and foreign fisheries, acute and chronic environmental pollution, and natural events such as climatic and oceanographic fluctuations. Cumulative effects are each rated according to the same significance criteria as the direct/indirect effects of the fishery and are based on the potential for population-level effects.

<u>Mortality</u>

Bairdi Tanner, Opilio Tanner, Red King, and Blue King Crab in the BSAI

- **Direct/Indirect Effects.** Under PA.1 and PA.2, predicted catch of these crab species does not reflect large deviations from the current baseline condition, however, catch trends do vary throughout the five-year period. Although current bycatch limits and quota-setting processes are responsive to fluctuations in stock and account for crab bycatch in other state and federal fisheries, these stocks are currently considered depressed, and in some instances, overfished. Under these proposed FMPs, it is expected that bycatch of crab could decrease as a result of bycatch reduction incentives built into rationalization programs. Furthermore, additional protection measures could enhance habitat and possible recovery of depressed stocks, but these changes are not expected to significantly affect the crab population in the BSAI as a whole. Under PA.1 and PA.2, it is possible that bycatch of crab could decrease, and additional protection measures could enhance habitat and possible recovery of depressed stocks, but these changes are not expected to significantly affect the crab populations in the BSAI as a whole. Thus, PA.1 and PA.2 are considered to have insignificant effects on bairdi Tanner, opilio Tanner, red king, and blue king crab stocks in the BSAI because no sign of recovery for these stocks has been shown to date.

- **Persistent Past Effects**. Direct catch and bycatch of crab are associated with past foreign fisheries. Crab bycatch is common in yellowfin sole and Pacific ocean perch fisheries. During the 1960s, foreign fleets in the BSAI experienced record catch of yellowfin sole and Pacific ocean perch. It is inferred that bycatch of crab during this time increased proportionally with the direct catch of these fisheries. The United States initiated bilateral agreements with Japan and Russia in the mid-1960s in order to reduce gear conflicts and allocate crab resources between State of Alaska crab fisheries and foreign fisheries. These bilateral agreements are thought to have been marginal management measures providing no benefit or protection to crab stocks overall. Thus, adverse past effects of mortality on BSAI and GOA crab stocks from directed crab catch and bycatch could still exist.

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab, scallop, and subsistence fisheries continue to occur, managed by ADF&G in cooperation with NOAA Fisheries. These fisheries are considered to have a potential adverse effect on bairdi Tanner, opilio Tanner, red king, and blue king crab stocks in the BSAI since no signs of recovery have been shown. Formal stock rebuilding plans are in place for the BSAI bairdi and opilio Tanner crab stocks. The St. Matthew Island blue king crab stock has a rebuilding plan in effect. In the Pribilof Islands, a blue king crab rebuilding plan is currently being developed, but is not in effect at this time. These rebuilding plans may have beneficial effects on recovery of these stocks as a whole over time. The BSAI red king crab stocks do not have rebuilding plans in effect, and the populations are currently considered depressed. Long-term climate changes and regime shifts are not expected to result in direct mortality of crab stocks, and are not considered contributing factors to potential changes in mortality.

- **Cumulative Effects.** ADF&G crab management plans are responsive to changes in stock status, and quota-setting processes account for crab bycatch in other state and federal fisheries. Persistent past effects on crab populations in the BSAI may still exist, and stocks are considered depressed with no signs of recovery to date. It is unclear if additional protection measures and decreased bycatch of crab will mitigate the combined effects of mortality resulting from past events, internal bycatch, and reasonably foreseeable future external events on depressed stocks. Thus, cumulative effects of PA.1 and PA.2 on BSAI crab stocks cannot be determined at this time.

Golden King Crab in the BSAI and GOA

- **Direct/Indirect Effects.** Under PA.1 and PA.2, predicted catch of golden king crab in the BSAI and GOA were combined with predictions for blue king crab. The BSAI predictions showed increases in catch for PA.1 and decreases in catch for PA.2 over the next five years when compared to current catch rates. Model projections for GOA catch showed decreases in catch for PA.1 and PA.2 compared to current catch in this region. Crab bycatch could decrease as a result of bycatch reduction incentives built into rationalization programs. However, significance of these predicted changes in catch on mortality is unknown due to lack of survey information for determining current stock status. Thus, effects of PA.1 and PA.2 on mortality of BSAI and GOA golden king crab are unknown.

- **Persistent Past Effects**. Adverse past effects of mortality on BSAI and GOA crab stocks from directed crab catch and bycatch could still exist (see the previous discussion of persistent past effects on crab in the BSAI).

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab fisheries, scallop fisheries, and subsistence fisheries continue to occur, managed by ADF&G in cooperation with NOAA Fisheries. Survey data collected by ADF&G in specific areas of the GOA have shown depressed stock status for golden king crab, but the overall stock status of golden king crab stocks in the BSAI and GOA are currently unknown. Thus, the potential effects of these fisheries on mortality are not known. Long-term climate changes and regime shifts are not expected to result in direct mortality of crab stocks, and are not considered contributing factors to potential changes in crab mortality.

- **Cumulative Effects**. ADF&G crab management plans are responsive to changes in stock status and quota-setting processes account for crab bycatch in other State of Alaska and federal fisheries. Under PA.1 and PA.2, it is possible that bycatch of golden king crab could decrease and additional protection measures could enhance habitat and possible recovery of depressed stocks. Some GOA stocks are considered depressed, but the overall stock status of golden king crab in the BSAI and GOA is unknown. Thus, potential combined effects of mortality, resulting from past events, internal bycatch, and reasonably foreseeable future external events cannot be determined at this time.

Bairdi Tanner, Red King, and Blue King Crab in the GOA

Opilio Tanner crab populations are not encountered during ADF&G surveys in the GOA. It is inferred that this crab species is not prevalent in this region. Therefore, opilio Tanner crab is not included in this analysis.

- **Direct/Indirect Effects.** Under PA.1 and PA.2, predicted catch of bairdi Tanner, red king, and blue king crab in the GOA showed decreases from current baseline for the next 5 years. Under these proposed FMPs, it is expected that bycatch of bairdi Tanner, red king, and blue king crab in the GOA crab could decrease, likely as a result of bycatch reduction incentives built into rationalization programs.

  However, significance of these predicted changes in catch on mortality is unknown for bairdi Tanner and blue king crab due to lack of survey information for determining current stock status as a whole. Thus, effects of PA.1 and PA.2 on mortality of GOA bairdi Tanner and blue king crab are unknown. GOA red king crab stocks are considered severely depressed according to ADF&G survey information, but it is unclear if possible decreases in crab catch proposed under the PA will mitigate driving factors of mortality in these stocks. PA.1 and PA.2 are considered insignificant for mortality effects on GOA red king crab populations due to the lack of recovery that has been observed in these stocks to date.

- **Persistent Past Effects**. Adverse past effects of mortality on GOA crab stocks from directed crab catch and bycatch could still exist (see previous section of persistent past effects on GOA crab).

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab fisheries, scallop fisheries, and subsistence fisheries continue to occur. Survey data collected by ADF&G in specific areas of the GOA have shown depressed stock status for bairdi Tanner and blue king crab, but their overall stock status in the GOA is currently unknown. Thus, the potential effects of these fisheries on mortality of bairdi Tanner and blue king crab stocks are not known. GOA stocks of red king crab are considered severely depressed according to current ADF&G surveys. The depressed nature of these stocks, in addition to external mortality associated with State of Alaska fisheries (directed, subsistence, and scallop), could adversely impact recovery and sustainability of red king crab stocks in the GOA. Long-term climate changes and regime shifts are not expected to result in direct mortality of crab stocks and are not considered contributing factors to potential changes in crab mortality.

- **Cumulative Effects.** ADF&G crab management plans are responsive to changes in stock status, and quota-setting processes account for crab bycatch in other state and federal fisheries. However, persistent past effects on bairdi Tanner, red king, and blue king crab stocks in GOA may still exist. Some GOA stocks of bairdi Tanner and blue king crab are considered depressed but their overall stock status is unknown. Thus, potential combined effects of mortality resulting from past events, internal bycatch, and reasonably foreseeable future external events cannot be determined for bairdi Tanner and blue king crab stocks at this time. It is unclear if additional protection measures and decreased bycatch of crab put forth under the PA will mitigate the combined effects of mortality, resulting from past events, internal bycatch, and reasonably foreseeable future external events on severely depressed red king crab stocks. Cumulative effects of PA.1 and PA.2 on GOA red king crab cannot be determined at this time.

Change in Biomass

Bairdi Tanner, Opilio Tanner, Red King, and Blue King Crab in the BSAI

- **Direct/Indirect Effects.** Under PA.1 and PA.2, predicted catch of these crab species do not reflect large deviations from the current baseline condition, although catch trends vary throughout the five-year period. Under the PA, it is possible that bycatch of crab could decrease and additional protection measures could enhance habitat and possible recovery of depressed stocks Under these proposed FMPs, it is expected that bycatch of crab could decrease as a result of bycatch reduction incentives built into rationalization programs, but these changes are not expected to significantly affect crab biomass in the BSAI as a whole. Thus, PA.1 and PA.2 are considered to have insignificant effects on changes in biomass of bairdi Tanner, opilio Tanner, red king, and blue king crab stocks in the BSAI because no signs of recovery for these stocks have been shown to date.

- **Persistent Past Effects.** Adverse past effects of mortality on BSAI and GOA crab stocks from directed crab catch and bycatch could still exist (see previous discussion of persistent past effects on crab).

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab, scallop, and subsistence fisheries continue to occur and are considered to have a potential adverse effect on bairdi Tanner, opilio Tanner, red king, and blue king crab stocks in the BSAI, since no signs of recovery have been shown. Formal stock rebuilding plans are in place for BSAI bairdi and opilio Tanner crab stocks. The St. Matthew Island blue king crab stock has a rebuilding plan in effect. In the Pribilof Islands, a blue king crab rebuilding plan is currently being developed, but is not in effect at this time. These rebuilding plans may have beneficial effects on recovery of these stocks as a whole over time. The BSAI red king crab stocks do not have rebuilding plans in effect, and the population is currently considered depressed. Potential effects of long-term climate changes and regime shifts on crab biomass have not been determined.

- **Cumulative Effects.** ADF&G crab management plans are responsive to changes in stock status, and quota-setting processes account for crab bycatch in other state and federal fisheries. Persistent past effects on crab populations in the BSAI may still exist, and stocks are considered depressed with no signs of recovery to date. It is unclear if additional protection measures and decreased bycatch of crab will mitigate the combined effects of mortality and subsequent changes to biomass resulting from past events, internal bycatch, and reasonably foreseeable future external events on depressed stocks. Thus, cumulative effects of PA.1 and PA.2 on BSAI crab stocks cannot be determined at this time.

Golden King Crab in the BSAI and GOA

- **Direct/Indirect Effects**. Due to lack of survey information for determining current biomass of golden king crab in the BSAI and GOA, potential effects of PA.1 and PA.2 on changes to biomass cannot be determined.

- **Persistent Past Effects**. The potential effects of past fishing mortality on biomass of golden king crab stocks in the BSAI and GOA cannot be determined because catch composition is unknown and biomass estimates over time do not exist for these stocks.

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab, scallop, and subsistence fisheries continue to occur. Survey data collected by ADF&G in specific areas of the GOA have shown depressed stock status for golden king crab. However, the overall stock status of golden king crab stocks in the BSAI and GOA is unknown, and biomass estimates have not been determined. Thus, the potential effects of these fisheries on biomass are not known. Effects of long- term climate changes and regime shifts on crab biomass have not been determined.

- **Cumulative Effects.** ADF&G crab management plans are responsive to changes in stock status, and quota-setting processes account for crab bycatch in other state and federal fisheries. Under the PA, it is possible that bycatch of golden king crab could decrease and additional protection measures could enhance habitat and possible recovery of depressed stocks. However, persistent past effects on these crab populations in the BSAI and GOA may still exist. Some GOA stocks are considered depressed, but the overall stock status and biomass estimates of golden king crab in the BSAI and GOA are unknown. Thus, potential combined effects of changes in biomass resulting from past events, internal bycatch, and reasonably foreseeable future external events cannot be determined at this time.

Bairdi Tanner, Red King, and Blue King Crab in the GOA

Opilio Tanner crab populations are not encountered during ADF&G surveys in the GOA. It is inferred that this crab species is not prevalent in this region. Therefore, opilio Tanner crab is not included in this analysis.

- **Direct/Indirect Effects.** Under PA.1 and PA.2, predicted catch of bairdi Tanner, red king, and blue king crab in GOA shows decreases from currently observed catch over the next five years. Under these proposed FMPs, it is expected that bycatch of crab could decrease as a result of bycatch reduction incentives built into rationalization programs. However, significance of these predicted changes in catch on the change in biomass mortality is unknown for bairdi Tanner and blue king crab due to lack of survey information for determining current stock status as a whole. Thus, effects of PA.1 and PA.2 on biomass of GOA bairdi Tanner and blue king crab are unknown. GOA red king crab stocks are considered severely depressed according to ADF&G survey information, but it is unclear if possible decreases in crab catch proposed under these FMPs will mitigate driving factors of mortality in these stocks. PA.1 and PA.2 are considered insignificant to potential changes in biomass for GOA red king crab populations due to the lack of recovery that has been observed in these stocks to date.

- **Persistent Past Effects**. Adverse effects of past fishing mortality on biomass of bairdi Tanner, blue king, and red king crab stocks in GOA may still exist as recovery of depressed stocks has not been observed.

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab, scallop, and subsistence fisheries continue to occur. Survey data collected by ADF&G in specific areas of the GOA have shown depressed stock status for bairdi Tanner and blue king crab, but their overall stock status in GOA is currently unknown. Thus, the potential effects of these fisheries on biomass of bairdi Tanner and blue king crab stocks cannot be determined. GOA stocks of red king crab are considered severely depressed according to current ADF&G surveys. The depressed nature of these stocks, in addition to external mortality associated with State of Alaska fisheries (directed, subsistence, and scallop), could adversely impact recovery and sustainability of red king crab stocks in GOA. Effects of long-term climate changes and regime shifts of crab biomass have not been determined.

- **Cumulative Effects.** ADF&G crab management plans are responsive to changes in stock status, and quota-setting processes account for crab bycatch in other State of Alaska and federal fisheries. However, persistent past effects on bairdi Tanner, red king, and blue king crab stocks in the GOA may still exist. Some GOA stocks of bairdi Tanner and blue king crab are considered depressed, but their overall stock status and biomass estimates are unknown. Thus, potential combined effects of changes in biomass, resulting from past events, internal bycatch, and reasonably foreseeable future external events cannot be determined for bairdi Tanner and blue king crab stocks at this time. It is unclear if additional protection measures and decreased bycatch of crab put forth under the PA will mitigate the combined effects of mortality and corresponding changes to biomass resulting from past events, internal bycatch, and reasonably foreseeable future external events on severely depressed red king crab stocks. Therefore, the cumulative effects on GOA red king crab cannot be determined at this time.

<u>Change in Reproductive Success</u>

Bairdi Tanner, Opilio Tanner, Red King, and Blue King Crab in the BSAI

- **Direct/Indirect Effects.** These stocks are currently considered depressed and in some instances, overfished. Changes in reproductive success within the BSAI crab populations may be an underlying factor in the depressed nature of these stocks. However, a direct causal link between reproductive success and depressed stock status cannot be concluded at this time. Potential effects of PA.1 and PA.2 on changes to reproductive success cannot be determined.

- **Persistent Past Effects**. As discussed earlier, past fisheries may have indirectly impacted reproductive success of these stocks by removing vital brood stocks and/or adversely impacting spawning and nursery habitat as a result of bottom trawling. Past effects may still exist as these stocks have not shown signs of recovery to date.

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab, scallop, and subsistence fisheries continue to occur. Crab seasons are set to avoid mating and molting periods therefore, these fisheries are not considered to be contributing factors to changes in reproductive success of bairdi Tanner, opilio Tanner, red king, and blue king crab stocks in the BSAI. Formal stock rebuilding plans are in place for the BSAI bairdi and opilio Tanner crab stocks. The St. Matthew Island blue king crab stock has a rebuilding plan in effect. In the Pribilof Islands, a blue king crab rebuilding plan is currently being developed, but is not in effect at this time. These rebuilding plans may have beneficial effects on the recovery of these stocks as a whole over time. BSAI red king crab stocks do not have rebuilding plans in effect, and the population is currently considered depressed. The potential effects of long-term climate changes and regime shifts on reproductive traits of crab are unknown.

- **Cumulative Effects.** Crab seasons are set to avoid mating and molting periods; however, persistent past effects on crab populations in the BSAI may still exist. Stocks are considered depressed with no signs of recovery to date. Thus, potential effects on reproductive success, resulting from past events, internal catch and internal bycatch, and reasonably foreseeable future external events, are unknown for PA.1 and PA.2.

Golden King Crab in the BSAI and GOA

- **Direct/Indirect Effects**. Due to lack of survey information for determining current stock status of golden king crab in the BSAI and GOA, potential effects of PA.1 and PA.2 on changes to reproductive success cannot be determined.

- **Persistent Past Effects**. Current stock status of BSAI and GOA golden king crab has not been determined, so potential past effects on reproductive success are also unknown.

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab, scallop, and subsistence fisheries continue to occur. Crab seasons are set as to avoid mating and molting periods therefore, these fisheries are not considered contributing factors to changes in reproductive success of golden king crab. The potential effects of long-term climate changes and regime shifts on reproductive traits of crab are unknown.

- **Cumulative Effects.** Crab seasons are set to avoid mating and molting periods. However, persistent past effects on golden king crab populations in the BSAI and GOA are not known. Potential effects on reproductive success resulting from past events, internal bycatch, and reasonably foreseeable future external events, are unknown for PA.1 and PA.2.

Bairdi Tanner, Red King, and Blue King Crab in the GOA

Opilio Tanner crab populations are not encountered during ADF&G surveys in the GOA. It is inferred that this crab species is not prevalent in this region. Therefore, opilio Tanner crab is not included in this analysis.

- **Direct/Indirect Effects.** Due to lack of survey information for determining current stock status of blue king crab in the GOA, potential effects of PA.1 and PA.2 on changes to reproductive success cannot be determined. Survey data collected by ADF&G for certain bairdi Tanner crab stocks in western GOA show signs of possible recovery, while other GOA stocks are still considered depressed. Red king crab populations in the GOA are at historic lows according to ADF&G survey information. Changes in reproductive success within the GOA crab populations may be an underlying factor in the depressed nature of these stocks. However, a direct causal link between reproductive success and depressed stock status cannot be concluded at this time. Potential effects of this PA on changes to reproductive success cannot be determined for bairdi Tanner and red king crab populations in the GOA.

- **Persistent Past Effects**. As discussed earlier, past fisheries may have indirectly impacted reproductive success of these stocks by removing vital brood stocks and/or adversely impacting spawning and nursery habitat as a result of bottom trawling. Past effects may still exist as these stocks have not shown signs of recovery to date.

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab, scallop, and subsistence fisheries continue to occur, and are managed by ADF&G in cooperation with NOAA Fisheries. Crab seasons are set to avoid mating and molting periods; therefore, these fisheries are not considered contributing factors to changes in the reproductive success of these stocks. The potential effects of long-term climate changes and regime shifts on reproductive traits of crab are unknown.

- **Cumulative Effects.** Crab seasons are set to avoid mating and molting periods. However, persistent past effects on crab populations in the GOA may still exist. Some stocks are considered depressed with no signs of recovery to date. Thus, potential effects on reproductive success resulting from past events, internal catch/internal bycatch, and reasonably foreseeable future external events, are unknown for PA.1 and PA.2.

Change in Prey Availability

Bairdi Tanner, Opilio Tanner, Red King, Blue King, and Golden King Crab in the BSAI and GOA

Opilio Tanner crab populations are not encountered during ADF&G surveys in the GOA. It is inferred that this crab species is not prevalent in this region. Therefore, only BSAI opilio Tanner crab is included in this analysis.

- **Direct/Indirect Effects.** Diet composition of crab has not been determined, but crab are known to be benthic feeders. Competition for prey species of crab resulting from groundfish fisheries' catch has not been shown, and it is unclear if PA.1 and PA.2 would impact prey structure and availability for all species of crab throughout BSAI and GOA. Thus, potential effects of the PA on changes in prey availability cannot be determined.

- **Persistent Past Effects**. Crab are benthic feeders and generally feed on invertebrates. Catch of crab prey in current and past groundfish fisheries is minimal. Thus, past effects on crab prey structure and availability in the BSAI and GOA have not been identified.

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab, scallop, and subsistence fisheries continue to occur, and are managed by ADF&G in cooperation with NOAA Fisheries. Competition for prey species of crab resulting from groundfish fisheries' catch has not been shown, and these fisheries are not considered contributing factors to changes in prey availability. Rebuilding plans currently in effect in the BSAI do not address crab prey structure and availability and are not considered contributing factors to potential changes in prey availability. Long-term climate changes and regime shifts may impact crab prey structure depending on the direction of the change. However, it is impossible to determine the possible effects that these changes may have on crab populations throughout the BSAI and GOA.

- **Cumulative Effects.** Diet composition of crab has not been determined, and potential changes to prey structure, resulting from internal effects and reasonably foreseeable future events, cannot be determined for all species of crab in the BSAI and GOA for PA.1 and PA.2.

<u>Change in Habitat</u>

Bairdi Tanner, Opilio Tanner, Red King, and Blue King Crab in the BSAI

- **Direct/Indirect Effects.** These stocks are currently considered depressed and in some instances, overfished. However, a direct causal link between habitat and depressed stock status cannot be concluded at this time. It is inferred that current crab management plans are mitigating past habitat disruption and providing protection for crab stocks, but recovery has not been shown. Under PA.1 and PA.2, it is possible that additional protection measures could enhance recovery of crab habitat, but it is impossible to realize the potential population-level effects that may result. Thus, PA.1 and PA.2 are considered to have insignificant effects on changes in habitat of bairdi Tanner, opilio Tanner, red king, and blue king crab stocks in the BSAI because no signs of recovery for these stocks have been shown to date.

- **Persistent Past Effects.** Past fisheries may have directly or indirectly impacted spawning and nursery habitat as a result of bottom trawling. Past effects may still exist, as these stocks have not shown signs of recovery to date.

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab, scallop, and subsistence fisheries continue to occur and are considered potential adverse factors in possible changes to crab habitat based on the lack of recovery that has been observed for these stocks under current management plans. Formal stock rebuilding plans are in place for BSAI bairdi and opilio Tanner crab stocks. The St. Matthew Island blue king crab stock has a rebuilding plan in effect. In the Pribilof Islands, a blue king crab rebuilding plan is currently being developed, but is not in effect at this time. These rebuilding plans may have beneficial effects on recovery of these stocks as a whole over time and offer protection of critical habitat. BSAI red king crab stocks do not have rebuilding plans in effect, and the population is currently considered depressed with possible habitat- related effects unclear. Long-term climate changes and regime shifts are not expected to directly affect the physical habitat and are not considered contributing factors in possible changes that may occur.

- **Cumulative Effects.** Persistent past effects on crab habitat in the BSAI may still exist and stocks are considered depressed with no signs of recovery to date. Although much of the known habitat areas of BSAI crab are currently protected by no trawl zones and conservation zones, it is possible that other critical habitat areas are not included in these measures or those proposed under the PA. Thus, potential effects on crab habitat, resulting from past events, internal bycatch, and reasonably foreseeable future external events cannot be determined.

Golden King Crab in the BSAI and GOA

- **Direct/Indirect Effects**. Due to lack of survey information for determining current stock status of golden king crab in the BSAI and GOA, it is difficult to identify habitat-related effects as they pertain to changes in these crab populations throughout the BSAI and GOA. Potential effects of PA.1 and PA.2 to crab habitat are unknown.

- **Persistent Past Effects**. As discussed in the analysis of cumulative effects on mortality of Bairdi tanner, Opilio tanner, red king and blue king crab, past fisheries may have directly or indirectly impacted spawning and nursery habitat as a result of bottom trawling. Past effects may still exist as many of these stocks have not shown signs of recovery to date.

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab, scallop, and subsistence fisheries continue to occur, and are considered potential adverse factors in possible changes to crab habitat based on the lack of recovery that has been observed for many of the crab stocks under current management plans, and the current depressed nature of some golden king crab stocks in the GOA. Long-term climate changes and regime shifts are not expected to directly affect the physical habitat and are not considered contributing factors in possible changes that may occur.

- **Cumulative Effects.** Some GOA golden king crab stocks are considered depressed, and past effects may still exist as many of these stocks have not shown signs of recovery to date. Although much of the known habitat areas of BSAI and GOA crab are currently protected by no trawl zones and conservation areas, it is possible that other critical habitat areas are not included in these measures or those proposed under the PA. Thus, potential effects on golden king crab habitat resulting from past events, internal bycatch, and reasonably foreseeable future external events cannot be determined without first establishing the overall population and essential habitat status of this species.

Bairdi Tanner, Red King, and Blue King Crab in the GOA

Opilio Tanner crab populations are not encountered during ADF&G surveys in the GOA. It is inferred that this crab species is not prevalent in this region. Therefore, opilio Tanner crab is not included in this analysis.

- **Direct/Indirect Effects.** Red king and bairdi Tanner stocks in the GOA are currently considered depressed, while blue king crab stock status is unknown. Data on bairdi Tanner crab is limited, but stocks are presumed to be depressed based on available survey data. The red king crab stocks are considered severely depressed according to ADF&G surveys. However, a direct causal link between habitat and depressed stock status cannot be concluded at this time. It is inferred that current crab management plans are mitigating past habitat disruption and providing protection for crab stocks, but recovery of stocks has not been shown. Under PA.1 and PA.2, it is possible that additional protection measures could enhance recovery of crab habitat, but it is impossible to realize the potential population-level effects that may result. Thus, PA.1 and PA.2 are considered to have insignificant effects on changes in habitat of red king crab stocks in the GOA because no signs of recovery for these stocks have been shown to date. Thus, the cumulative effects on habitat suitability for these stocks cannot be determined. Under the PA, it is possible that additional protection measures could enhance recovery of crab habitat, but it is impossible to realize the potential population-level effects that may result. Thus, the potential effects of PA.1 and PA.2 on changes to bairdi Tanner, red king, and blue king crab habitat in the GOA are unknown.

- **Persistent Past Effects.** Past fisheries may have directly or indirectly impacted spawning and nursery habitat as a result of bottom trawling. Past effects may still exist as some of these stocks have not shown signs of recovery to date (see previous discussions of persistent past effects).

- **Reasonably Foreseeable Future External Effects.** State of Alaska crab, scallop, and subsistence fisheries continue to occur, and are considered potential adverse factors in possible changes to crab habitat based on the lack of recovery that has been observed for some of these stocks under current management plans. Long-term climate changes and regime shifts are not expected to directly affect the physical habitat and are not considered contributing factors in possible changes to GOA crab habitat that may occur.

- **Cumulative Effects.** Persistent past effects on crab habitat in the GOA may still exist, and stocks are considered depressed with no signs of recovery to date. Although much of the known habitat areas of GOA crab are currently protected by no trawl zones and conservation areas, it is possible that other critical habitat areas are not included in these measures, nor those proposed under this PA. Thus, potential cumulative effects on GOA bairdi Tanner, red king, and blue king crab habitat resulting from past events, internal bycatch, and reasonably foreseeable future external events cannot be determined.

4.9.3 Other Species Preferred Alternative Analysis

The other species category consists of the following species:

- Squid (order Teuthoidea).

- Sculpin (family Cottidae).

- Shark (Somniosus pacificus, Squalus acanthias, Lamna ditropis).

- Skate (genera Bathyraja and Raja).

- Octopi (*Ocotopus dofleini*, *Opistholeutis california*, and *Octopus leioderma*).

Current management practices provide for the establishment of an aggregate TAC, which limits the catch of species in this category. Within the other species category, only shark are identified to the species level by fishery observers. Furthermore, accuracy of catch estimates depends on the level of coverage in each fishery. Observer coverage in the BSAI is estimated at 70-80 percent, whereas the GOA has approximately 30 percent observer coverage. Coverage can vary for certain target fisheries and vessel sizes (Gaichas 2002). Further description of this management of the Other Species category is described in detail in Section 3.5.3.

Formal stock assessments for other species are not currently conducted in the BSAI and GOA, and biomass estimates for the species included in this category are limited and often unreliable. Thus, changes in total biomass, reproductive success, genetic structure of population, habitat, or mortality rates under any FMP alternative cannot be determined due to the lack of information needed to establish the baseline condition. While changes in bycatch relative to the comparative baseline are reported here, it is important to emphasize that determinations cannot be made as to how these changes in catch actually impact other species populations, or whether these impacts might be beneficial, adverse, or insignificant. There are numerous direct and indirect effects that may impact the current and future status of individual species within this group and/or this group as a whole. These effects are summarized in the section that follows.

Direct/Indirect Effects PA.1 – Other Species

Direct and indirect effects for other species include mortality, changes in reproductive success, genetic structure of population, and habitat. The significance of these effects caused by changes in catch for any of the non-target species groups are unknown. In order to determine how these stocks respond to changes in catch, information on stock status is needed. For many non-target species, the differences in catch between the comparative baseline and the proposed alternatives are relatively small, such that diverse FMPs may have similar (unknown) effects on each stock. A summary of these effects is shown in Table 4.9-2.

Under PA.1, total catch of BSAI and GOA other species is predicted to increase by several thousand mt per year. This is due to predicted increases in catches in the target fisheries where other species are caught as bycatch. Most of this increase is predicted in the catch of skate and sculpin in both areas. Catch projections for specific groups within the BSAI and GOA other species are presented below.

Squid

In the BSAI, squid catch is predicted to increase and then decrease to just above the current level over the five-year projection, likely following trends in the pollock fishery. Squid catch is predicted to double over the five-year projection period in the GOA, likely reflecting increasing catches in the pollock fishery. However, observed GOA squid catch has been low historically, so doubling may not cause different population impacts than current catch levels.

Sculpin

Catches of BSAI sculpin are predicted to remain very close to currently observed catches. GOA sculpin catch is predicted to increase slightly from current catch amounts, but the significance of this change cannot be determined.

Shark

BSAI and GOA shark species have been separated into Pacific sleeper shark, salmon shark, dogfish, and other shark. Catches of all of these species in the BSAI are predicted to remain stable throughout the projection period under PA.1. All shark catch in the GOA is predicted to be relatively low, and catches of other shark remain close to current catch levels. Pacific sleeper shark catch is predicted to decrease to about one-third of current catch levels and then slowly increase over the five-year projection period to levels just below those observed currently. Salmon shark catch is predicted to decrease slightly. Catch of dogfish in the GOA is predicted to gradually increase over the five-year projection period showing an average increase of more than 50 percent compared to current catch levels.

Skate

The increased catch of skate in the BSAI may reflect increased catches in both longline fisheries for Pacific cod and in bottom trawl fisheries for cod and flatfish. In the GOA, skate catch is predicted to increase by about 1,000 mt. These increases in catch rates for BSAI and GOA may warrant increased management attention if they actually were to occur.

Adoption of Amendment 63 by NPFMC would result in the separation of GOA skate species from the other species complex. In turn, they would be added to the Target Species category with an ABC and TAC set for skates and skate complexes (NPFMC 2003a). The NPFMC has requested a separate OFL and ABC for combined Big and Longnose skates in the Central GOA due to concerns regarding a developing fishery. Efforts to address existing data gaps for skate species are underway, and improved collection of data is expected under this amendment.

Octopi

Octopi catch in the BSAI is predicted to remain stable at 300 to 400 mt per year. The trace amounts of octopi catch reported in the GOA are predicted to decrease over the projection period, with no discernable differences in the currently unknown population impacts.

Direct/Indirect Effects PA.2 – Other Species

A summary of the direct and indirect effects associated with PA.2 is shown in Table 4.9-2.

Under PA.2, total catch of BSAI other species is predicted to decrease by several thousand mt per year, and total catch of GOA other species is predicted to remain in a similar range to current levels,. This is due to predicted decreases in catches of target species where other species are bycatch. Most of the decrease in the BSAI is predicted in the catch of skate and sculpin. Catch projections for specific groups within the BSAI and GOA other species are presented below.

Under PA.2, it is proposed that criteria be developed for applying TAC-setting procedures to specific species groups within the other species category. Sharks and skates have been the focus of this effort, but other species may be added as population data becomes available. By implementing specific TAC-setting measures into species classes that have traditionally been included in the overall other species TAC, improved management of these individual species may minimize potential population-level impacts resulting from bycatch mortality. In addition, improved observer coverage and species identification for non-target species, as proposed in PA.2, may provide improved bycatch data further supporting the need for more comprehensive management of particular species within the other species complex.

Squid

In the BSAI, squid catch is predicted to decrease slightly below the current level over the five-year projection, likely following trends in the pollock fishery. GOA squid catch is predicted to remain within the same range as current catches over the first few years of the projection period with a gradual increase thereafter, likely reflecting increasing catches in the pollock fishery. However, observed GOA squid catch has been low historically, so this increase may not result in significant population-level impacts.

Sculpin

Catches of BSAI sculpin are predicted to decrease slightly by 1,000 mt relative to current catches. The decreased catch of sculpin are due primarily to bycatch reduction incentives included in rationalization programs under PA.2. GOA sculpin catch is predicted to increase slightly each year throughout the five-year projection period, but averages a level similar to currently observed levels over time.

Shark

BSAI and GOA shark species have been separated into Pacific sleeper shark, salmon shark, dogfish, and other shark. Under PA.2, BSAI shark catch for all species remains relatively similar to those levels currently observed. GOA salmon shark are predicted to experience a decrease in catch over the five-year projection period by approximately 40 percent of currently observed levels. On average, GOA Pacific sleeper sharks show a decrease in catch by approximately 50 percent of current catch levels throughout the five-year projection period. Projected dogfish catch levels in the GOA remain similar to current levels.

Skate

The catch of BSAI skate is predicted to decrease by nearly 3,000 mt to about 15,500 mt over the projection period under PA.2. The decreased catch of skate is due primarily to bycatch reduction incentives included in rationalization programs under PA.2. This decrease in catch of skate may reflect decreased catches in both longline fisheries for Pacific cod and in bottom trawl fisheries for cod and flatfish. In the GOA, skate catch is predicted to remain close to currently observed levels.

Adoption of Amendment 63 by NPFMC would result in the separation of GOA skate species from the other species complex. In turn, they would be added to the Target Species category with an ABC and TAC set for skates and skate complexes (NPFMC 2003a). The NPFMC has requested a separate OFL and ABC for combined Big and Longnose skates in the Central GOA due to concerns regarding a developing fishery. Efforts to address existing data gaps for skate species are underway and improved collection of data is expected under this amendment.

Octopi

Octopi catch in the BSAI is predicted to remain stable at 200 to 300 mt per year. The trace amounts of octopi catch reported in the GOA are predicted to decrease over the five-year projection period by approximately 25 percent on average.

Cumulative Effects Analysis PA.2 – Other Species

A summary of the cumulative effects analysis associated with PA.1 and PA.2 is shown in Table 4.5-81. For further information on persistent past effects included in this analysis, see Section 3.5.3 of this Programmatic SEIS.

Mortality

- **Direct/Indirect Effects.** The potential effect of fishing mortality on BSAI and GOA other species is unknown under PA.1 and PA.2. The current baseline condition is unknown. Species-specific catch information is lacking for this complex, since species identification does not occur in the fisheries.

- **Persistent Past Effects**. It is possible under current other species management in the BSAI and GOA, that a species or even a species group could be disproportionately exploited while the overall aggregate other species TAC is not reached. In addition, the highest observed catches of non-target species are within the categories receiving the least intensive management under the current FMP: other species and non-specified species. It is difficult to determine how much protection is afforded by a TAC set with the use of data-poor criteria.

- **Reasonably Foreseeable Future External Effects.** In the BSAI and GOA, state-managed commercial fisheries, IPHC halibut longline fisheries, and state sport halibut fishery continue to take other species as bycatch. However, potential impacts to the specific-species within this complex are unknown, since the current baseline condition has not been determined. Long-term climate changes and regime shifts are not expected to result in direct mortality.

- **Cumulative Effects**. For all members of the other species complex, life history and distribution information are minimal in both the BSAI and the GOA. Species identification does not occur in the fisheries and potential impacts of mortality on this species complex as a whole are unknown. The combined effects of mortality on other species resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown.

Change in Reproductive Success

- **Direct/Indirect Effects.** The potential effects of changes in reproductive success on BSAI and GOA other species are unknown under PA.1 and PA.2. The current baseline condition is unknown, and species-specific reproductive status has not been determined.

- **Persistent Past Effects**. Current reproductive status of the other species complex is unknown. It is possible under current other species management in the BSAI and GOA, that a species or even a species group could be disproportionately exploited while the overall aggregate other species TAC is not reached. In addition, the highest observed catches of non-target species, other species, and non-specified species, are within the categories receiving the least intensive management under the current FMP. This possible overexploitation could have impacts to reproductive success if sex-ratios of these species are significantly altered, or if sex-specific aggregations are overfished. However, persistent past effects on the population have not been determined.

- **Reasonably Foreseeable Future External Effects.** In the BSAI and GOA, state-managed commercial fisheries, IPHC halibut longline fisheries, and state sport halibut fishery continue to take other species as bycatch. However, potential impacts to reproductive success of the specific species within this complex are unknown since the current baseline condition and species-specific reproductive status have not been determined. Long-term climate changes and regime shifts could have impacts to the reproductive success of the other species depending on the direction of the shift. It has been shown in other aquatic species that warm trends favor recruitment while cool trends weaken recruitment, but it is currently not known how the other species will respond to climatic fluctuations.

- **Cumulative Effects.** For all members of the other species complex, life history and distribution information are minimal in both the BSAI and the GOA. Current reproductive status of species within this complex are unknown and persistent past effects have not been identified. The combined effects of changes to reproductive success on other species resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown.

Change in Genetic Structure of Population

- **Direct/Indirect Effects.** The potential effects of changes in genetic structure of the other species population in the BSAI and GOA are unknown under PA.1 and PA.2. The current baseline condition is unknown, and the genetic structure of species-specific populations within this complex has not been determined.

- **Persistent Past Effects**. The current genetic composition of the other species complex is unknown. It is possible under current other species management in the BSAI and GOA, that a species or even a species group could be disproportionately exploited while the overall aggregate other species TAC is not reached. In addition, the highest observed catches of non-target species are within the categories receiving the least intensive management under the current FMP (i.e. other species and non- specified species). This possible overexploitation could have impacts to the genetic structure of the population if the genetic composition within these species groups has been significantly altered. It is unclear if persistent past effects on the populations exist.

- **Reasonably Foreseeable Future External Effects.** In the BSAI and GOA, state-managed commercial fisheries, IPHC halibut longline fisheries, and state sport halibut fishery continue to take other species as bycatch. However, their potential impacts to the genetic structure of the specific species populations within this complex are unknown. Long-term climate changes and regime shifts are not expected to result in direct mortality and would not be considered contributing effects to changes in genetic structure of populations.

- **Cumulative Effects**. For all members of the other species complex, life history and distribution information are minimal in both the BSAI and the GOA. Current genetic structure of species-specific populations within this complex are unknown, and persistent past effects have not been identified. The combined effects of changes to genetic structure of populations within the other species complex resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are, therefore, unknown.

Change in Biomass

- **Direct/Indirect Effects.** The potential effect of change in biomass on BSAI and GOA other species is unknown under PA.1 and PA.2. The current baseline condition is unknown and species-specific catch information is lacking for this complex, since species identification does not occur in the fisheries. Formal stock assessments are not conducted for other species, and most biomass estimates for BSAI and GOA other species are unreliable or not known.

- **Persistent Past Effects**. It is possible under current other species management in the BSAI and GOA, that a species or even a species group could be disproportionately exploited while the overall aggregate other species TAC is not reached. In addition, the highest observed catches of non-target species, other species, and non-specified species are within the categories receiving the least intensive management under the current FMP. Although persistent past effects potentially impacting biomass could exist, without a baseline condition established, they remain unknown.

- **Reasonably Foreseeable Future External Effects.** In the BSAI and GOA, state-managed commercial fisheries, IPHC halibut longline fisheries, and state sport halibut fisheries continue to take other species as bycatch. However, potential impacts to the specific species within this complex are unknown since the current baseline condition has not been determined. Long-term climate changes and regime shifts could have impacts on the biomass of the other species depending on the direction of the shift. It has been shown in other aquatic species that warm trends favor recruitment while cool trends weaken recruitment, but it is currently not known how the other species will respond to climatic fluctuations.

- **Cumulative Effects**. For all members of the other species complex, life history and distribution information are minimal in both the BSAI and the GOA. Species identification does not occur in the fisheries and potential impacts of changes in biomass on this species complex as a whole are unknown. Although persistent past effects potentially impacting biomass could exist, without a baseline condition established, they remain unknown. The combined effects of these changes on other species resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown.

Change in Habitat

- **Direct/Indirect Effects.** The potential effects of habitat changes to BSAI and GOA other species is unknown under PA.1 and PA.2. A current baseline condition has not been determined.

- **Persistent Past Effects**. Under current management in the BSAI and GOA, impacts to habitat could be occurring for some of the species within the other species complex. However, the species included in this complex have diverse habitat preferences and distribution patterns. Although persistent past effects potentially impacting habitat for some or all of these species could exist, without a baseline condition established, they remain unknown.

- **Reasonably Foreseeable Future External Effects.** In the BSAI and GOA, state-managed commercial fisheries, IPHC halibut longline fisheries, and state sport halibut fisheries continue to take other species as bycatch. However, potential impacts to the habitat of the specific species within this complex are unknown. Long-term climate changes and regime shifts are not expected to result in significant changes to physical habitat and are not considered contributing factors to potential effects.

- **Cumulative Effects**. For all members of the other species complex, life history and distribution information are minimal in both the BSAI and the GOA. These species have diverse habitat preferences. Although persistent past effects potentially impacting habitat could exist, without a baseline condition established, they remain unknown. The combined effects of changes to habitat on other species resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown.

4.9.4 Forage Fish Preferred Alternative Analysis

The BSAI and GOA FMPs were amended in 1998 to establishing a forage species category to prevent the development of directed fisheries on these ecologically important non-target species. Forage fish are described in more detail in Section 3.5.4.

Direct/Indirect Effects of PA.1 and PA.2 – BSAI and GOA Forage Fish

Total and Spawning Biomass

Total and spawning biomass of BSAI and GOA forage fish is unknown at this time. The incidental catch rates predicted for PA.1 and PA.2 are not expected to affect biomass.

Catch/Fishing Mortality

A directed fishery on forage species is prohibited by Amendments 36 and 39 in the BSAI and GOA FMPs. However, forage fish are taken in small amounts as incidental catch in several target fisheries. The bulk (>90 percent most years) of the forage fish bycatch is made up of smelt species (Osmeridae) from the pollock fishery. In the BSAI region, model projections for PA.1 and PA.2 indicate incidental catch of forage fish would remain low at a level similar to the current catch (Table H.4-63 in Appendix H). Over the next five years, pollock catch in the GOA is projected to grow rapidly under PA.1 and PA.2 (Table H.4-82 in Appendix H). The increased pollock catch under these FMPs is projected to result in greater incidental catches of forage fish.

Fishing mortality of BSAI and GOA forage fish is unknown at this time. As described above, forage fish bycatch and fishing mortality in the BSAI is predicted to remain relatively low under PA.1 and PA.2. The predicted increase in forage fish bycatch in the GOA would intuitively lead to an increase in fishing mortality. However, since the fishing mortality is currently thought to be very low, there is no evidence that this increase will lead to an adverse affect on the population.

Under PA.1, NOAA Fisheries and NPFMC will initiate a cumulative effects study to determine the impacts of reopening the Aleutian Islands pollock fishery on Steller sea lions and other members of the BSAI ecosystem. If the Aleutian Islands fishery were to be reopened at the conclusion of the study, this would likely increase the bycatch of forage fish.

Measures that may reduce forage fish mortality under PA.1 include reduced PSC limits in the BSAI (0 to 10 percent) and 2002 Steller sea lion measures, which may further restrict the target fisheries (discussed under change in habitat suitability). Under PA.2, PSC limits could be further reduced in the BSAI (0 to 20 percent) and GOA (0 to 10 percent). The 2002 Steller sea lion measures would be adopted and the Aleutian Islands closures, and critical habitat designations could be revised, as necessary. Furthermore, under PA.2, 0 to 20 percent of the Bering Sea and Aleutian Islands and GOA would be designated as MPAs or no-take reserves. In the GOA, inseason bycatch closures would be developed, and the effectiveness of current closures would be reevaluated in the BSAI. Also, the BSAI pollock bottom trawl closures would be extended throughout the GOA.

Spatial/Temporal Concentration of Fishing Mortality

Little is known about the current spatial or temporal concentration of fishing mortality in forage species. It is unknown how the spatial or temporal concentration of fishing effort is expected to change under PA.1. The existing closure areas will remain under PA.1; therefore, bycatch of forage species is unlikely to change substantially with regards to spatial concentration. Increased PSC limits for the BSAI fisheries may affect the temporal concentration of forage fish bycatch, although the impact is expected to be minimal. Under PA.2, reduced PSC limits and an increased number of closure areas may affect the spatial and temporal characteristics of forage fish bycatch; however, the impact of these changes are unknown.

Status Determination

The MSST of forage fish species is unknown at this time, but it is highly unlikely that management practices under PA.1 and PA.2 would lead to stocks declining to an unsustainable level.

Age and Size Composition and Sex Ratio

The age and size composition of species in the forage fish group is unknown. However, it is assumed that the age and size composition of forage fish would not change under PA.1. The sex ratio of forage fish is assumed to be 50:50. There is no information available that would suggest a potential change under PA.1.

Habitat-Mediated Impacts

Little is known about the relationship between forage fish and their habitat. It is unknown how any of the considered FMPs would change the habitat occupied by forage fish. The 2002 Steller sea lion closures prohibit fishing in Seguam Pass, establishes three nm no-transit zones around rookeries, and establishes trawl and fixed gear closures in nearshore and critical habitat areas. Programs to identify and designate EFH and HAPC will continue under PA.1, and mitigation measures for EFH and HAPC would be developed under PA.2. As mentioned above, under PA.2, 0 to 20 percent of the Bering Sea, Aleutian Islands and GOA could be established as MPAs and no-take reserves. These measures may reduce the potential adverse impacts to BSAI and GOA forage fish habitat where overlap with fisheries occurs.

Predation-Mediated Impacts

The predator-prey interactions of forage fish are very complex and difficult to predict. With the available data, it would be extremely difficult to accurately assess the predator-prey impacts of PA.1.

See Table 4.9-2 for a summary of the direct/indirect effects on BSAI and GOA forage fish under PA.1.

Cumulative Effects Analysis of PA.1 and PA.2 – BSAI and GOA Forage Fish

Mortality

- **Direct/Indirect Effects**. The effect of fishing mortality on BSAI and GOA forage fish is rated as insignificant under PA.1 and PA.2.

- **Persistent Past Effects** have not been identified for fishing mortality in the BSAI or GOA forage fish stock.

- **Reasonably Foreseeable Future External Effects** on mortality are indicated due to potential adverse contributions of marine pollution, since acute and/or chronic pollution events could result in forage fish mortality. Climate change and regime shifts are considered non-contributing factors, since it is unlikely that the change in water temperatures would be of sufficient magnitude to result in mortality of forage fish (see Sections 3.5.4 and 3.10). Alaska subsistence and personal use fisheries are identified as potential adverse contributors to forage fish mortality, however, the removal of these fisheries is expected to be minimal.

- **Cumulative Effects.** A cumulative effect is identified for mortality of BSAI and GOA forage fish but is rated insignificant. Projected levels of removals are small and not expected to have a population-level impact. The combined effects of internal and external removals is unlikely to jeopardize the capacity of the stock to maintain current population levels.

Change in Biomass Level

- **Direct/Indirect Effects.** The total and spawning biomass for BSAI and GOA forage fish is unknown at this time.

- **Persistent Past Effects** have not been identified for changes in biomass to the BSAI and GOA forage fish stock.

- **Reasonably Foreseeable Future External Effects** on the change in biomass are indicated due to the potential adverse contributions of marine pollution since acute and/or chronic pollution events could result in forage fish mortality. Climate changes and regime shifts have been identified as having potential beneficial or adverse contributions on the forage fish biomass level. A strong Aleutian Low and increased water temperatures tend to result in weak recruitment of some forage species (see Sections 3.5.4 and 3.10). The Alaska subsistence and personal use fisheries have been identified as potential adverse contributors to changes in biomass level of BSAI and GOA forage fish. Subsistence and personal use fisheries concentrate on smelt species, however, it is unlikely that these fisheries would have a population-level effect.

- **Cumulative Effects.** A cumulative effect is possible for the change in biomass level of BSAI and GOA forage fish, but impacts of the effect are unknown. Total and spawning biomass are unavailable for the forage fish species at this time.

Spatial/Temporal Concentration of Catch

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the effect of the fisheries on the spatial/temporal characteristics of forage fish stocks is unknown.

- **Persistent Past Effects** on the genetic structure of BSAI and GOA forage fish have not been identified. Climate changes and regime shifts may influence reproductive success of BSAI and GOA forage fish. For example, some Osmeridae species have shown a decline in recruitment since the late 1970s, coinciding with an increase in water temperature (see Sections 3.5.4 and 3.10).

- **Reasonably Foreseeable Future External Effects** on reproductive success of forage fish due to climate changes and regime shifts are potentially beneficial or adverse. Marine pollution has been identified as a potential adverse contribution since acute and/or chronic pollution events could alter genetic structure and/or reproductive success of BSAI and GOA forage fish. The Alaska subsistence and personal use fisheries are identified as potential adverse contributors to the genetic structure and reproductive success of BSAI and GOA forage species. As stated above, these fisheries target smelt species; however, it is unlikely that removals in these fisheries would jeopardize the capacity of the stocks to maintain current population levels.

- **Cumulative Effects.** A cumulative effect could result from changes to spatial/temporal characteristics of forage fish; however, this effect is unknown. Information on spatial/temporal characteristics of the BSAI and GOA forage fish stocks is currently lacking.

Change in Prey Availability

- **Direct/Indirect Effects**. Under PA.1 and PA.2, the change in prey availability for the BSAI and GOA forage fish is unknown.

- **Persistent Past Effects** on changes to prey availability of the BSAI and GOA forage fish stock exists and include climate changes and regime shifts. Crab and shrimp have shown variation in abundance associated with changes in climate and water temperatures. However, studies on most benthic invertebrates have not been conducted (see Sections 3.5.4 and 3.10).

- **Reasonably Foreseeable Future External Effects** of climate changes and regime shifts on the BSAI and GOA forage fish stock are potentially beneficial or adverse. A strong Aleutian Low and increased water temperatures tend to result in weak recruitment in some species. Marine pollution has been identified as a potentially adverse contributor since acute and/or chronic pollution events could reduce prey availability or prey quality, thus jeopardizing the stocks' ability to maintain current population levels. Alaska subsistence and personal use fisheries are identified as potentially adverse contributors in prey availability of BSAI and GOA forage fish. However, the catch/bycatch of these species is expected to be minimal and is unlikely to have a population-level impact.

- **Cumulative Effects**. Although a cumulative effect on prey availability for forage species could exist, potential population-level impacts are not known. Information on forage fish prey interactions is insufficient.

Change in Habitat Suitability

- **Direct/Indirect Effects**. Under PA.1 and PA.2, the change in habitat suitability for the BSAI and GOA forage fish is unknown.

- **Persistent Past Effects** identified for BSAI and GOA forage fish include climate changes and regime shifts. A strong Aleutian Low and increased water temperatures tend to result in weak recruitment for some forage fish species (see Sections 3.5.4 and 3.10).

- **Reasonably Foreseeable Future External Effects** of climate change and regime shifts on the BSAI and GOA forage fish stocks are potentially beneficial or adverse. Marine pollution may be a potentially adverse contributor since acute and/or chronic pollution events could result in habitat degradation in spawning or rearing success. Alaska subsistence and personal use fisheries are identified as potentially adverse contributors to forage fish habitat suitability (see Section 3.6).

- **Cumulative Effects.** A cumulative effect is possible for BSAI and GOA forage fish habitat suitability; however, potential population-level impacts are unknown. Information on forage fish habitat and possible fishing effects on these habitats is largely unknown at this time.

See Tables 4.5-44 and 4.5-45 for a summary of the cumulative effects on BSAI and GOA forage fish, respectively.

4.9.5 Non-Specified Species Preferred Alternative Analysis

Grenadier have been chosen to illustrate potential effects to non-specified species because they are currently the major catch in this FMP category. Non-specified species is a huge and diverse category encompassing every species not listed in the current FMP as a target, prohibited, forage, or other species. Considering a single species group from this category, such as grenadier, cannot possibly represent the diverse effects to all species in the category. However, because information is lacking for nearly all non-specified species, and due to the small or unknown amounts of bycatch (due to a lack of reporting requirements in this category), only potential effects to grenadier are discussed.

Formal stock assessments are not conducted for grenadier. Thus, changes in total biomass, reproductive success, genetic structure of population, habitat, or mortality rates under any FMP alternative cannot be determined due to the lack of information needed to establish the baseline condition . Changes in bycatch of grenadier were predicted based on modeled changes in target species catches and population trajectories (sablefish target fisheries account for the highest grenadier bycatch). While changes in bycatch mortality relative to the comparative baseline are reported here, it is important to emphasize that determinations cannot be made as to how these changes actually impact grenadier populations, or whether these impacts might be adverse, beneficial, or insignificant.

Direct/Indirect Effects PA.1 and PA.2 – Grenadier

Direct and indirect effects for grenadier include mortality, changes in reproductive success, genetic structure of population, and habitat. The significance of these effects caused by changes in catch for any of these non-target species groups are unknown, because information on stock status is lacking.

Under PA.1, catch of grenadier in both the BSAI and GOA is predicted to remain within or above the currently observed range. In both areas, grenadier catch is predicted to increase initially and then decrease; however, catch rates still remain higher than those currently observed. The significance of these changes to grenadier and other species populations within the non-specified species group cannot be determined, and potential population-level impacts cannot be characterized.

Under PA.2, catch of grenadier in both the BSAI and GOA is predicted to decrease relative to the currently observed catch. In the BSAI, grenadier catch is predicted to decrease by one-half of currently observed levels. In the GOA, catch is predicted to decrease from an estimated 11,000 mt to approximately 8,000 mt per year. The decreased catch of grenadier is due primarily to bycatch reduction incentives included in rationalization programs under PA.2. As stated above, the significance of these changes to grenadier and other species populations within the non-specified species category cannot be determined.

As proposed under PA.2, development of TAC-setting criteria, allowing for a non-specified species to become a managed category, may result in improved management of individual species within the non-specified species group, and minimize potential population-level impacts resulting from bycatch mortality. In addition, improved observer coverage and species identification for non-target species, as proposed in PA.2, may provide reliable bycatch data further supporting the need for more comprehensive management of particular species within the non-specified group.

Cumulative Effects Analysis PA.1 and PA.2 – Grenadier

A summary of the cumulative effects analysis associated with PA.1 and PA.2 are shown in Table 4.9-2. For further information on persistent past effects included in this analysis, see Section 3.5.5 of this Programmatic SEIS.

Mortality

- **Direct/Indirect Effects.** The potential effects of PA.1 and PA.2 on mortality of grenadier in the BSAI and GOA is unknown. The current baseline condition is unknown and catch information is lacking for all members of the non-specified species category since species identification does not occur in the fisheries.

- **Persistent Past Effects**. No management or monitoring of any species in this category exists, and retention of any non-specified species is permitted. No reporting requirements for non-specified species exist, and there are no catch limitations or stock assessments. It is possible that grenadier, and all other species included in the non-specified species category in the BSAI and GOA, could be disproportionately exploited, but stock status remains unknown. Grenadier continue to constitute the largest portion on the non-target species bycatch in the GOA, and federal fishery-caused mortality is considered a persistent past effect.

- **Reasonably Foreseeable Future External Effects.** In the BSAI and GOA, the state-managed commercial fisheries and IPHC halibut longline fisheries continue to take grenadier and other non-specified species as bycatch. However, potential impacts to specific species within this complex are unknown, since the current baseline condition has not been determined. Long-term climate changes and regime shifts are not considered contributing factors as they are not expected to result in direct mortality.

- **Cumulative Effects**. For grenadier and other species within the non-specified complex, life history and distribution information are minimal in both the BSAI and the GOA. Species identification does not occur in the fisheries and potential impacts of mortality on this species complex as a whole are unknown. The combined effects of mortality on grenadier, and other species within the non-specified species complex resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown for PA.1 and PA.2.

<u>Change in Reproductive Success</u>

- **Direct/Indirect Effects.** The potential effects of changes in reproductive success on BSAI and GOA grenadier, and presumably all other species within the non-specified species complex, are unknown under PA.1 and PA.2. The current baseline condition is unknown, and species-specific reproductive status has not been determined.

- **Persistent Past Effects.** The current reproductive status of grenadier is unknown. It is possible that grenadier, and all other species included in the non-specified species category, in the BSAI and GOA, could be disproportionately exploited; however, stock status remains unknown. This possible overexploitation could have impacts to reproductive success if sex-ratios of these species are significantly altered or if sex-specific aggregations are overfished. This overfishing could lead to reduced recruitment. It is unknown if persistent past effects on the population exist.

- **Reasonably Foreseeable Future External Effects.** In the BSAI and GOA, state-managed commercial fisheries (specifically sablefish and Greenland turbot longline) and IPHC halibut longline fisheries continue to take grenadier (and other non-specified species) as bycatch. However, potential impacts to reproductive success of the specific species within this complex are unknown, since current baseline condition and species-specific reproductive status have not been determined. Long-term climate changes and regime shifts could have impacts to the reproductive success of grenadier (and other non-specified species) depending on the direction of the shift. It has been shown in other aquatic species that warm trends favor recruitment while cool trends weaken recruitment, but it is currently not known how grenadier and all other members of the non-specified species category, will respond to climatic fluctuations.

- **Cumulative Effects**. For grenadier, and all other species within the non-specified species category, life history and distribution information are minimal in both the BSAI and the GOA. Current reproductive status of species with this complex are unknown and persistent past effects have not been identified. The combined effects of changes to reproductive success on grenadier and other non-specified species resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown for PA.1 and PA.2.

<u>Change in Genetic Structure of Population</u>

- **Direct/Indirect Effect of the Alternative.** The potential effects of changes in genetic structure of grenadier and other species within the non-specified species complex in the BSAI and GOA are unknown under PA.1 and PA.2. The current baseline condition is unknown, and the genetic structure of species-specific populations within this complex has not been determined.

- **Persistent Past Effects**. The current genetic composition of the non-specified species complex is unknown. It is possible that grenadier, and all other species included in the non-specified species category, in the BSAI and GOA, could be disproportionately exploited; however, however, stock status remains unknown. This possible overexploitation could have impacted the genetic structure of the population if genetic composition within these species groups has been significantly altered. It is unclear if persistent past effects on the populations exist.

- **Reasonably Foreseeable Future External Effects.** In the BSAI and GOA, state-managed commercial fisheries (specifically sablefish and Greenland turbot longline) and IPHC halibut longline fisheries continue to take grenadier (and other non-specified species) as bycatch. However, their potential impacts to genetic structure of the specific species populations within this complex are unknown. Long-term climate changes and regime shifts are not expected to result in direct mortality and would not be considered contributing factors in changes to genetic structure of populations.

- **Cumulative Effects**. For grenadier, and all members of the non-specified species category, life history and distribution information are minimal in both the BSAI and the GOA. Current genetic structure of species-specific populations within this complex are unknown and persistent past effects have not been identified. The combined effects of changes to genetic structure of populations within the non-specified species complex resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown for PA.1 and PA.2.

Change in Biomass

- **Direct/Indirect Effects.** The potential effect of change in biomass on BSAI and GOA grenadier is unknown under PA.1 and PA.2. The current baseline condition is unknown for all members of the non- specified complex, and species-specific catch information is lacking since species identification does not occur in the fisheries. Formal stock assessments are not conducted and grenadier biomass estimates in the BSAI and GOA, other than those conducted since 1999 for the giant grenadier, are not known.

- **Persistent Past Effects.** It is possible that grenadier, and all other species included in the non-specified species category, in the BSAI and GOA, could be disproportionately exploited; however, however, stock status remains unknown. The current non-management of grenadier could mask declines in individual grenadier species and lead to overfishing of a given grenadier species. Although persistent past effects potentially impacting biomass could exist, without a baseline condition established, they remain unknown.

- **Reasonably Foreseeable Future External Effects.** In the BSAI and GOA, state-managed commercial fisheries (specifically sablefish and Greenland turbot longline) and IPHC halibut longline fisheries continue to take grenadier (and other non-specified species) as bycatch. However, potential impacts to the specific species within this complex are unknown, since the current baseline condition has not been determined. Long-term climate changes and regime shifts could have impacts on the biomass of grenadier and all other members of the non-specified species group depending on the direction of the shift. It has been shown in other aquatic species that warm trends favor recruitment while cool trends weaken recruitment, but it is currently not known how these non-specified species will respond to climatic fluctuations.

- **Cumulative Effects**. For all members of the non-specified species complex, life history and distribution information are minimal in both the BSAI and the GOA. Species identification does not occur in the fisheries and potential impacts of changes in biomass to grenadier and all other non-specified species are unknown. Although persistent past effects of changes to biomass could exist, without a baseline condition established, they remain unknown. The combined effects of these changes on BSAI and GOA grenadier and all other species in the non-specified species group, resulting from internal bycatch and reasonably foreseeable future external events (both human controlled and natural) are unknown for PA.1 and PA.2.

4.9.6 Habitat Preferred Alternative Analysis

Direct/Indirect Effects PA.1 – Habitat

Example PA.1 illustrates a management approach that accelerates precautionary management measures by increasing constraints where necessary, formalizing precautionary practices in the FMPs, and initiating scientific review of existing practices as a necessary precursor to the decision of how best to incorporate adequate precaution. Three components of the bookend are specific to habitat:

- Developing an MPA process.
- Identifying and designating EFH and HAPC pursuant to MSA rules.
- Maintaining current closed/restricted areas.

The first two components are discussed qualitatively in Appendix F-3 and summarized below. The analysis of direct and indirect effects on habitat of maintaining the current closure areas follows.

Developing an MPA Process

Specific to developing an MPA process as required by Executive Order (EO) 13158, PA.1 incorporates an initiative to develop and adopt definitions of MPAs, marine reserves, marine fishery reserves, and protected marine habitats (see Section 1.0 of Appendix F-3). PA.1 seeks to develop an MPA efficacy methodology including program goals, objectives, and criteria for establishing MPAs. Appendix F-3 discusses specific actions to achieve the objectives for MPA establishment that have been recommended by ADF&G. Section 5.1 of Appendix F-3 suggests a three-phase method for the MPA designation process that could be used under this framework. The methodology employs and expands upon EFH/HAPC considerations, the ADF&G (2002b) recommendations, and suggestions provided by the NRC (2001). As discussed in the appendix, the public, recognized ecological and socioeconomic experts (organized into teams or forums), and interested federal and state agency representatives all have the opportunity to provide input into each step of the MPA candidate selection, designation, and management process.

Identify and Designate EFH and HAPC

As described in Section 1.1 of Appendix F-3, EFH definitions for all managed species are currently being reviewed by the NPFMC and NOAA Fisheries through its EFH amendment process. A decision on the Alaska EFH definitions will be made by August 2005. The Assistant Administrator of NOAA Fisheries determined that the agency would prepare new regional EISs to include all FMPs covered by the EAs. The proposed action to be addressed in the EFH EIS is the development of the mandatory EFH provisions of all five FMPs of the NPFMC; the BSAI groundfish FMP, GOA groundfish FMP, BSAI king and Tanner crab FMP, scallop fishery off Alaska FMP, and the FMP for the salmon fisheries in the EEZ off the coast of Alaska. At present NOAA Fisheries and the NPFMC are identifying feasible alternatives for analysis in the EIS for NPFMC's eventual selection of a preferred alternative. The Alaska Groundfish Programmatic SEIS is not intended to replace or supercede the EFH EIS, but will provide overarching policy guidance for EFH and will set the stage for future FMP actions.

According to the Final Rule implementing the EFH provisions of the MSA (50 CFR Part 600), to identify EFH basic information is needed to understand the usage of various habitats by each managed species. Pertinent information includes the geographic range and habitat requirements by life stage, the distribution and characteristics of those habitats, and current and historic stock size as it affects occurrence in available habitats. Temporal and spatial distribution of each life history stage is necessary to understand each species' relationship to, or dependence on, its various habitats. Data summarizing all environmental and habitat variables that control or limit distribution, abundance, reproduction, growth, survival, and productivity of the managed species should be provided.

The NPFMC (1999) identified EFH information levels for groundfish, crab, scallops, and salmon in the Alaska regions. Level 2 data is available for some adult life history stages of groundfish, crabs, and shellfish. Level 2 data is available for some stocks of red and blue king crab, and Tanner and snow crab stocks in some regions, at the egg, larval, late juvenile, and adult stages. The remainder of the data for all other crab stocks is either at Level 1 or unknown. Level 1 data is available for the eggs, larvae, early juvenile, and late juvenile stages of pollock, and for the late juvenile stages of most other groundfish species. Even minimal (Level 1) data are not available for forage fish at all life stages, so distribution and habitat use are considered to be unknown. Salmon EFH data are highly variable and cross Levels 1 through 4 depending on species, stock, and life stage. The majority of the data available for adults in the freshwater stage ranges from Levels 1 to 3. The information levels for all EFH are continually being refined and updated and will be presented in the EIS currently being developed for EFH.

Maintaining Current Closed and Restricted Areas

There are no additional bottom trawl closures relative to the baseline, and there will be decreases in fishing effort. Figure 4.2-8 (bookend first appears in a previous section) illustrates the PA.1 suite of year-round closures in the BSAI and GOA management areas. Since the closure areas remain the same as in FMP 1, FMP 2.2, and FMP 3.1, impacts to habitat under PA.1 should be similar to those described previously for these FMPs. A summary of direct and indirect impacts of PA.1 is provided in Table 4.9-3.

As shown on Table 4.9-3, direct and indirect effects of the FMP on habitat are discussed for changes to living habitat through direct mortality of benthic organisms and changes to benthic community structure through benthic community diversity and geographic diversity of impacts and protection. Due to their habitat type differences, the BSAI and GOA are rated and discussed separately.

Changes to Living Habitat – Direct Mortality of Benthic Organisms

The habitat impacts model predicts the following effects for PA.1 on biostructure relative to the baseline:

- **Bering Sea.** There is no predictable difference from the baseline where mean impacts are low when averaged over entire fishable EEZ. As with the baseline, impacts to biostructure ranged from 1.8 to 9.3 percent of the fishable EEZ and from 8.2 to 41.9 percent of the fished area (see Table 4.1-26). Based on these results, we conclude that there would be an insignificant change to mortality and damage to living habitat as a result of PA.1 as compared to the baseline. However, the baseline condition is considered to be already adversely impacted. Thus, the rating is based on the insignificant change between PA.1 projections and the comparative baseline.

- **Aleutian Islands.** There is no predictable difference from baseline (Table 4.1-26). Therefore, we rate the change resulting from PA.1 on the baseline as insignificant. However, the prevalence of long-lived species of coral in the bycatch is a particular concern in the Aleutian Islands under PA.1. With a recovery rate for red tree coral possibly as low as $\rho = 0.005$ (200 years) and sensitivity $q_h = .27$, the habitat impact model indicates that fishing intensity as low as $f = 0.10$ (total area swept once every ten years) results in an equilibrium level reduction of 85 percent relative to the unfished level. About 9 percent of the area is estimated to be fished at $f = 0.10$ or greater. This amounts to 3,590 square miles of area. Thus, continued bycatch and damage to living habitat at PA.1 bycatch levels may have adverse consequences on habitat quality, and PA.1 would not change this risk.

- **GOA.** There is no predictable difference from baseline where estimates of equilibrium impact on biostructure averaged over entire fishable EEZ range from 0.9 to 6.9 percent of the fishable area and 3.8 percent to 29.0 percent of the fished areas (see Table 4.1-26). Only 2 percent of the fishable EEZ is impacted to a level potentially below 32 percent of unfished levels, but amounts to about 2,418 square miles of habitat in scattered concentrations. Therefore, for PA.1, we rate this change to mortality and damage to living habitat as insignificant. However, the baseline condition is considered to be already adversely impacted.

Changes to Benthic Community Structure – Benthic Community Diversity and Geographic Diversity of Impacts and Protection

- **Bering Sea.** Identical to the baseline and FMP 1, PA.1 closures in the Bering Sea are mostly concentrated on sand substrate (Table 4.5-47). Only 27 percent of the geographical- habitat zones have greater than or equal to 20 percent of their area closed to bottom trawling. Figure 4.1-10 shows that the amount of large contiguous areas of high fishing intensity—that is, areas that are swept at least once each year with bottom trawls—exceeds 8,000 square miles (Table 4.1-26). Table 4.5-49 shows that of the Bering Sea fishable area, 19.3 percent is closed to bottom trawling under FMP 1 and is identical to PA.1. However, very little geographic diversity of fishing impacts occurs within the closed habitats, and nearly all of the closures are not year-round. Figure 4.5-4 shows areas closed to trawling only at various times of the year under FMP 1 and PA.1, while Figure 4.5-5 depicts just those areas closed to fixed gear only.

Application of the habitat impacts model indicated that, depending on the sensitivity and recovery parameters thought plausible, fishing of this intensity could reduce the amount of biostructure in the area by 13 to 75 percent of its unfished level equilibrium level (Table 4.1-26). Such biostructure includes sponges, soft corals, tunicates, and anemones (Heifetz 2002, Malecha *et al.* 2003). In these habitat areas, no existing closure areas abut these intensely fished areas to provide a diverse level of impact. While existing closures tend to be large and cover all of the particular habitat, they provide little diversity in fishing impacts. The primary focus of these past regulations has been to prevent potential damage to vulnerable crab habitat from bottom trawl gear, and they do not necessarily cross a wide range of habitat types. Some of the trawl closures are in effect year-round while others are seasonal (see Section 3.6). However, compared to the existing baseline the predicted effects of PA.1 on benthic community diversity are insignificant. Similarly, the predicted effects of PA.1 on geographic diversity of impacts are predicted to be insignificant. However, as described above for direct mortality, the baseline condition is considered to be already adversely impacted.

- **Aleutian Islands.** Identical to the baseline and FMP 1, PA.1 closures in the Aleutian Islands are concentrated in shallow water where only 4 percent of the area is closed to bottom trawling year-round for all species. However, as shown on Table 4.5-49, about 43 percent of the fishable area in the Aleutian Islands is closed to bottom trawling at one time or another during the year under FMP 1, and similarly under PA.1. These closures are associated with sea lion rookeries. As in the baseline, there is very little diversity in protection. Less than one percent of the deep area is closed to bottom trawling. Figure 4.1-10 shows that none of the closure areas extends over any blocks of significant fishing effort. Figures 4.5-4 and 4.5-5 show the closure areas under PA.1 broken down by gear type for bottom trawl and fixed gear, respectively. The Aleutian Islands bathymetry and habitat are distributed on a very fine scale, with fishing effort that is very patchy and in very small clusters. Based on comparison of these observations to the baseline, the predicted effects of PA.1 on benthic community diversity and geographic diversity of impacts are insignificant, but the baseline condition is considered to have already experienced adverse impacts.

- **GOA.** Figure 4.5-6 shows that, as in the baseline, minimal geographic diversity of impact or protection results from the current suite of closed areas. Except for the southeast trawl closure which covers several entire habitats, all other closures are inshore, and none exists on the outer shelf or slope (see Figure 4.5-6). As shown on Table 4.5-49 and Figures 4.5-4 and 4.5-5, PA.1 closes nearly 46 percent of the fishable area in the GOA to trawling at one time or another during the year. The inshore closure areas tend to be large relative to the size of bathymetric and habitat resolution scale and thus tend to encompass much of a bathymetric feature. Based on these results, the predicted effects of PA.1 on benthic community diversity and geographic diversity of impacts are insignificant, but the baseline condition is considered to be in an adversely impacted state.

Cumulative Effects PA.1 – Habitat

Cumulative effects on habitat for PA.1 are summarized on Table 4.5-50. The following discussion of the results presented on the table is broken down by geographic area.

Bering Sea

Changes to Living Habitat – Direct Mortality of Benthic Organisms

- **Direct/Indirect Effects.** As described above, this effect is judged to be insignificant, but the baseline is considered to be already adversely impacted.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the Bering Sea. Mortality of long-lived species such as tree corals and other sessile epifauna is likely to be persistent in these areas. The areas historically and recently closed to fishing described in Section 3.6 may have recovered or be recovering with past mortality effects becoming less evident over time.

- **Reasonably Foreseeable Future External Effects.** Offal discharge, port expansion and use and marine pollution all have the potential to cause direct mortality of benthic organisms and changes to living habitat. Offal discharge can occur from offshore catcher processors and onshore processors. However, impacts which include mortality due to smothering and/or reduced oxygen are expected to be more prevalent in inshore, closed bay locations. Improvements in offal pre-treatment and discharge regulations in recent years have reduced impacts and potentially improved conditions. Port expansion and increased use is possible at several locations in the Bering Sea area including Port Moller, Port Heiden, Dillingham, St. Paul and St. George. Again the impacts include mortality due to smothering and/or burying and would affect only nearshore zones and bays. Marine pollution is identified as having a reasonably foreseeable potential adverse contribution, since acute and/or chronic pollution events, if large enough in scale, could cause mortality to benthic organisms. Again, areas more likely to be impacted would be located nearer to shore. Natural events such as storm surges and waves have the potential to cause direct morality through burial. These effects, like the others, would be expected in shallow waters where the wave energy is transmitted to the bottom without much attenuation through the water column. Climate changes and regime shifts are not expected to cause direct mortality of benthic organisms.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for mortality of Bering Sea benthic organisms. The additional external impacts described above will add to the lingering past mortality impacts and contribute to impacts that are already evident. Thus, even though the direct/indirect effect of PA.1 is rated as insignificant, bycatch and damage to living habitat in the Bering Sea will continue and add to the adverse consequences on benthic living habitat.

Changes to Benthic Community Structure

- **Direct/Indirect Effects.** As described above, this effect is judged to be insignificant; however, the community structure is considered to be already impacted.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the Bering Sea. Changes to benthic community structure including a reduction in species diversity have been observed in heavily fished areas of the world (see Section 3.6 for discussion and references). However, the areas historically and recently closed to fishing described in Section 3.6 may have recovered or be recovering with past mortality effects becoming less evident over time.

- **Reasonably Foreseeable Future External Effects.** Offal discharge, port expansion and use, marine pollution, all have the potential to cause changes to benthic communities. If long-term, as in the case of a change to a weather pattern, wind induced waves and surges could cause sufficient changes to the substrate such that the benthic community is impacted. As discussed above, all of these impacts are more likely to be observed in nearshore areas. Regime shifts, and large-scale environmental fluctuations associated with ENSO and La Niña events have been identified as having impacts on both the physical and biological systems in the North Pacific. These changes could have either beneficial or adverse effects on the benthic community (see Sections 3.6 and 3.10).

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in benthic community structure of the Bering Sea. The additional external impacts described above will add to the lingering past mortality impacts and contribute to impacts that are already evident. Thus, even though the direct/indirect effect of PA.1 is rated as insignificant, bycatch and damage to living habitat in the Bering Sea will continue and add to the adverse consequences to benthic living habitat.

Geographic Diversity of Impacts and Protection

- **Direct/Indirect Effects.** As described above, this effect is judged to be insignificant, but the baseline is considered to be already adversely impacted.

- **Persistent Past Effects.** Persistent past effects are expected since fishing effort and distribution have changed over time as areas have been closed and remain closed. Figures 3.6-6 and 3.6-7 illustrate the spatial measures that were in effect before 1980 or were later established by regulations following the publication of the Final Groundfish SEIS in November of 1980. As discussed in Section 3.6, during the late 1970s and early 1980s, there was little domestic fishing for groundfish species. Most of the restricted areas were implemented to spatially and temporally restrict the foreign fishery to prevent conflicts with domestic fisheries through bycatch of species important to U.S. fishermen, or grounds preemption and gear conflicts. Most domestic fishing effort focused on crab, salmon, and herring. Figures 3.6-6 and 3.6-7 illustrate that back in 1980, there were more restrictions placed on foreign fixed gear fisheries than trawl fisheries. This again was due to the need to give priority to the domestic fisheries that used similar gear and fishing grounds. Table 4.5-51 shows that in 1980 almost 9 percent of the fishable area in the Bering Sea was closed to trawling with 2.2 percent closed to all fishing. There were no longline-only closures in the Bering Sea at that time.

- **Reasonably Foreseeable Future External Effects.** These include port expansion and the potential resultant changes to offal discharge and marine pollution events. As ports in the Bering Sea are expanded and new ports created, additional dock space for harboring the fishing fleet is made available. While the fleet might not necessarily expand, the opening of new ports may allow vessels of all sizes to access new or relatively unfished areas. On the other hand, depending on distribution, fishing pressure in heavily fished areas may be eased as access to other areas becomes available. Of course, closed areas proposed to continue under PA.1 would not be affected by the redistribution of home ports. Depending on the distribution of fishing effort, previously un-impacted areas could be impacted by offal discharge and marine pollution. Natural events are not expected to be contributing factors in this case.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in distribution of fishing effort. The maps and statistics discussed above show that PA.1 would protect more benthic habitat from trawl gear in the future (19 percent) than was protected in 1980 (8.6 percent). However, the spatial distribution of the closed areas under PA.1 will not protect the full range of habitat types or provide for a diversity of impacts within fished areas. Existing closures tend to be large and cover all of particular habitat. They provide little diversity in fishing impacts since the primary focus of these past regulations has been to prevent potential damage to vulnerable crab habitat from bottom trawl gear. (See direct/indirect effects discussion and baseline description in Section 3.6). The additional external impacts do not provide any protection and could add to the lingering past mortality impacts and to impacts that are already evident. This is particularly important since FMP 1 does not require a reduction in TAC. The benefits provided by the closed areas are uncertain since previously unfished areas would likely be fished and impacts would occur in areas not previously impacted.

Aleutian Islands

<u>Changes to Living Habitat – Direct Mortality of Benthic Organisms</u>

- **Direct/Indirect Effects.** As described above, this effect is judged to be insignificant; however, the baseline is considered to be already impacted.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the Aleutian Islands. Prevalence of long-lived species of coral makes impacts a particular concern in the Aleutian Islands. Mortality of long-lived species such as tree corals and other sessile epifauna is likely to be persistent in these areas. The areas historically and recently closed to fishing described in Section 3.6 may have recovered or be recovering with past mortality effects becoming less evident over time.

- **Reasonably Foreseeable Future External Effects.** Dredging, longline fisheries, pot fisheries, offal discharge, port expansion and use, and marine pollution all have the potential to cause direct mortality of benthic organisms and changes to living habitat. Dredging due to scallop fisheries and/or navigation can occur in localized areas, often in conjunction with port development and can cause burial or smothering of benthic fauna. Damage to living substrates by longline and pot fisheries (see Section 3.6) has been documented and is expected to continue in those heavily fished areas. Offal discharge can occur from offshore catcher processors and onshore processors. However, impacts which include mortality due to smothering and/or reduced oxygen are expected to be more prevalent at inshore closed bay locations. However, improvements in offal pre-treatment and discharge regulations in recent years have reduced impacts and potentially improved conditions. Port expansion and increased use is possible at several locations in the Aleutian Islands including Atkutan, Adak, Unalaska, Cold Bay, Dutch Harbor, and King Cove. Again the impacts include mortality due to smothering, and/or burying and would affect only nearshore zones and bays. Marine pollution is identified as having a reasonably foreseeable potential adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to benthic organisms. Natural events such as storm surges and waves have the potential to cause direct morality through burial. These effects, like the others, would be expected in shallow waters where the wave energy is transmitted to the bottom without much attenuation through the water column. Climate changes and regime shifts are not expected to cause direct mortality of benthic organisms.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for mortality of Aleutian Islands benthic organisms. Long-lived species such as tree coral are more prevalent in the Aleutian Islands. The additional external impacts described above will add to the lingering past mortality impacts and contribute to impacts that are already evident. Thus, even though the direct/indirect effect of PA.1 is rated as insignificant, bycatch and damage to living habitat in the Aleutians will continue and will add to the adverse consequences to benthic living habitat.

<u>Changes to Benthic Community Structure</u>

- **Direct/Indirect Effects.** As described above, this effect is judged to be insignificant; however, the community structure is considered to be already impacted.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the Aleutian Islands. Changes to benthic community structure including a reduction in species diversity have been observed in heavily fished areas of the world (see Section 3.6). However, the areas historically and recently closed to fishing described in Section 3.6 may have recovered or be recovering with past mortality effects becoming less evident over time.

- **Reasonably Foreseeable Future External Effects.** Dredging, longline and pot fisheries, offal discharge, port expansion and use, and marine pollution all have the potential to cause changes to benthic communities. If long-term, as in the case of a change to a weather pattern, wind induced waves and surges could cause sufficient changes to the substrate such that the benthic community is impacted. As discussed above for mortality, all of these impacts are more likely to be observed in nearshore areas. Regime shifts and large-scale environmental fluctuations associated with ENSO and La Niña events have been identified as having impacts on both the physical and biological systems in the North Pacific (see Sections 3.6 and 3.10). These changes could have either beneficial or adverse effects on the benthic community.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in benthic community structure of the Aleutian Islands. The additional external impacts described above will add to the lingering past mortality impacts and contribute to impacts that are already evident. Thus, even though the direct/indirect effect of PA.1 is rated as insignificant, continued bycatch and damage to living habitat will add to the adverse consequences on the benthic community.

<u>Geographic Diversity of Impacts and Protection</u>

- **Direct/Indirect Effects.** As described above, this effect is judged to be insignificant; however, the baseline is considered to be already impacted.

- **Persistent Past Effects.** Persistent past effects are expected since fishing effort and distribution have changed over time as areas have been closed and remain closed. As discussed above for the Bering Sea, during the late 1970s and early 1980s, there was little domestic fishing for groundfish species. Most domestic fishing effort focused on crab, salmon, and herring. Figures 3.6-6 and 3.6-7 illustrate that in 1980, there were more restrictions placed on foreign fixed gear fisheries than trawl fisheries. They gave priority to the domestic fisheries that used similar gear and fishing grounds. Table 4.5-51 shows that in 1980 about 31 percent of the fishable area in the Aleutian Islands was closed to trawling with about 6 percent closed to all fishing. There were no longline only closures in the Aleutian Islands at that time.

- **Reasonably Foreseeable Future External Effects.** These include other fisheries, port expansion, and the potential resultant changes to offal discharge and marine pollution episodes. Depending on changes in distribution of fishing effort, sensitive areas could either be additionally impacted or allowed to recover. As with the Bering Sea, ports in the Aleutian Islands will be expanded and new ports created, and additional dock space for harboring the fishing fleet will be made available. While the fleet might not necessarily expand, the distribution of fishing effort is likely to change and previously unimpacted areas could be impacted by offal discharge and marine pollution. Natural events are not expected to be contributing factors in this case.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in distribution of fishing effort. The maps and statistics discussed above show that PA.1 would protect more benthic habitat from trawl gear in the future (43 percent) than was protected in 1980 (31 percent). However, the spatial distribution of the closed areas under the current FMPs may not protect the full range of habitat types.

GOA

Changes to Living Habitat – Direct Mortality of Benthic Organisms

- **Direct/Indirect Effects.** As described above, this effect is judged to be insignificant; however, the benthic community is considered to be already impacted.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the GOA. Mortality of long-lived species such as tree corals and other sessile epifauna is likely to be persistent in these areas. The areas historically and recently closed to fishing described in Section 3.6 may have recovered or be recovering with past mortality effects becoming less evident over time.

- **Reasonably Foreseeable Future External Effects.** As described for the BSAI, dredging, longline fisheries, pot fisheries, offal discharge, port expansion and use, and marine pollution all have the potential to cause direct mortality of benthic organisms and changes to living habitat. Port expansion and increased use is possible at several locations in the GOA including Kodiak, Sand Point, Chignik, Port Lions, Ouzinkie, Valdez, and Seward. The impacts include mortality due to smothering and/or burying and would likely affect only nearshore zones and bays. Marine pollution is identified as having a reasonably foreseeable potential adverse contribution since acute and/or chronic pollution events, if large enough in scale, could cause mortality to benthic organisms. Natural events such as storm surges and waves have the potential to cause direct morality through burial. These effects, like the others, would be expected in shallow waters where the wave energy is transmitted to the bottom without much attenuation through the water column. Climate changes and regime shifts are not expected to cause direct mortality of benthic organism.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for mortality of GOA benthic organisms. The additional external impacts described above will add to the lingering past mortality impacts and contribute to impacts that are already evident. Thus, even though the direct/indirect effect of PA.1 is rated as insignificant, continued bycatch and damage to living habitat in the GOA will add to the adverse consequences of fishing on the mortality of benthic organisms.

Changes to Benthic Community Structure

- **Direct/Indirect Effects.** As described above, this effect is judged to be insignificant; however, the community structure is considered to be already impacted.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the GOA. Changes to benthic community structure including a reduction in species diversity have been observed in heavily fished areas of the world (see Section 3.6). However, the areas historically and recently closed to fishing described in Section 3.6 may have recovered or be recovering with past mortality effects becoming less evident over time.

- **Reasonably Foreseeable Future External Effects.** As with the other regions, dredging, longline and pot fisheries, offal discharge, port expansion and use, marine pollution, and natural events all have the potential to cause changes to GOA benthic communities. As discussed above, these changes could have either beneficial or adverse effects on the benthic community.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in benthic community structure of the GOA. The additional external impacts described above will add to the lingering past impacts and contribute to impacts that are already evident. Thus, even though the direct/indirect effect of PA.1 is rated as insignificant, bycatch and damage to living habitat will continue in the GOA and will add to the adverse consequences of fishing.

Geographic Diversity of Impacts and Protection

- **Direct/Indirect Effects.** As described above in Section 4.9.6, this effect is judged to be insignificant; however, the baseline is considered to be already impacted.

- **Persistent Past Effects.** Persistent past effects are expected since fishing effort and distribution have changed over time as areas have been closed and remain closed. As discussed for the other groups, during the late 1970s and early 1980s, there was little domestic fishing for groundfish species. Most domestic fishing effort focused on crab, salmon, and herring, and there were more restrictions placed on foreign fixed gear fisheries than trawl fisheries. Figures 3.6-6 and 3.6-7 and Table 4.5-51 show that in 1980 about 5 percent of the fishable area in the GOA was closed to trawling, and about 7 percent was closed to all fishing. The largest closures in the GOA concerned longline fishing where almost 61 percent of the fishable area was closed to longlining. Therefore, in 1980 about 73 percent of the fishable area in the GOA was closed to fishing of one type or another at one time throughout the year.

- **Reasonably Foreseeable Future External Effects** include other fisheries, port expansion, and the potential resultant changes to offal discharge and marine pollution episodes. Depending on changes in distribution of fishing effort, sensitive areas could either be additionally impacted or allowed to recover. As ports in the GOA are expanded and new ports are created, additional dock space for harboring the fishing fleet is made available, and changes in the distribution of fishing effort would result. Depending on the distribution of fishing effort, previously unimpacted areas could be impacted by offal discharge and marine pollution. Natural events are not expected to be contributing factors in this case.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in distribution of fishing effort. The maps and statistics discussed above show that PA.1 would protect much more benthic habitat from trawl gear in the future (46 percent) than was protected in 1980 (16 percent). However, the spatial distribution of the closed areas under the PA.1 may not protect the full range of habitat types. Also, in 1980 more benthic habitat was protected from fixed gear (over 60 percent of the fishable area) than would be protected under PA.1 (less than one percent of the fishable area in the GOA). While fixed gear impacts are believed to cause less of an impact on benthic communities, research has shown that considerable bycatch of coral and other large benthic structures occur with this gear type. The additional external impacts described above will add to the lingering impacts and contribute to impacts that are already evident.

Direct/Indirect Effects PA.2 – Habitat

This FMP contains a composite of several different concepts for habitat protection and mitigation. Figure 4.2-9 illustrates the suite of year-round closures in the BSAI and GOA management areas. These areas are essentially the same as those proposed for and analyzed under FMP 3.2 and can be considered a proxy for what might actually be implemented by NPFMC under this PA. The conceptual strategies for the proxy include:

- Review all existing closures to see if the areas qualify for MPAs. An MPA could include no-take marine reserves, establishing specific gear restrictions, or restrictions on specific fisheries. An example under PA.2 would be bottom trawl closures located in specific areas on the GOA upper slope that possess sensitive hard bottom habitats impacted by the rockfish fishery.

- Consider adopting 0 to 20 percent of the BSAI and GOA as MPAs and no-take marine reserves (e.g., 5 percent no take and 15 percent MPA across a range of habitat types). A proxy for this strategy would be to incorporate a band-approach where closures would be oriented perpendicular to depth contours from nearshore to deep water assuring protection of a diversity of habitat types across a range geographic areas.

- Develop a special conservation area in the Aleutian Islands to protect sensitive cold water coral communities.

- Implement rotational closures in the Bering Sea to mitigate for impacts.

In the following analysis, we examine qualitatively the relative merits of these conceptual approaches.

- **Slope Rockfish Closures.** The basis for these conceptual closures is to illustrate how the effects of fishing on EFH can be mitigated by reducing the impacts caused by a particular fishery. This concept is currently being developed for the GOA slope rockfish fishery by the NPFMC EFH committee. The GOA closure scheme selected by the EFH committee was based on a very preliminary run of the habitat impacts model. Further research may identify other fisheries and areas that would be better candidates for habitat mitigation. Note that the exact location used in the analysis presented here does not correspond to those areas being studied by the NPFMC and NOAA Fisheries in the EFH SEIS. They only serve to illustrate the concept. Independent of the habitat impacts model, it is worth noting that GOA rockfish fisheries are responsible for a considerable portion of the bycatch of living substrates, especially coral and sponges.

It must be emphasized that the NPFMC and NOAA Fisheries need to carefully consider the location of closures so that unintended consequences do not occur. Displacement of effort to new areas with more sensitive habitat may be an unintended consequence. If closures are placed primarily in areas with high fish densities and displacement of effort occurs in areas of low densities, then increased effort and potentially more habitat impacts may occur overall. For this ,reason the NRC (2002) suggests that for closures to be most effective they should be combined with some effort controls. The example PA.2 does illustrate a scenario of reduced TACs, and the use of fishery cooperatives combined with no-take reserves and MPAs. However, it is important to point out that closures alone, if they are strategically placed within historically fished areas, can provide benefits to habitat overall without necessarily requiring a reduction in TACs. The benefits to habitat can be enhanced by having areas selected for closure to be located within historically fished areas. This patchiness promotes habitat diversity (Duplisea *et al.* 2002).

- **Rotational Closures.** These closures have been suggested as a concept of protecting seafloor habitat while not permanently closing an area to fishing and illustrate how the year-round closures shown in Figure 4.2-9 could be managed. Conceptually, rotational closures are not that much different from the concept of rotating crops. The theory is that by allowing some areas (fields) to go to seed and recover to a more natural state, benefits accrue to both habitat and food production objectives. However, rotational closures are not appropriate for highly structured seafloor habitats with long-lived species. Rotational closures need to be tied to recovery times of living habitats and may only be a viable alternative in sandy energetic habitats inhabited by short-lived animals. Specific knowledge of recovery times is required because if the rotation schedule is less than the recovery time then all areas may be maintained in a disturbed state with little benefits to habitat or yield. For example, during a temporary trawl closure in the North Sea, fishing effort was displaced outside the closed area and then returned when the area was re-opened several years later (Rijnsdorp *et al.* 2001). The net result was a more homogeneous distribution of fishing effort and habitat disturbance than in years prior to the closure. From a habitat perspective it is preferable to keep fishing effort patchy (Duplisea *et al.* 2002) because repeated tows of the same area cause a diminishing mortality of benthic species and some areas remain unfished. Thus, permanently closed areas are preferred over temporary or rotating closures (Collie *et al.* in review).

- **Aleutian Island Special Management Area.** The Aleutian Islands most likely harbor the highest diversity and abundance of cold water corals and sponges in the world (Heifetz 2002). A recent expedition to the Aleutian Islands used the manned submersible DSV Delta and scuba to explore coral and sponge habitat in the Aleutian Islands near the Andreanof Islands and on Petrel Bank (NPFMC 2002b). Dive observations confirmed that coral and sponges are widely distributed in that region; corals and sponges were found at 30 of 31 submersible dive sites. Disturbance to epifauna, likely anthropogenically induced, was observed at most dive sites and may have been more evident in heavily fished areas. Percent coverage of corals ranged from approximately 5 percent on low-relief pebble substrate to 100 percent coverage on high-relief bedrock outcrops. Unique coral habitat consisting of high density gardens of corals, sponges, and other sessile invertebrates was found at five sites between 150 and 350 m deep. These gardens were similar in structural complexity to tropical coral reefs and shared several important characteristics with tropical reefs including complex vertical relief and high taxonomic diversity. The uniqueness and fragility of this habitat points to the need for the design of special management regime that protects this habitat yet allows fishing. Strategically placed closures in areas of sensitive habitat would protect such habitat as long as the displaced fishing effort does not occur to new areas with equally or more sensitive habitat. Unfortunately, there exists little information on the locations of these fragile habitats throughout the Aleutian Islands. Locating and mapping these areas is a priority for research. In the interim, one precautionary measure would be to restrict fishing to those areas that are known to have little or no sensitive habitat.

- **Band Approach.** Incorporation of a band-approach where closures are oriented perpendicular to depth contours from nearshore to deep water would assure protection of diversity of habitat types across a range of geographic areas. This concept has appeal in situations where little is known about benthic habitat types and location. Ideally these closures would be placed to ensure a diversity of habitat types are protected. However, lacking good scientific information on distribution of habitat types, alternatives would randomly or systematically place the closures equidistant apart. In theory, this strategy should promote habitat diversity and protect a wide range habitat types from the effects of fishing. Mitigation and diversity of impacts can occur if closures incorporate fished and unfished areas. One adverse aspect of such random placement is that such closures could have serious social and economic consequences. Determining where to apply this broad approach, should include consultation with the fishing industry and nearby communities.

As shown on Table 4.9-3, direct and indirect effects of the FMP on habitat are discussed for changes to living habitat through direct mortality of benthic organisms and changes to benthic community structure through benthic community diversity and geographic diversity of impacts and protection. Due to their habitat type differences the BSAI and GOA are rated and discussed separately.

Changes to Living Habitat – Direct Mortality of Benthic Organisms

In the GOA, the multi-species model results indicate that the bycatch of coral is projected to decline under PA.2. This is realistic because PA.2 has reduced TAC levels for some target species, especially rockfish. These reduced TACs should result in less fishing effort.

If the magnitude of such declines are actually realized, then this could have beneficial impacts on living substrates possibly resulting in increased abundance of some species of living substrates over baseline levels. Such abundance increases for short-lived biota with fast recovery rates may occur relatively quickly. For other species of living substrates such as long-lived corals and perhaps some sponges that have been permanently eradicated from some areas, increases over baseline levels may not occur or occur very slowly. Conceptual deductions from the habitat impacts model yield the following inferences:

- **Bering Sea.** Based on the location of the PA.2 closures relative to the distribution of fishing intensity shown in Figure 4.7-1, the change relative to the baseline in total impact to biostructure would likely be slight and insignificant. The baseline condition is considered to already be adversely impacted. However, there are some reductions in TAC which may result in some reduction in impacts. Most of the closure areas are located in sand habitat with moderate amounts of closure in sand/mud habitat and almost no closures in mud habitat. The closed areas are located in areas that have been lightly fished compared to large areas of heavy fishing that are left open. Whether mean impact increases or decreases depends on relative density of target species and habitat in the open and closed areas, and the respective impact/recovery parameters (q, q_h, and ρ) in the open and closed areas. There is little information to indicate that habitat density and the parameters would differ between the open and closed areas. One would expect target species density to be lower in areas of low fishing intensity and higher in the areas of high fishing intensity. If closed areas are of lower historical fishing density, benefits to habitat are likely minimal. If target species density is higher in the closed areas, benefits to habitat from the closure would increase.

- **Aleutian Islands.** A decrease in mean equilibrium impact would probably occur in the Aleutian Islands due to the specific closures depicted by the PA.2 bookend. Closures where fishing occurs seem to bisect the cluster of historical fishing patterns leaving the adjacent area open (Figure 4.7-1). Some reductions in TAC may result in less habitat impacts. Based on these results, we conclude that there would be a significantly beneficial change to mortality and damage to living habitat as a result of PA.2. However, as described above, the baseline condition is considered to already be adversely impacted.

- **GOA.** The mean impact will increase in the GOA, as many of the closed areas are centered on high effort areas which would be expected to have higher target fishery species densities (Figure 4.7-2). This results in a much higher effort to catch fish in lower density open areas. This much higher effort will result in enough of an increase in habitat impacts to negate impact reduction in the closed areas. It is not clear whether decreased TACs for some species will offset this increase in habitat impacts. Based on these results, we conclude that, under certain conditions, there could be significantly adverse changes to mortality and damage to living habitat as a result of PA.2. Therefore, the internal effect is rated as conditionally significant adverse, and the baseline condition is considered to already be adversely impacted.

Changes to Benthic Community Structure – Benthic Community Diversity and Geographic Diversity of Impacts and Protection

- **Bering Sea.** Closures are fairly well distributed among geographical-habitat types. Some improvement in geographic diversity would be achieved. While large expanses of high fishing intensity still remain open in this FMP, there is at least one closure area that covers a portion of high fishing intensity as shown in Figure 4.7-1. This provides some improvement in the geographic diversity of impacts. An overall improvement to geographic diversity of impacts could be realized with smaller closure areas, some of which covering a small fraction of the heavily fished areas. Some of the closures for this FMP are located where light levels of fishing occur and may provide some low-level of contrast and diversity. Table 4.5-49 shows that of the Bering Sea fishable area, nearly 33 percent is closed to bottom contact at one time or another during the year under PA.2. Figure 4.7-3 shows areas closed to trawling only at various times of the year under this FMP, while Figure 4.7-4 depicts those areas closed to fixed gear only. Based on these results, the predicted effects of PA.2 on benthic community diversity are conditionally significant beneficial. The predicted effects of PA.2 bookend on geographic diversity of impacts are significantly beneficial. However, the baseline is considered to already be adversely impacted.

- **Aleutian Islands.** Closures illustrated in PA.2 bookend are well distributed among geographical-habitat types. Improvement in geographic diversity of impacts would occur under this FMP scenario. As shown on Table 4.5-49, about 80 percent of the fishable area in the Aleutian

Islands is closed to bottom contact at one time or another during the year under this FMP, and these closures are well distributed over a range of geographical-habitat zones. Figures 4.7-3 and 4.7-4 show the closure areas under PA.2 broken down by gear type; bottom trawl and fixed gear, respectively. While the closure areas are especially large compared to the resolution of the bathymetry and fishing distribution and encompass different habitat types at a time, it may well be that a similar mix of habitat types occur adjacent to the closure areas. Also, Figure 4.7-1 shows that some closure areas happen to bisect apparent historic clusters of fishing patterns, thus providing a contrast in impact for the habitat being fished. Based on these results, the effects of PA.2 on benthic community diversity are significantly beneficial. The predicted effects of PA.2 bookends on the geographic diversity of impacts are significantly beneficial. However, the baseline is considered to already be adversely impacted.

- **GOA.** Closures illustrated by the PA.2 bookend are well distributed among geographical-habitat types. However, slight, if any, improvement in geographic diversity of impact would result. As shown on Table 4.5-49 and Figures 4.7-3 and 4.7-4, PA.2 closes over 72 percent of the fishable area in the GOA to bottom contact at one time or another during the year. The closure areas are large in relation to the GOA spatial habitat or bathymetric resolution, and thus tend to encompass much of a bathymetric feature. Figure 4.7-2 shows that closures often encompass clusters of historically high fishing intensity, leaving little diversity or contrast of fishing intensity within a bathymetric feature or habitat type. An overall improvement to geographic diversity of impacts could have been realized with smaller closure areas strategically placed to not encompass entire habitat types or clusters of fishing intensity. For example, the closure areas on the upper slope should include some portion of areas where high fishing intensity has occurred, but need not be as large in size as illustrated in this PA.2 scenario. Based on these results, the predicted effects of PA.2 bookend on benthic community diversity and geographic diversity of impacts are found to be insignificant relative to the baseline. However, the baseline is considered to already be adversely impacted.

Cumulative Effects PA.2 – Habitat

Cumulative effects of habitat for PA.2 are summarized on Table 4.9-3.

The following discussion of the results presented on the table is broken down by geographic area.

Bering Sea

<u>Changes to Living Habitat – Direct Mortality of Benthic Organisms</u>

- **Direct/Indirect Effects.** As described above, this effect is judged to be insignificant, but the baseline is considered to be already adversely impacted.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the Bering Sea. These effects include persistent mortality of long-lived species such as tree corals and other sessile epifauna (see the cumulative effects discussion for PA.1 in this section).

- **Reasonably Foreseeable Future External Effects.** Offal discharge, port expansion and use, marine pollution, and natural events all have the potential to cause direct mortality of benthic organisms and changes to living habitat (see the Bering Sea PA.1 cumulative effects discussion in this section).

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for mortality of Bering Sea benthic organisms. There is little information to indicate that habitat density and the parameters would differ between the open and closed areas. The baseline condition is considered to be adversely impacted. Although some benefits accrue within the proposed MPAs, impacts from fishing are not totally eliminated, and TAC effort is likely to remain high. While there is an incremental expansion of no-take MPAs, the closures analyzed under this FMP are not refined and may not be effective. We do not know for certain where future closures may be, or whether they would be no-take reserves or a form of gear-specific/species-specific MPA. Due to this uncertainty, along with the already impacted baseline, and with the addition of the external impacts on mortality described above, the cumulative effect of the FMP on mortality could be conditionally significant adverse.

  However, if the closures proposed under PA.2 were to be further defined based on additional information regarding important habitats in need of protection, and were properly designed and located to protect the sensitive habitats, future closures could provide successful mitigation of the effects of fishing. Overtime, valued habitat that has been adversely affected by fishing could recover. Therefore, under that condition, cumulative effects may have more of a conditionally significant beneficial rating rather than conditionally significant adverse.

<u>Changes to Benthic Community Structure</u>

- **Direct/Indirect Effects.** As described above, this effect is judged to be conditionally significant beneficial, but the baseline is considered to be already adversely impacted.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the Bering Sea (see the Bering Sea PA.1 cumulative effects discussion in this section).

- **Reasonably Foreseeable Future External Effects.** Offal discharge, port expansion and use, marine pollution, and natural events all have the potential to cause changes to benthic communities as described for PA.1. These changes could have either beneficial or adverse effects on the benthic community.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in benthic community structure of the Bering Sea. This FMP provides some improvement in the geographic diversity of impacts. However, some of the closures for this FMP are located where light levels of fishing occur and may provide some low level of contrast and diversity. As described above for mortality, while benefits accrue due to the MPAs, the closure areas are not refined and may not be effective in protecting benthic community structure (see the discussion provided above for mortality). For these reasons, along with the already impacted state of the communities and the external adverse impacts, the FMP is rated as conditionally significant adverse in the cumulative case.

  However, as described above for mortality, if the closures proposed under PA.2 were to be further defined and designed to protect important habitats, mitigation of fishing-related impacts could occur. Cumulative effects may have more of a conditionally significant beneficial rating rather than conditionally significant adverse.

Geographic Diversity of Impacts and Protection

- **Direct/Indirect Effects.** As described above, this effect is judged to be significantly beneficial, but the baseline is considered to be already adversely impacted.

- **Persistent Past Effects.** Persistent past effects are expected since fishing effort and distribution have changed over time as areas have been closed and remain closed. Figures 3.6-6 and 3.6-7 and Table 4.5-51 show that in 1980 almost 9 percent of the fishable area in the Bering Sea was closed to trawling, with 2.2 percent closed to all fishing. There were no longline-only closures in the Bering Sea at that time. The cumulative effects section for PA.1 provides additional discussion regarding these past effects.

- **Reasonably Foreseeable Future External Effects.** These include port expansion and the potential resultant changes to distribution of fishing effort, offal discharge, and marine pollution episodes (see the discussion for PA.1 in this section). Depending on the distribution of fishing effort, previously un-impacted areas could be impacted by offal discharge and marine pollution. Natural events are not expected to be contributing factors in this case.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in distribution of fishing effort. The maps and statistics discussed above show that PA.2 would protect more benthic habitat from trawl gear in the future (33 percent) than was protected in 1980 (8.6 percent). Closure areas under this scenario cover a portion of high fishing intensity, thereby providing improvement in the geographic diversity of impacts. However, since TAC is likely to remain high and the locations of the proposed MPAs are not refined, the benefits provided by the closed areas are uncertain. Previously unfished areas would likely be fished and impacts would occur in areas not previously impacted. The additional external effects in combination with the past and predicted internal effects are judged to be conditionally significant adverse. However, as described above for mortality and community diversity, better definition and focus of the closures could lead to a conditionally significant beneficial rating.

Aleutian Islands

Changes to Living Habitat – Direct Mortality of Benthic Organisms

- **Direct/Indirect Effects.** As described above, this effect is judged to be significantly beneficial, but the baseline is considered to be already adversely impacted.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the Aleutian Islands. Prevalence of long-lived species of coral makes impacts a particular concern in the Aleutian Islands. Mortality of long-lived species such as tree corals and other sessile epifauna is likely to be persistent in these areas (see the PA.1 cumulative effects discussion in this section).

- **Reasonably Foreseeable Future External Effects.** As described for PA.1 cumulative effects in the Aleutian Islands, dredging, longline fisheries, pot fisheries, offal discharge, port expansion and use, and marine pollution all have the potential to cause direct mortality of benthic organisms and changes to living habitat.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for mortality of Aleutian Islands benthic organisms. As described above for the Bering Sea, the baseline condition is considered to be already adversely effected. The proposed no-take MPAs will allow some benefits to accrue, but impacts will still occur, especially since TAC remains high. Therefore, the overall effect would be significantly adverse under certain conditions. However, as described for the Bering Sea, further definition and refinement of the closure areas may allow for a conditionally significant beneficial cumulative effects rating.

Changes to Benthic Community Structure

- **Direct/Indirect Effects.** As described above, this effect is judged to be significantly beneficial; however the baseline is considered to be already adversely impacted.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the Aleutian Islands. Changes to benthic community structure including a reduction in species diversity have been observed in heavily fished areas of the world (see the Aleutian Islands PA.1 cumulative effects discussion in this section).

- **Reasonably Foreseeable Future External Effects.** As described for PA.1, dredging, longline and pot fisheries, offal discharge, port expansion and use, marine pollution, and natural events all have the potential to cause changes to benthic communities. These changes could have either beneficial or adverse effects on the benthic community.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in benthic community structure of the Aleutian Islands. As described above for mortality of benthic organisms, the existing impacted baseline, combined with the uncertain benefits of the proposed MPAs, leads to a conclusion of significantly adverse under certain conditions in the cumulative case. However, as described for the Bering Sea, further definition and refinement of the closure areas may allow for a conditionally significant beneficial cumulative effects rating.

Geographic Diversity of Impacts and Protection

- **Direct/Indirect Effects.** As described above, this effect is judged to be significantly beneficial, but the baseline is considered to be already adversely impacted.

- **Persistent Past Effects.** Persistent past effects are expected since fishing effort and distribution have changed over time as areas have been closed and remain closed. Figures 3.6-6 and 3.6-7 and Table 4.5-51 show that in 1980 about 31 percent of the fishable area in the Aleutian Islands was closed to trawling with about 6 percent closed to all fishing. There were no longline-only closures in the Aleutian Islands at that time (see the PA.1 Aleutian Islands cumulative effects discussion in this section).

- **Reasonably Foreseeable Future External Effects.** These include other fisheries, port expansion, the potential resultant changes to distribution of fishing effort, offal discharge, and marine pollution episodes. Depending on the distribution of fishing effort, previously un-impacted areas could be impacted by offal discharge and marine pollution. Natural events are not expected to be contributing factors in this case (see the Aleutian Islands PA.1 cumulative effects discussion in this section).

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in distribution of fishing effort. The maps and statistics discussed above show that PA.2 would protect more benthic habitat from trawl gear in the future (80 percent) than was protected in 1980 (31 percent). Closures illustrated in PA.2 bookend are well distributed among geographical-habitat types; thus, improvement in geographic diversity of impacts would occur under this FMP scenario. However, since TAC is likely to remain high, and the locations of the proposed MPAs are not refined, the benefits provided by the closed areas are uncertain. Previously unfished areas would likely be fished and impacts would occur in areas not previously impacted. The additional external effects in combination with the past and predicted internal effects are judged to be conditionally significant adverse. However, as described for the Bering Sea, further definition and refinement of the closure areas may allow for a conditionally significant beneficial cumulative effects rating.

GOA

<u>Changes to Living Habitat – Direct Mortality of Benthic Organisms</u>

- **Direct/Indirect Effects.** As described above, this effect is judged to be conditionally significant adverse, since there would be much higher effort to catch fish in lower density open areas. It is not clear whether decreased TACs for some species will offset an increase in habitat impacts. Under certain conditions, there could be significantly adverse impacts on mortality of benthic organisms.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the GOA. Mortality of long-lived species such as tree corals and other sessile epifauna is likely to be persistent in these areas (see the GOA PA.1 cumulative effects discussion in this section).

- **Reasonably Foreseeable Future External Effects.** As described for PA.1, dredging, longline fisheries, pot fisheries, offal discharge, port expansion and use, marine pollution, and natural events all have the potential to cause direct mortality of benthic organisms and changes to living habitat.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for mortality of GOA benthic organisms. The external effects identified above have the potential to provide additional mortality to benthic organisms. Therefore, under certain conditions, the cumulative effects on mortality could be significantly adverse.

<u>Changes to Benthic Community Structure</u>

- **Direct/Indirect Effects.** As described above, this effect is judged to be insignificant; however, the baseline is considered to be already adversely impacted.

- **Persistent Past Effects.** Persistent past effects are expected in heavily fished areas of the GOA. Changes to benthic community structure including a reduction in species diversity have been observed in heavily fished areas of the world (see the GOA PA.1 cumulative effects discussion in this section).

- **Reasonably Foreseeable Future External Effects.** As described for PA.1 in the GOA, dredging, longline and pot fisheries, offal discharge, port expansion and use, marine pollution, and natural events all have the potential to cause changes to benthic communities. These changes could have either beneficial or adverse effects on the benthic community.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in benthic community structure of the GOA. As described above for the BSAI, while the FMP provides for additional closure area and no-take MPAs, impacts are not totally eliminated, and the proposed MPAs might not be effective. Therefore, the combination of internal and external impacts on benthic communities is judged to be conditionally significant adverse in the cumulative case. However, as described for the Bering Sea, further definition and refinement of the closure areas may allow for a conditionally significant beneficial cumulative effects rating.

Geographic Diversity of Impacts and Protection

- **Direct/Indirect Effects.** As described above, this effect is judged to be insignificant, but the baseline is considered to be adversely impacted.

- **Persistent Past Effects.** Persistent past effects are expected, since fishing effort and distribution have changed over time as areas have been closed and remain closed. Figures 3.6-6 and 3.6-7 and Table 4.5-51 show that in 1980 about 5 percent of the fishable area in the GOA was closed to trawling, with about seven percent closed to all fishing. The largest closures in the GOA concerned longline fishing where almost 61 percent of the fishable area was closed to longlining. Therefore, in 1980 about 73 percent of the fishable area in the GOA was closed to fishing of one type or another at one time throughout the year (see the GOA PA.1 cumulative effects discussion in this section).

- **Reasonably Foreseeable Future External Effects.** These include other fisheries, port expansion, the potential resultant changes to distribution of fishing effort, offal discharge, and marine pollution events (see the GOA PA.1 cumulative effects discussion in this section). Depending on the distribution of fishing effort, previously un-impacted areas could be impacted by offal discharge and marine pollution. Natural events are not expected to be contributing factors in this case.

- **Cumulative Effects.** Conditionally significant adverse cumulative effects are identified for changes in distribution of fishing effort. The maps and statistics discussed above show that PA.2 would protect much more benthic habitat from trawl gear in the future (72 percent) than was protected in 1980 (16 percent). Closures illustrated by the PA.2 bookend are well distributed among geographical-habitat types. However, slight, if any, improvement in geographic diversity of impact would result. As described above for the BSAI, the proposed MPAs might not be effective. Further refinement of the proposed MPAs may lead to a conditionally significant beneficial rating.

4.9.7 Seabirds Preferred Alternative Analysis

The seabird-specific policy goal of the Preferred Alternative (PA) is the same as all the other Alternatives, to "Avoid Impacts to Seabirds and Marine Mammals". The PA contains one policy objective that is specific to protecting seabirds, "Continue to cooperate with USFWS to protect ESA-listed species and, if appropriate and practicable, other seabird species". The NPFMC could adopt a range of specific management measures in order to implement the policy objectives. The illustrative FMP bookends provide examples of specific management measures the NPFMC would take to implement the Preferred Alternative policy objectives. PA.1 includes the following measures: 1) Take of more than 4 short-tailed albatross within 2 years triggers consultation in groundfish longline fisheries, 2) Maintain current seabird avoidance measures for the longline fleet that were approved at the December 2001 NPFMC meeting, 3) Cooperate with USFWS to develop scientifically-based fishing methods that reduce incidental take of ESA-listed seabird species in the trawl sector. PA.2 retains the first objective for short-tailed albatross take and substitutes the following for the other two objectives: 2) For the longline sector, cooperate with USFWS to develop scientifically-based fishing methods that reduce incidental take for all seabird species, 3) For the trawl sector, cooperate with USFWS to evaluate and implement scientifically-based fishing methods that reduce incidental take of ESA-listed, and if appropriate and practicable, other seabird species. The PA also includes several goals and objectives that would have indirect effects on seabirds, such as the ban on directed forage fish fisheries, modification and potential expansion of the Observer Program based on scientific data needs, the development of ecosystem indicators for use in the TAC-setting process, and the potential establishment of Marine Protected Areas.

Two important agency actions that are pertinent to BSAI/GOA seabirds and the following analysis have occurred since the Draft PSEIS was published in 2003. First, the USFWS issued two Biological Opinions (BiOps) in September 2003 as part of their ESA Section 7 consultations on the federal groundfish fisheries (see NOAA Fisheries website: http://www.fakr.noaa.gov/protectedresources/seabirds.html.). One BiOp takes a programmatic look at the impacts of the BSAI/GOA groundfish FMPs and associated fisheries on the endangered short-tailed albatross and the threatened Steller's eider (USFWS 2003a) while the other BiOp concerns the TAC-setting process for these fisheries (USFWS 2003b). These documents conclude that the fisheries would not likely jeopardize the continued existence or recovery of either the short-tailed albatross or Steller's eider and would not adversely modify Steller's eider critical habitat (no critical habitat has been designated for short-tailed albatross in U.S. waters). The TAC-setting BiOp included updated Incidental Take Statements for these species. For short-tailed albatross, incidental take on longline gear is anticipated to be the same as previous years, with up to 4 birds taken every two years. In addition, for the first time the USFWS included an anticipated take for short-tailed albatross through collisions with trawl gear. Unlike the situation with the longline fleet where there is over ten years of Observer Program data on take of albatross, the USFWS and NOAA Fisheries have only recently begun investigating how frequently albatross may be colliding with trawl gear. Because of this uncertainty, the Incidental Take Statement anticipates up to 2 birds could be taken by the trawl fleet but the time period was left open until the BiOp is superceded by a new one. This open-ended period allows USFWS and NOAA Fisheries to continue gathering data on the potential risk of trawl gear before a new Section 7 consultation is initiated.

The TAC-setting BiOp also included mandatory terms and conditions that NOAA Fisheries must follow in order to be in compliance with the ESA. One is the implementation of seabird deterrent measures for the longline fisheries as proposed by NOAA Fisheries in February 2003 (see below). Other provisions include continued outreach and training of fishing crews as to proper deterrence techniques, continued training of observers in seabird identification, retention of all seabird carcasses until observers can identify and record takes, continued analysis and publication of estimated incidental take in the fisheries, collection of information regarding the efficacy of seabird protection measures, cooperation in reporting sightings of short-tailed albatross, and continued research and reporting on the incidental take of short-tailed albatross in trawl gear.

The second pertinent agency action was the publication of new seabird protection regulations for longline vessels that were based on the joint recommendations of NOAA Fisheries, USFWS, and the Washington Sea Grant Program, approved by the NPFMC in December 2001, proposed by NOAA Fisheries in February 2003 (68 FR 6386), and were enacted in final regulations on January 13, 2004 (69 FR 1930) . These regulations are in effect as of February 2004 and vary by length of vessel, area fished, type of gear, and other factors. They are available at NOAA Fisheries website: http://www.fakr.noaa.gov/protectedresources/seabirds.html.

4.9.7.1 Short-Tailed Albatross

Direct/Indirect Effects of PA.1 and PA.2

Incidental Take

Incidental take of the endangered short-tailed albatross in the groundfish fishery is a very rare event, with the last recorded takes occurring in 1998 (see Section 3.7.4 for a history of takes and agency actions taken to protect this species under the ESA). The seabird protection measures that were in effect for the longline fleet prior to the 2004 fishing season had been in place since 1997 and constitute the baseline condition for this analysis. These measures had been strongly influenced by the goal of protecting short-tailed albatross but had not eliminated incidental take, as evidenced by two takes of short-tailed albatross in one month in 1998. A great deal of research and development has been conducted since 1997 to improve the efficacy of seabird protection techniques in the longline fleet. PA.1 would maintain the new seabird protection measures for longline vessels that were enacted in January 2004 (69 FR 1930) . These new regulations are based on the demonstrated effectiveness of using particular deterrent devices to reduce the incidental take of other albatross species (Melvin *et al.* 2001) and are expected to substantially reduce the chances of taking short-tailed albatross on longlines.

Under PA.1, NOAA Fisheries and USFWS would continue current research to develop ways to reduce the risk of short-tailed albatross colliding with trawl gear. Under PA.2, NOAA Fisheries would continue to cooperate with USFWS and other groups to scientifically develop and implement mitigation measures that further reduce the risk of taking short-tailed albatross in both the longline and trawl sectors.

Given the extreme rarity of short-tailed albatross, numbering less than 2,000 birds worldwide, any level of mortality is a conservation concern. For this reason, management actions that substantially reduce the chance of anthropogenic mortality occurring, even if the chance is not totally eliminated, have been pursued under the ESA and are included under the Preferred Alternative. From the perspective of research, management, and fishing industry efforts to reduce the chance of taking short-tailed albatross, the new protection measures have been very substantial. However, the short-tailed albatross population has been increasing at a near-maximum rate under the baseline conditions so a reduced chance of mortality in the fishery, when the measurable frequency of that mortality already approaches zero, may not result in measurable benefits for the population. The risk of incidental take under both PA.1 and PA.2 would be reduced from baseline conditions and would be considered to have insignificant effects on the population of short-tailed albatross.

Availability of Food

Short-tailed albatross forage over vast areas of ocean on species that are taken in minimal amounts by the groundfish fishery and are unlikely to be affected by any potential localized disturbance or depletion of prey from the fishery as managed under either PA bookend. Both PA.1 and PA.2 are considered to have insignificant effects on short-tailed albatross through availability of food.

Benthic Habitat

Short-tailed albatross are not benthic feeders and are not expected to be affected by any changes in benthic habitat that might occur as a result of fishery management under either PA bookend. Both PA.1 and PA.2 are considered to have no effects on short-tailed albatross through benthic habitat.

Cumulative Effects of PA.1 and PA.2

The past/present effects on short-tailed albatross are described in Section 3.7.4 (Table 3.7-11) and the predicted direct and indirect effects of the groundfish fishery under the PA.1 and PA.2 are described above (Table 4.9-4). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in a cumulative way. The cumulative effects for this species would be dominated by factors external to the groundfish fisheries and would be the same as those described in Section 4.5.7.1 (Table 4.5-52) and summarized below.

Mortality

- **Direct/Indirect Effects.** Under both PA.1 and PA.2, new seabird protection measures on the longline fleet (Section 3.7.1) and possibly the trawl fleet should substantially reduce the chances of taking short-tailed albatross incidentally in the groundfish fishery. Incidental take of short-tailed albatross is predicted to be a very rare event in the groundfish fishery and is considered insignificant at the population level.

- **Persistent Past Effects.** The most important persistent influence on the short-tailed albatross population is their near extinction due to commercial feather hunting. Conservation efforts have allowed the population to recover at or near to its biologically maximum rate. The total fishery-related mortality of short-tailed albatross is unknown, but it does not appear to be having an overriding effect on the population growth rate.

- **Reasonably Foreseeable Future External Effects.** The short-tailed albatross population may be substantially affected by several natural and human-caused mortality factors that may or may not occur in the future. These include volcanic eruptions on their main breeding site, Torishima Island, and increased rates of incidental take in fisheries throughout their range. If the species experiences a substantial increase in mortality that threatens its recovery, such increases may lead to further efforts to protect the species from fishery interactions.

- **Cumulative Effects.** Since the population of short-tailed albatross is susceptible to several natural and human-caused mortality factors that may or may not occur in the future, including incidental take in the groundfish fisheries under the PA, the cumulative effect on short-tailed albatross is considered to be conditionally significant adverse at the population level through mortality.

Changes in Food Availability

- **Direct/Indirect Effects**. The groundfish fisheries would continue to take a very small amount of squid and forage fish as bycatch under both PA.1 and PA.2. This effect is considered insignificant at the population level for short-tailed albatross.

- **Persistent Past Effects.** Short-tailed albatross primarily prey on squid and small schooling fishes that have been targeted by fisheries in various parts of their range. While these fisheries may have caused some localized depletions of prey, their effect on overall prey abundance is considered to be minimal compared to natural fluctuations in primary productivity and oceanographic factors. Pollution from a variety of land and marine sources has potentially affected short-tailed albatross prey in the past, but specific toxicological effects on forage fish populations are unknown.

- **Reasonably Foreseeable Future External Effects.** There are no foreseeable fisheries that will likely have more than a negligible effect on short-tailed albatross prey availability. Pollution is likely to affect short-tailed albatross prey in the future, but specific predictions on the nature and scope of the effects, especially as they relate to the availability of prey to short-tailed albatross, can not be made at this time.

- **Cumulative Effects**. Since the population decline of short-tailed albatross was caused by hunting rather than changes in habitat, and the habitat once supported millions of these birds, the population recovery of the species is not considered to be limited by food availability. The cumulative effect of all fisheries on the abundance and distribution of short-tailed albatross prey is considered to be insignificant at the population level.

Benthic Habitat

Since short-tailed albatross feed at the surface and their prey live in the upper and middle levels of the water column, potential changes in benthic habitat from groundfish trawls or any other fishing gear would have no discernable effect on their prey. Therefore, no cumulative effect on benthic habitat is identified for short-tailed albatross.

4.9.7.2 Laysan Albatross and Black-Footed Albatross

Direct/Indirect Effects of PA.1 and PA.2

Incidental Take

The incidental take of Laysan and black-footed albatross are reported in the Observer Program data from 1993-2001 and include the unidentified albatross and an unknown number of the unidentified tubenoses (Tables 3.7-1 through 3.7-5). The number of albatross taken under the baseline condition of seabird protection measures can be estimated from the 1997-2001data since these measures were implemented in 1997. The estimated number of Laysan albatross taken in this period averaged 650 birds per year in the BSAI longline sector (including a share of the unidentified albatross category), 126 birds per year on GOA longlines, and 90 birds per year (mean of low and high estimates) in the BSAI and GOA trawls, for a total estimated average take of 866 birds per year in the groundfish fishery. The latest population estimate for the species is 2.4 million birds (Cousins *et al.* 2000). Mortality from the groundfish fishery under the baseline conditions is thus estimated at 0.04 percent of the population and is therefore considered insignificant. For black-footed albatross, estimated mortality in the groundfish fisheries averaged 12 birds per year in the BSAI longline sector (including a share of the unidentified albatross category) and 158 birds per year on GOA longlines (with no observed takes in the BSAI and GOA trawls), for a total estimated average take of 170 birds per year in the groundfish fishery. The latest population estimate for the species is 300,000 birds (Cousins and Cooper 2000). Mortality from the groundfish fishery under the baseline conditions is thus estimated at 0.06 percent of the population and is therefore considered insignificant.

The new seabird protection measures for longline vessels under PA.1 and PA.2 would be expected to result in a substantial reduction of incidental take of Laysan and black-footed albatross relative to the baseline condition (Melvin *et al.* 2001). In addition, as was the case with the longline hazzard research, research on the risk of incidental take of short-tailed albatross in trawl gear would likely be based on measured impacts of the much more common Laysan albatross. PA.1 would incorporate any mitigation measures for the trawl fleet that arise from this research if it appears to reduce the chances of incidentally taking short-tailed albatross. Potential future mitigation of take from trawl third wire collisions would therefore reduce incidental take of Laysan albatross and probably black-footed albatross as well. Under PA.2, scientific research would be used to develop practical and effective measures to further reduce incidental take of ESA-listed and other species on longline and trawl gear. Although reductions in take of Laysan and black-footed albatross would be used to evaluate the most effective techniques to protect short-tailed albatross, research on reducing take of other species could potentially yield additional benefits for the albatross species.

NOAA Fisheries recently finalized the new seabird deterrent regulations for the longline fleet that will be in effect for the 2004 fishing season (69 FR 1930). Most of the BSAI freezer longline fleet and many smaller vessels in the GOA began using the new seabird deterrent devices on a voluntary basis during the 2002 fishing season. Incidental take data from the 2002 season (NPFMC 2003b) indicates that estimated take of Laysan albatross in the BSAI longline fisheries declined from an average of 643 birds per year (1997-2001) to an estimated 48 birds per year in 2002. In the GOA longline fisheries, Laysan albatross take was reduced from an average of 124 birds per year (1997-2001) to 0 birds in 2002. In this same period, incidental take of black-footed albatross on BSAI longlines declined from an average of 11 birds per year to 0 in 2002. In the GOA, incidental take of black-footed albatross declined from an average of 156 birds per year to 33 birds in 2002. It should be noted that there are a number of factors that influence the number of birds that are caught in any one year besides the type of seabird avoidance measures that are used. These include the spatial and temporal distribution of fishing effort, weather, sea state, and previously observed inter-annual variations in overall food availability that appear to affect the intensity with which seabirds attack baited hooks. It may not be possible to ascertain how much different factors may have contributed to the reduced level of take in 2002 and it remains to be seen whether this reduced level of take will continue in the future. However, it is expected that fleet-wide compliance with the new regulations, which include equipment specifications and deployment standards, should result in a dramatic decline in take of albatross on longline gear.

Since the baseline level of incidental take from all groundfish fisheries is considered insignificant at their respective population levels for both Laysan and black-footed albatross, and incidental take of these species would likely be reduced under both PA.1 and PA.2, the overall effect of the PA.1 and PA.2 on incidental take of both albatross species is considered insignificant.

Availability of Food

Albatross forage over vast areas of ocean on prey that are taken only in negligible amounts by the groundfish fisheries and which do not appear to be affected on an ecosystem level by the groundfish harvest (see Forage Fish and Ecosystem Sections 4.5.4 and 4.5.10). Albatross are therefore unlikely to be affected by any potential localized disturbance or depletion of prey from the fishery as managed under either PA bookend. Both PA.1 and PA.2 are considered to have insignificant effects on these species through availability of food.

Benthic Habitat

Albatross are not benthic feeders and are not expected to be affected by any changes in benthic habitat that might occur as a result of fishery management under either PA bookend. Both PA.1 and PA.2 are considered to have no effects on these species through benthic habitat.

Cumulative Effects of PA.1 and PA.2

The past/present effects on these albatross species are described in Sections 3.7.2 and 3.7.3 (Tables 3.7-6 and 3.7-7) and the predicted direct and indirect effects of the groundfish fishery are described above (Table 4.9-4). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in a cumulative way. The cumulative effects for these species would be dominated by factors external to the groundfish fisheries and would be the same as those described in Section 4.5.7.2 (Table 4.5-53) and summarized below.

Mortality

- **Direct/Indirect Effects.** Under PA.1 and PA.2, the new seabird protection measures for the longline fleet are expected to reduce incidental take of both albatross species. Mitigation measures for the trawl fleet may also be developed that would reduce incidental take of these species under both PA.1 and PA.2. Incidental take is considered insignificant at the population level for both species in this group.

- **Persistent Past Effects.** For black-footed and Laysan albatross, past mortality factors include large contributions from foreign longline fisheries and Hawaiian pelagic longline fisheries, smaller contributions from the BSAI/GOA longline and trawl fisheries, and unknown contributions from other longline fisheries (IPHC), other gear-type fisheries, and vessel collisions throughout their range. Both species have been experiencing population declines over the past decade. The contribution of toxic and plastic pollution on their nesting grounds and in the marine environment to mortality is unknown for both albatross species in this group.

- **Reasonably Foreseeable Future External Effects.** New seabird protection measures have recently been established for the Hawaiian pelagic longline fleets that are expected to reduce take of albatross in those fisheries. It is expected that incidental take of black-footed and Laysan albatross in foreign longline fisheries will remain high and will continue to exceed the threshold for population level effects.

- **Cumulative Effects.** Since the populations of black-footed and Laysan albatross are undergoing measurable declines and several human-caused mortality factors have been identified and are expected to continue in the future, including contributions from the groundfish fisheries under the PA.1 and PA.2, the cumulative effects on black-footed and Laysan albatross are considered to be significantly adverse at the population level through mortality.

Changes in Food Availability

- **Direct/Indirect Effects.** The groundfish fisheries would continue to take a very small amount of squid and forage fish as bycatch under the PA.1 and PA.2. This effect is considered insignificant at the population level for both albatross species. While groundfish vessels contribute to overall marine pollution through accidental spills and vessel accidents, the effects of this pollution on albatross prey populations can not be assessed at this time.

- **Persistent Past Effects.** Albatross primarily prey on squid species and small schooling fish that have been targeted by fisheries in various parts of their range. While these fisheries may have caused some localized depletions of prey, their effect on overall prey abundance is considered to be minimal compared to climate and oceanographic factors. Pollution from a variety of land and marine sources has potentially affected albatross and shearwater prey in the past. However, very little is known about the specific toxicological effects on prey species important to these seabirds or what sources of pollution may be the most important.

- **Reasonably Foreseeable Future External Effects.** There are no foreseeable fisheries that will likely have more than a minimal effect on albatross prey availability. Pollution is likely to affect albatross prey in the future, but specific predictions on the nature and scope of the effects, especially as they relate to the availability of prey to albatross, cannot be made at this time.

- **Cumulative Effects.** The cumulative effect of all fisheries on the abundance and distribution of albatross prey is considered to be insignificant at the population level for both species.

Benthic Habitat

Since albatross feed at the surface or with shallow dives and their prey live in the upper and middle levels of the water column, potential changes in benthic habitat from groundfish trawls or any other fishing gear would have no discernable effect on their prey. Therefore, no cumulative effect is identified for these species.

4.9.7.3 Shearwaters

Direct/Indirect Effects of PA.1 and PA.2

Incidental Take

The incidental take of shearwaters is reported in the Observer Program data from 1993-2001, including an unknown number of the unidentified tubenoses (Tables 3.7-1 through 3.7-5). The number of shearwaters taken under the baseline condition of seabird protection measures can be estimated from the 1997-2001data since these measures were implemented in 1997. The estimated mortality of shearwaters in the groundfish fisheries averaged 578 birds per year in the BSAI longline sector, 18 birds per year on GOA longlines, and 799 birds per year (mean of low and high estimates) in the BSAI and GOA trawls, for a total estimated average take of 1395 birds per year in the groundfish fishery. Population estimates of short-tailed and sooty shearwaters are 23 million and 30 million birds, respectively (Everett and Pitman 1993, Springer *et al.* 1999). Incidental take of these species in the groundfish fisheries under the baseline conditions is much less than 0.01 percent of their populations and is thus considered insignificant.

The new seabird protection measures for longline vessels (in effect as of the 2004 fishing season) are not effective for shearwaters because they are able to dive deeper than albatross and fulmars in pursuit of baited hooks (Melvin *et al.* 2001). Expected incidental take of shearwaters on longlines would therefore be similar to the baseline condition under PA.1. Under PA.2, additional research would be conducted to further reduce incidental take of all species on longline gear. This would likely include continued research into integrated weighted groundlines and other techniques which may prove effective for deterring diving birds such as shearwaters.

In the trawl sector, PA.1 would develop methods to reduce the risk of short-tailed albatross colliding with trawl gear. These efforts may also reduce the incidental take of shearwaters if they interact with trawl vessels in a similar manner. Under PA.2, additional research would be conducted to develop practical ways to reduce incidental take of non-ESA species in trawl gear. Since shearwaters are the second most commonly taken species group in trawl gear (after northern fulmars), they would likely receive substantial attention during development of potential mitigation measures under PA.2.

Since the baseline level of incidental take for these species is considered insignificant at their respective population levels and incidental take of these species could be reduced under both PA.1 and PA.2, the overall effect of the PA.1 and PA.2 on incidental take of both shearwater species is considered insignificant.

<u>Availability of Food</u>

Shearwaters forage over vast areas of ocean on planktonic prey that are taken only in negligible amounts by the groundfish fisheries and which do not appear to be affected on an ecosystem level by the groundfish harvest (see Forage Fish and Ecosystem Sections 4.5.4 and 4.5.10). Shearwaters are therefore unlikely to be affected by any potential localized disturbance or depletion of prey from the fishery as managed under either PA bookend. Both PA.1 and PA.2 are considered to have insignificant effects on these species through availability of food.

<u>Benthic Habitat</u>

Shearwaters are not benthic feeders and are not expected to be affected by any changes in benthic habitat that might occur as a result of fishery management under either PA bookend. Both PA.1 and PA.2 are considered to have no effects on these species through benthic habitat.

Cumulative Effects of PA.1 and PA.2

The past/present effects on sooty and short-tailed shearwaters are described in Section 3.7.6 (Table 3.7-14) and the predicted direct and indirect effects of the groundfish fishery are described above (Table 4.9-4). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in a cumulative way. The cumulative effects for these species would be dominated by factors external to the groundfish fisheries and would be the same as those described in Section 4.5.7.2 (Table 4.5-54) and summarized below.

Mortality

- **Direct/Indirect Effects.** Under PA.1, the new seabird protection measures for the longline fleet would be adopted but are not expected to reduce incidental take of shearwaters. Additional research and future mitigation measures could reduce incidental take of these species under PA.2. Mitigation measures for the trawl fleet under PA.1 and PA.2 may also reduce incidental take of shearwaters in the trawl sector. Expected incidental take is considered insignificant at the population level for both shearwater species.

- **Persistent Past Effects.** For sooty and short-tailed shearwaters, mortality factors include large contributions from subsistence and commercial harvest of chicks on the nesting grounds as well as climatic and oceanic fluctuations that cause periodic mass starvation, substantial contributions from foreign, Hawaiian, and BSAI/GOA groundfish longline and trawl fisheries, and a smaller contribution from vessel collisions throughout their range. It is difficult to assess the population trends in these abundant and widespread species, but there is some indications that both species may be declining. The contribution of toxic and plastic pollution on their nesting grounds and in the marine environment to mortality is unknown for both species in this group.

- **Reasonably Foreseeable Future External Effects.** New seabird protection measures have recently been established for the Hawaiian pelagic longline fleets that are similar to those proposed for the Alaskan fisheries. These measures are not expected to reduce incidental take of shearwaters in those fisheries. It is expected that incidental take of shearwaters in foreign fisheries will likely continue as in the past unless longline and trawl deterrence techniques are developed and applied that are effective for diving species.

- **Cumulative Effects.** Since the populations of shearwaters may be undergoing declines and several human-caused mortality factors have been identified and are expected to continue in the future, including contributions from the groundfish fisheries under PA.1 and PA.2, the cumulative effects on sooty and short-tailed shearwaters are considered to be conditionally significant adverse at the population level through mortality.

Changes in Food Availability

- **Direct/Indirect Effects.** The groundfish fisheries would continue to take a very small amount of squid and plankton as bycatch under PA.1 and PA.2. This effect is considered insignificant at the population level for both shearwater species. While groundfish vessels contribute to overall marine pollution through accidental spills and vessel accidents, the effects of this pollution on shearwater prey populations can not be assessed at this time.

- **Persistent Past Effects.** Short-tailed and sooty shearwaters are susceptible to periodic widespread food shortages that have caused massive die-offs in Alaskan waters. Natural fluctuations in primary productivity and oceanographic factors are considered to be the driving forces that determine the abundance of their main prey (euphausiids) rather than competitive interactions with other predators. Since shearwaters can forage over huge areas, they are unlikely to have been affected by localized disturbance or depletion of their prey fields caused by fisheries. Pollution from a variety of land and marine sources has potentially affected shearwater prey in the past. However, very little is known about the specific toxicological effects on species important to these seabirds or what sources of pollution may be the most important.

- **Reasonably Foreseeable Future External Effects.** There are no foreseeable fisheries that will likely have more than a minimal effect on shearwater prey availability. Pollution is likely to affect shearwater prey in the future, but specific predictions on the nature and scope of the effects, especially as they relate to the availability of prey to shearwaters, cannot be made at this time.

- **Cumulative Effects.** The cumulative effect of all fisheries on the abundance and distribution of shearwater prey is considered to be insignificant at the population level for all species.

Benthic Habitat

Since shearwaters feed at the surface or with shallow dives and their prey live in the upper and middle levels of the water column, potential changes in benthic habitat from groundfish trawls or any other fishing gear would have no discernable effect on their prey. Therefore, no cumulative effect on benthic habitat is identified for these species.

4.9.7.4 Northern Fulmar

Direct/Indirect Effects of PA.1 and PA.2

Incidental Take

Northern fulmars make up a majority of all birds taken in all three gear sectors. The numbers of fulmars taken are reported in the Observer Program data under their own species listing plus an unknown number of the unidentified tubenoses and unidentified seabird groups (Tables 3.7-1 through 3.7-5). The number of fulmars taken under the baseline condition of seabird protection measures can be estimated from the 1997-2001data since these measures were implemented in 1997. The estimated number of fulmars taken in this period averaged 10,689 birds per year in the BSAI longline sector, 406 birds per year on GOA longlines, 3,083 birds per year (mean of low and high estimates) in the BSAI and GOA trawls, and 42 birds per year in BSAI and GOA pots, for an estimated average identified take of 14,220 birds per year in the groundfish fishery. This total does not include any portion of the “unidentified seabird” category in the data set or any estimate of birds killed by vessel strikes. Given the high proportion of fulmars in the identified categories, one could reasonably assume that a large number of the unidentified bird remains were actually fulmars. For this analysis, the portion of unidentified birds in the data that were actually fulmars will be approximated as an additional 1,000 birds per year, mostly from the BSAI longline sector. Vessel strike data have been collected in an *ad hoc* manner but existing records indicate that an average of at least 80 fulmars are killed each year by trawl third wires. Adding these approximations to the identified fulmar takes gives a total estimated average take of about 15,300 birds per year from all fisheries. The latest population estimate for fulmars in the BSAI and GOA is about 2 million birds, with 4 to 5 million in the North Pacific (Hatch and Nettleship 1998). Mortality from the groundfish fishery is thus equal to about 0.76 percent of the BSAI and GOA population.

This baseline level of incidental take is considered to be insignificant at the overall population level. However, because fulmars only breed in a few large colonies in the BSAI/GOA, there is some concern that incidental take from the fisheries could have a colony level effect if a disproportionate amount of the overall take comes from only one colony, particularly the Pribilof Islands since it is the smallest colony. The USFWS has established permanent sample plots on the Pribilof Islands but the usefulness of those census plots to measure potential colony level changes of fulmars is questionable (see Section 3.7.5). The U.S. Geological Survey/Biological Resource Division (USGS/BRD) has recently begun to research the issue using satellite telemetry and genetic analysis to determine the movement patterns of fulmars and the colony of provenance of birds taken in the fishery. Other factors that may cause population levels to fluctuate, including variable environmental conditions, will be investigated as well.

Since northern fulmars constitute the majority of birds taken incidentally in all sectors of the groundfish fisheries, they would likely benefit the most from improved seabird protection measures in both the longline and trawl fleets. Under PA.1, the new seabird protection measures would be expected to substantially reduce incidental take of fulmars from longlines, which accounts for much of the incidental take under baseline conditions. Most of the BSAI freezer longline fleet and many smaller vessels in the GOA began using the new seabird deterrent devices on a voluntary basis during the 2002 fishing season. Incidental take data from the 2002 season (NPFMC 2003b) indicates that estimated take of fulmars in the BSAI longline fisheries declined from an average of 10,689 birds per year (1997-2001) to an estimated 701 birds per year in 2002. In the GOA longline fisheries, fulmar take was reduced from an average of 406 birds per year (1997-2001) to 129 birds in 2002. As described above for albatross, many different factors may have contributed to the reduced level of take in 2002. However, it is expected that fleet-wide compliance with the new regulations, which include equipment and deployment standards, should result in a dramatic decline in take of fulmars on longline gear. Under PA.2, additional research into weighted groundlines and other techniques would likely further reduce incidental take of fulmars.

In the trawl sector, potential new mitigation measures to reduce the risk of collisions with short-tailed albatross would likely be based on measured reductions in take of other albatross and fulmars, as was done for the longline deterrence measures. New seabird protection measures for the trawl fleet under PA.1 would therefore likely reduce incidental take of fulmars. Under PA.2, additional research on reducing take of non-ESA species would also likely benefit fulmars since they are the most frequently taken species in trawl gear.

Incidental take of fulmars in longlines and trawl gear is expected to be greatly reduced from baseline levels under both PA.1 and PA.2. Since the baseline level of incidental take is already considered insignificant at the population level, the substantially reduced levels of take expected under the PA.1 and PA.2 are also considered insignificant at the population level. These reductions in take would greatly reduce concerns about potential colony level effects on the Pribilof Islands although the USGS/BRD would likely continue to investigate the issue.

Availability of Food

Fulmars forage over vast areas of ocean on prey that are taken in very small amounts by the groundfish fisheries and which do not appear to be affected on an ecosystem level by the groundfish harvest (see Forage Fish and Ecosystem Sections, 4.5.4 and 4.5.10). Both PA.1 and PA.2 would continue to ban directed fishing on forage fish species and size classes and would develop ecosystem indicators for use in the TAC-setting process that would be intended to minimize potential adverse effects on non-target species. Fulmars are therefore unlikely to be affected by any potential localized disturbance or depletion of prey from the fishery as managed under either PA bookend. Both PA.1 and PA.2 are considered to have insignificant effects on fulmars through availability of food.

Benthic Habitat

Fulmars are not benthic feeders and are not expected to be affected by any changes in benthic habitat that might occur as a result of fishery management under either PA bookend. Both PA.1 and PA.2 are considered to have no effects on fulmars through benthic habitat.

Cumulative Effects of PA.1 and PA.2

The past/present effects on northern fulmars are described in Section 3.7.5 (Table 3.7-13) and the predicted direct and indirect effects of the groundfish fishery are described above (Table 4.9-4). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in a cumulative way. The effects considered in this analysis are listed in Table 4.5-55 and summarized below.

Mortality

- **Direct/Indirect Effects.** Under the PA.1 and PA.2, the new seabird protection measures for the longline fleet would be adopted and potential mitigation measures for the trawl fleet would be developed. These measures are expected to substantially reduce incidental take of fulmars below the baseline level of incidental take such that mortality from incidental take would be considered insignificant at the population level.

- **Persistent Past Effects.** For northern fulmars, past mortality factors include large contributions from the BSAI/GOA groundfish fisheries and other net and longline fisheries in the North Pacific and Bering Sea. There is no indication of an area-wide population decline, but there is some concern that particular colonies may be experiencing declines. Other potential mortality factors that have been identified include acute and chronic effects of pollution, underestimated mortality in all fisheries, and higher than normal rates of natural mortality (i.e. starvation) due to climatic and oceanographic fluctuations.

- **Reasonably Foreseeable Future External Effects.** Incidental take of fulmars is expected to continue in all offshore fisheries in the BSAI/GOA. The IPHC fisheries will be subject to new seabird avoidance measures, so incidental take from the halibut and sablefish fleet is expected to decline substantially. Future oil spills and other incidents of pollution are likely, but their effects on fulmars will depend on many factors that can not be predicted.

- **Cumulative Effects.** Since the regional population of northern fulmars appears to be stable and the primary human-caused mortality factors, including contributions from the groundfish fisheries under PA.1 and PA.2, are expected to decline in the future, the cumulative effects on fulmars are considered to be insignificant at the population level through mortality.

Changes in Food Availability

- **Direct/Indirect Effects.** The groundfish fisheries would continue to take a small amount of forage fish and pelagic invertebrates as bycatch under both PA.1 and PA.2. This effect is considered insignificant at the population level for northern fulmars. While groundfish vessels contribute to overall marine pollution through accidental spills and vessel accidents, the effects of this pollution on fulmar prey populations can not be assessed at this time.

- **Persistent Past Effects.** Fulmars prey on squid and small schooling fishes that have been targeted by fisheries in various parts of their range. While these fisheries may have caused some localized depletions of prey, their effect on overall prey abundance is considered to be minimal compared to climate and oceanographic factors. Since fulmars can forage over huge areas, they are unlikely to have been affected by localized disturbance or depletion of their prey fields caused by fisheries. Pollution from a variety of land and marine sources has potentially affected fulmar prey in the past. However, very little is known about the specific toxicological effects on species important to fulmars or what sources of pollution may be the most important.

- **Reasonably Foreseeable Future External Effects.** There are no foreseeable fisheries that will likely have more than a negligible effect on fulmar prey availability. Pollution is likely to affect fulmar prey in the future, but specific predictions on the nature and scope of the effects, especially as they relate to the availability of prey to fulmars, cannot be made at this time.

- **Cumulative Effects.** The cumulative effect of all fisheries on the abundance and distribution of fulmar prey is considered to be insignificant at the population level.

Benthic Habitat

Since fulmars feed at the surface or with shallow dives and their prey live in the upper and middle levels of the water column, potential changes in benthic habitat from groundfish trawls or any other fishing gear would have no discernible effect on their prey. Therefore, no cumulative effect is identified for this species.

4.9.7.5 Species of Management Concern (Red-Legged Kittiwakes, Marbled and Kittlitz's Murrelets)

Direct/Indirect Effects of PA.1 and PA.2

Incidental Take

The population of red-legged kittiwakes is estimated at around 150,000 birds, almost 80 percent of which nest on St. George Island in the Pribilofs. The combination of their restricted breeding area and substantial declines on permanent census plots led to their classification as a USFWS species of management concern. Red-legged kittiwakes have a separate species code in the Observer Program data on incidental take and may also be reported under the "gull" category and potentially under "unidentified seabirds" (Tables 3.7-1 through 3.7-5). Between 1993 and 2000, no specified red-legged kittiwakes were recorded as taken in any of the BSAI and GOA groundfish fisheries. One red-legged kittiwake was observed to be taken in a BSAI longline fishery in 2002, yielding an estimated 1-14 birds taken by the fleet. One red-legged kittiwake was found in an observer sample in a Bering Sea trawl in 2001 and one in 2002 (NPFMC 2003b). Because of different numbers and proportions of sampled hauls, these observed takes yielded estimated takes for the trawl fleet of 1- 37 birds in 2001 and 9-124 birds in 2002.

The new seabird avoidance measures for the longline fleet are expected to substantially reduce the incidental take of surface-feeding seabirds under PA.1. Since the incidental take of red-legged kittiwakes on longlines is apparently already very rare, a reduced level of take would be considered insignificant at the population level. Incidental take in trawl gear is also apparently rare and may or may not be reduced by potential mitigation measures that would be developed for the trawl fleet under PA.1 and PA.2. Since very few red-legged kittiwakes are likely to be taken in the groundfish fisheries under PA.1 and PA.2, the effect of this mortality is considered insignificant on the population-level.

Marbled and Kittlitz's murrelets are species of management concern in Alaska due to recent dramatic declines in their numbers in core habitats in southeast Alaska. Both of these species have separate species codes in the Observer Program data and may also be reported under the "alcids" and perhaps the "unidentified seabird" groups. No marbled or Kittlitz's murrelets have been specifically reported taken in the observed groundfish fisheries between 1993 and 2001 (Tables 3.7-1 through 3.7-5). Given their nearshore preferences and non-gregarious behavior, it is unlikely that murrelets are taken regularly in any of the BSAI/GOA groundfish fisheries. Since alcids are taken so infrequently on longlines, seabird avoidance measures for longlines would likely not affect the incidental take of murrelets. Incidental take in trawl gear, if it occurs at all, may or may not be reduced by potential mitigation measures that would be developed for the trawl fleet under PA.1 and PA.2. Since the expected incidental take of marbled and Kittlitz's murrelets approaches zero under the PA, this source of mortality is considered insignificant at the population level for both species.

Availability of Food

Red-legged kittiwakes consume several species of small schooling fish as well as zooplankton. Given the wide variety of foods used by red-legged kittiwakes and the extensive areas over which they forage, it seems unlikely that they would be susceptible to localized depletion of prey during the non-breeding season. During the breeding season, kittiwakes are more limited in their options and are more susceptible to localized depletions of prey around their colonies. They would be especially susceptible to prey depletions around the Pribilof Islands, where 80 percent of the population breeds. However, the species and size classes of forage fish and zooplankton that red-legged kittiwakes consume are taken only in negligible amounts as bycatch in the groundfish fisheries and the ban on directed fisheries on forage fish would remain in place under both PA.1 and PA.2. The abundance and distribution of kittiwake prey are not expected to be affected on an ecosystem level by the groundfish harvest under either PA.1 or PA.2 (see Forage Fish and Ecosystem Sections 4.9.4 and 4.9.10). PA.1 and PA.2 are therefore considered to have insignificant effects on the availability of food for red-legged kittiwakes.

Marbled and Kittlitz's murrelets forage in shallow waters within 5 kilometers (km) of shore and feed on small fish such as capelin and Pacific sandlance as well as zooplankton and other invertebrates. The groundfish fisheries have very little spatial overlap with murrelet foraging areas and, as described above for kittiwakes, are expected to have insignificant effects on the abundance and distribution of their prey species. The overall effect of PA.1 and PA.2 on the availability of food for these species is considered insignificant at the population level.

Benthic Habitat

Red-legged kittiwakes are not benthic feeders and are not expected to be affected by any changes in benthic habitat that might occur as a result of groundfish fishery management. Marbled and Kittlitz's murrelets feed on species that depend on benthic habitats for at least part of their life cycles. However, benthic habitats in their nearshore foraging areas would not be affected directly by groundfish trawls under PA.1 and PA.2 as these would take place further offshore. Both PA.1 and PA.2 are considered to have insignificant effects on marbled and Kittlitz's murrelets and no effects on red-legged kittiwakes through benthic habitat.

Cumulative Effects of PA.1 and PA.2

The past/present effects on red-legged kittiwakes, marbled murrelets, and Kittlitz's murrelets are described in Sections 3.7.13 and 3.7.17 (Tables 3.7-22 and 3.7-26), and the predicted direct and indirect effects of the groundfish fishery are described above (Table 4.9-4). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in a cumulative way. The cumulative effects for these species would be dominated by factors external to the groundfish fisheries and would be the same as those described in Section 4.5.7.5 (Table 4.5-56) and summarized below.

<u>Mortality</u>

- **Direct/Indirect Effects.** Under both PA.1 and PA.2, the incidental take of red-legged kittiwakes and both murrelets is expected to be rare and insignificant at the population level.

- **Persistent Past Effects.** Past sources of mortality that may continue to have an effect on these species include subsistence hunting and egging (red-legged kittiwakes), incidental take in coastal salmon gillnet and other net fisheries (murrelets), oil spills (murrelets), logging of nest trees (marbled murrelets), and climatic warming that reduces glacial habitat (Kittlitz's murrelet). Incidental take in the BSAI/GOA groundfish fisheries appears to have contributed very little to the mortality of these species.

- **Reasonably Foreseeable Future External Effects.** All of the mortality factors listed above in persistent past effects are likely to continue in the future. For red-legged kittiwakes, the introduction of nest predators or a large oil spill around the Pribilof Islands in nesting season could have significant effects on mortality. For the murrelet species, oil spills in nearshore habitats and incidental take in salmon and other coastal net fisheries are likely to remain the largest factors in the future. The contribution from chronic sources of pollution, both from terrestrial and marine sources, may also contribute to future mortality. If the Kittlitz's murrelet population continues to decline and the species is listed under the ESA, new regulations may be placed on the various nearshore net fisheries to monitor and reduce incidental take of the species. These measures would also benefit marbled murrelets.

- **Cumulative Effects.** The three species in this group have all experienced substantial population declines in the recent past and are all susceptible to future human-caused mortality factors including potentially small contributions from the groundfish fishery. The decline of red-legged kittiwakes on the Pribilofs may have been reversed recently but it is not clear if their recovery will continue in the future. The cumulative effect for red-legged kittiwake is considered conditionally significant adverse at the population level through mortality. Both murrelet species continue to decline in their core areas and are thus considered to have significantly adverse cumulative effects at the population level through mortality.

Changes in Food Availability

- **Direct/Indirect Effects.** The groundfish fisheries would continue to take a small amount of forage fish and pelagic invertebrates as bycatch. The effect of the fishery on the abundance and distribution of seabird prey species is considered insignificant at the population level for all three species in this group. While groundfish vessels contribute to overall marine pollution and disturbance, the effects of vessel hazards on seabird prey populations can not be assessed at this time.

- **Persistent Past Effects.** All three species prey on small schooling fishes, and an assortment of invertebrates that have been targeted or taken as bycatch by external fisheries in various parts of their range. While these fisheries may have caused some localized depletions of prey, their effect on overall prey abundance is considered to be small compared to climate and oceanographic factors. Pollution from a variety of land and marine sources, including the EVOS, has likely affected the prey of these species in the past. Since murrelets are easily disturbed by marine vessels of all kinds, high concentrations of vessel traffic in some areas may have effectively excluded murrelets from certain important foraging areas and contributed to their population declines.

- **Reasonably Foreseeable Future External Effects.** Future squid and herring fisheries as well as other net fisheries that take forage fish as bycatch may have an effect on prey availability for these species. Pollution is likely to affect prey in the future but specific predictions on the nature and scope of the effects, especially as they relate to the availability of prey on a scale important to the birds, can not be made at this time.

- **Cumulative Effects.** While the groundfish fisheries are considered to have an insignificant effect on prey availability on their own, the dynamic interaction of natural and human-caused events, including fisheries and pollution, on the availability of forage fish and invertebrate prey to seabirds is only beginning to be explored with directed research. The potential roles of changes in food availability to the observed population declines in these species are still under investigation. Since this dynamic could conceivably be adverse or beneficial depending on different circumstances, the cumulative effect on prey availability is considered to be unknown for these three species.

Benthic Habitat

Since red-legged kittiwakes are not benthic feeders and are not expected to be affected by any changes in benthic habitat that might occur as a result of the groundfish fishery, no cumulative effect is identified for this species through benthic habitat.

Marbled and Kittlitz's murrelets feed on species that depend on benthic habitats for at least part of their life cycles, but they forage in shallow waters that are inshore of the groundfish fishery. Although a number of natural and anthropogenic factors may impact benthic habitat important to murrelet prey, fluctuations in prey abundance have not been implicated in the population declines of either species. The cumulative effects on both murrelet species through changes in benthic habitat, including a minimal contribution from the groundfish fisheries, are therefore considered insignificant.

4.9.7.6 Other Piscivorous Species (Most Alcids, Gulls, and Cormorants)

Direct/Indirect Effects of PA.1 and PA.2

Incidental Take

The incidental take of species considered in this piscivorous group is reported in the Observer Program data under the gull, alcid, and "other" categories, as well as an unknown number of the "unidentified seabird" category (Tables 3.7-1 through 3.7-5). The number of piscivores taken under the baseline condition of seabird protection measures can be estimated from the 1997-2001 data since these measures were implemented in 1997. The estimated number of gulls taken in this period averaged 3,268 birds per year in the BSAI longline sector, 147 birds per year on GOA longlines, and 274 birds per year (mean of low and high estimates) in the BSAI and GOA trawls, for an estimated average take of 3,689 birds per year in the groundfish fishery. Even if a large proportion of the unidentified seabirds are gulls, this level of mortality is considered insignificant at the population level given the combined estimated abundance (2.5 million birds) of the different gull species in the BSAI and GOA (Table 3.7-21).

For the alcids, mortality from the groundfish fishery comes almost entirely from the trawl sector and averaged 259 birds per year (mean of low and high estimates) in the BSAI/GOA trawls. Given the estimated abundance of large alcids in these waters (approaching 20 million, Table 3.7-21), this level of mortality is considered insignificant at the population level. The 3 cormorant species all live and feed in nearshore waters and would thus be unlikely to be taken in the groundfish fisheries. Incidental take of cormorants would be included in the "other" category, which approaches zero and is therefore considered an insignificant source of mortality at the population level.

Under PA.1, the new seabird protection measures for the longline fleet would be expected to result in a substantial overall reduction in take of surface-feeding species such as gulls. Under PA.2, additional research into weighted groundlines and other techniques would also likely reduce take of gulls. These species may also benefit from reduced take in the trawl sector due to potential mitigation measures for the trawl fleet under both PA.1 and PA.2. Trawl gear protection measures would have more potential to reduce incidental take of alcids than any modifications to longline techniques because alcids are taken mostly in trawl gear. Since the baseline level of incidental take from all gear types is already considered insignificant at the population level for gulls and alcids, reduced levels of take under PA.1 and PA.2 are expected to have insignificant effects on piscivorous species through incidental take.

Availability of Food

Foraging success by piscivorous seabirds depends not only on the biomass of forage stocks in their feeding areas, but also on the availability of these stocks to the birds. The availability of prey is affected by a number of oceanographic and biological factors (see Section 3.7.1) that may vary substantially over short time periods and distances. The question of whether the intensity and structure of the groundfish fishery under the baseline condition has adverse or beneficial effects on the availability of forage fish for seabirds has not been addressed through directed research. Many of the data gaps identified in Section 5.1.2.8 address this issue. Although there are very little empirical data on how a fishery might affect the availability of forage fish to seabirds, it is assumed that fishing (with trawl gear at least) could disrupt the movements and structure of forage fish schools such that they would be less available to seabirds, at least for a short period of time. Localized depletion or disruption of prey species around seabird colonies could be particularly detrimental during the chick-rearing period for breeding seabirds. However, most of the groundfish fisheries are conducted during the non-summer months, with minor overlap in the late spring and early fall months. In addition, many species can forage up to 40 km from their colonies during chick-rearing with a few species ranging to 100 km so any localized and short term disruptions of forage fish would have minimal effects at the population level. The species and size classes of forage fish (and zooplankton) that piscivorous seabirds feed on are taken only in negligible amounts as bycatch and incidental take by the groundfish fisheries. The groundfish harvest does not appear to be "fishing down the food web" or otherwise affecting seabird prey on an ecosystem level (see Ecosystem, Section 4.5.10). The existing ban on the development of a commercial forage fish fishery (BSAI/GOA FMP Amendments 36/39) is considered to be beneficial to seabirds by preventing a potentially adverse fishery from developing. This ban would be maintained under both PA.1 and PA.2.

The fisheries provide an artificial yet nutritious supplement to seabird diets in the form of processing waste and offal. No studies have been conducted in Alaska on whether this food source provides a significant benefit to the survival rate or reproductive success of any species on the population or colony level. It is likely that the value of this supplemental food varies over time and space, fluctuating with the availability of natural food supplies and seasonal nutritional needs. Whereas some birds may benefit from the food supply provided by offal and processing waste, such waste also acts as an attractant that may lead to increased incidental take in fishing gear. In addition, some species, such as the large gulls, tend to be more successful at competing for fish scraps at vessels and processors and may thus receive a greater nutritional boost than the smaller species. Since the large gulls are also nest predators of other species, especially kittiwakes and murres, the supplemental food from fishery wastes may be beneficial to some species and detrimental to others within this species group. Thus, this indirect effect of the fishery potentially has both beneficial and adverse effects on seabirds and the net benefit or liability is unknown. Under PA.1 and PA.2, the contribution of the fishery to the food supply of gulls in the form of fishery discards would be about the same as the baseline or reduced as a result of bycatch reduction and IR/IU measures.

Population trends and reproductive success rates of most piscivorous species in the BSAI/GOA are mixed, with some species and colonies doing well in some areas and years while the same species show declines and breeding failures in other locations and years (Dragoo *et al.* 2001). Although some species are susceptible to periodic die-offs due to starvation, natural fluctuations in ocean currents and climatic variables could account for many of these episodes. There is no evidence that populations of the piscivorous seabirds considered in this group have been experiencing consistent or area-wide declines in productivity. Since the structure and intensity of the fisheries under PA.1 and PA.2 would be similar or reduced in scope from existing conditions, the potential impact of the fisheries on piscivorous seabirds through prey availability would be similar to the baseline condition and would be considered to be insignificant at the population level for all piscivorous seabirds.

<u>Benthic Habitat</u>

Cormorants and alcids have diverse diets that include both small schooling fishes (capelin and sand lance) as well as demersal fish species and crustaceans. These birds are capable of diving from 40 m to over 100 m deep and are thus able to reach the ocean floor in many areas. Some species, such as cormorants and guillemots, usually forage in coastal waters during the breeding season, but other species forage well away from land. Bottom trawl gear has the greatest potential to indirectly affect these diving seabirds via physical changes to benthic habitat but pelagic trawls (to various extents), pot gear, and longline gear also contact the ocean floor. Trawling (and to a lesser extent other fishing gear disturbance) can reduce habitat complexity and productivity (NRC 2002). Specific effects of trawling on seabird prey species in the BSAI/GOA (through habitat change rather than by direct take) are poorly known (see Sections 3.6 and 5.1.2.7 on EFH for a discussion of research needed to address data gaps in benthic habitat changes due to trawling). However, none of the species in this group appear to have experienced consistent or widespread population declines so there is no indication that the carrying capacity of the environment has been decreased through changes to benthic habitat (or any other mechanism). Overall trawl effort in the BSAI/GOA relative to the baseline conditions is predicted to be similar under PA.1 and reduced under PA.2. The effects on piscivorous seabirds through potential changes in benthic habitat are therefore considered insignificant at the population level.

Cumulative Effects of PA.1 and PA.2

The past/present effects on the species in this group, including most alcids, gulls, and cormorants, are described in their species accounts in Section 3.7 (Tables 3.7-16 and 3.7-20) and the predicted direct and indirect effects of the groundfish fishery are described above (Table 4.9-4). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in a cumulative way. The effects considered in this analysis are listed in Table 4.5-57 and summarized below.

<u>Mortality</u>

- **Direct/Indirect Effects.** Incidental take of surface-feeding piscivores is expected to decrease due to new seabird protection measures for the longline fleet. Incidental take of diving species may also be reduced if new mitigation measures are developed and implemented for the longline and trawl fleets under PA.2. The incidental take for all species in this group is expected to be insignificant at the population level under both PA.1 and PA.2.

- **Persistent Past Effects.** Past sources of mortality that may continue to have an effect on these species include subsistence hunting and egging, incidental take in a variety of foreign and U.S. coastal and pelagic fisheries, oil spills and other pollution, fox farming, and regime shifts that have caused episodes of mass starvation. Incidental take in the BSAI/GOA groundfish fisheries appears to have contributed relatively little to the mortality of these species.

- **Reasonably Foreseeable Future External Effects.** All of the mortality factors listed above in persistent past effects are likely to continue in the future except for fox farming. A similar, though unintentional, effect is the possible introduction of nest predators (i.e., rats) to seabird colonies. Conservation concerns focus on preventing potential impacts around breeding colonies during the nesting season since populations are concentrated in time and space. For some species, human impacts in nearshore habitats will likely have a much greater effect on their populations than offshore fisheries. The contribution from chronic sources of pollution, both from terrestrial and marine sources, may also contribute to future mortality.

- **Cumulative Effects.** Although a number of past and future human-caused mortality factors, including potentially small contributions from the groundfish fishery, have been identified for the species in this group, none of them have experienced substantial, consistent, or area-wide population declines in the recent past. The cumulative effects for these species are considered insignificant at the population level through mortality.

Changes in Food Availability

- **Direct/Indirect Effects.** The groundfish fisheries would continue to take a small amount of forage fish and invertebrate prey as bycatch and incidental take. The effect of the fishery on the abundance and distribution of seabird prey species is considered insignificant at the population level for all species in this group. While groundfish vessels contribute to overall marine pollution and disturbance, the effects of vessel hazards on seabird prey populations can not be assessed at this time.

- **Persistent Past Effects.** All species in this group prey on small schooling fishes and an assortment of invertebrates that have been targeted or taken as bycatch by external fisheries in various parts of their range. While these fisheries may have caused some localized depletions of prey, their effect on overall prey abundance is considered to be small compared to climate and oceanographic factors. Pollution from a variety of land and marine sources has likely affected the prey of these species in the past. Since some of the alcids are easily disturbed by marine vessels of all kinds, high concentrations of vessel traffic in some areas may have effectively excluded them from certain important foraging areas.

- **Reasonably Foreseeable Future External Effects.** Future squid and herring fisheries as well as other net fisheries that take forage fish as bycatch may have an effect on prey availability for these species. Pollution is likely to affect prey in the future but specific predictions on the nature and scope of the effects, especially as they relate to the availability of prey on a scale important to the birds, can not be made at this time.

- **Cumulative Effects.** The groundfish fisheries contribute to the dynamic interaction of natural and human-caused events that affect the availability of forage fish and invertebrate prey to seabirds. While this dynamic is only beginning to be explored with directed research, the lack of substantial, consistent, or area-wide population declines in these species indicates that the baseline conditions do not have an overriding adverse effect on the natural fluctuations of these seabird populations. Since no new major contributing factors are expected in the future under PA.1 and PA.2, the cumulative effect on prey availability is considered insignificant at the population level for these species.

Benthic Habitat

- **Direct/Indirect Effects.** Bottom trawls, and to a lesser extent pelagic trawls and pot gear, have the potential to modify benthic habitats and have indirect effects on the food web of diving piscivorous species. The overall effects on piscivorous seabirds through potential changes in benthic habitat are considered insignificant.

- **Persistent Past Effects.** Benthic habitats important to the diving species in this group have been affected by various foreign and U.S. fisheries for many years and include nearshore as well as offshore fisheries. The magnitude and longevity of the effects of these different types of fisheries have only begun to be investigated, so it is unclear what or where habitat effects are persistent, especially in regard to the indirect effects on prey species important to seabirds. Natural sources of benthic habitat disruption, such as strong ocean currents, ice scouring, and foraging by gray whales and walrus, may have persistent effects in certain areas.

- **Reasonably Foreseeable Future External Effects.** All future fisheries in the BSAI/GOA that use bottom contact fishing gear are likely to affect benthic habitat to some extent. Natural sources of benthic habitat disruption will continue.

- **Cumulative Effects.** The groundfish fisheries contribute to the many human-caused and natural factors that alter benthic habitats important to the food web of piscivorous seabirds. While there has been limited research on specific effects of benthic habitat disturbance on seabirds, the lack of substantial, consistent, or area-wide population declines in these species indicates that the baseline conditions do not have an overriding adverse effect on the natural fluctuations of these seabird populations. Since no new external contributing factors are expected in the future and the intensity of trawling is expected to remain the same under PA.1 and be reduced under PA.2, the cumulative effect on benthic habitat is considered insignificant at the population level for these species.

4.9.7.7 Other Planktivorous Species (Storm-Petrels and Most Auklets)

Direct/Indirect Effects of PA.1 and PA.2

Incidental Take

Leach's and fork-tailed storm-petrels are not identified to species in the Observer Program data but they do have an"unidentified storm-petrel" code and may be reported in the "unidentified tubenoses," "other," and "unidentified seabird" categories (Tables 3.7-1 through 3.7-5). The numbers of storm-petrels in these categories are unknown but likely to be small given their feeding behavior. Given the abundance of these species in the BSAI/GOA area, with a combined population estimate of over 10 million birds (Table 3.7-21), incidental take of storm-petrels under the baseline conditions is considered to be insignificant at the population level. Although some of the planktivorous auklets have individual species codes in the Observer Program data, they are reported in the "alcid" and "unidentified seabird" categories. It is unlikely that they are taken on longlines at all and probably constitute only a small fraction of the trawl take. Given their abundance in the BSAI/GOA, with a combined population of over 10 million birds (Table 3.7-21), incidental take of auklets under the baseline conditions is considered to be insignificant at the population level.

Under the PA.1 and PA.2, new seabird avoidance measures would be expected to reduce incidental take of surface-feeding and diving seabird species from both longlines and trawls. Since the incidental take of these species is considered to be insignificant under the baseline conditions, reduced levels of take would also be considered insignificant. The effects of both PA.1 and PA.2 on incidental take of planktivorous species are therefore considered to be insignificant at the population level.

Another means of incidental take in the fishery is by birds striking the vessel or rigging. The Observer Program does not record vessel strikes on a systematic basis so data on the frequency or extent of such strikes are very limited (NPFMC 2003b). Crested auklets do not seem to strike fishing vessels very frequently but when they do, the incidents often involve large numbers of birds. According to preliminary analysis of the observer records of bird-strikes from 1993-2000, 1,305 crested auklets were involved in 7 recorded collisions. In one historical account, approximately 6,000 crested auklets were attracted to lights and collided with a fishing vessel near Kodiak Island during the winter of 1977 (Dick and Donaldson 1978). Storm-petrels are also prone to periodic collisions involving many birds (631 birds in 19 recorded incidents). Bird strikes are probably most numerous during the night and during storms or foggy conditions when bright deck lights are on, which can cause the birds to be disoriented. Given the sporadic nature of these collisions and the small numbers of birds involved relative to their overall populations, the effect of the fisheries on these species through vessel collisions is considered insignificant at the population level under the baseline conditions. Since fishing effort under PA.1 and PA.2 would be similar to the baseline or reduced, the effect of PA.1 and PA.2 on incidental take from vessel collisions is considered insignificant.

Availability of Food

Storm-petrels are relatively small surface feeding seabirds that primarily target zooplankton and juvenile fish. The auklets feed on zooplankton (euphausiids), juvenile fish, and squid. The abundance and distribution of these prey species are affected by a number of oceanographic and biological factors (see Section 3.7.1) that may vary substantially over short time periods and distances. The groundfish fisheries could indirectly affect the availability of zooplankton and small schooling fish to seabirds through changes in the abundance and distribution of target fish species that also prey on small fish and zooplankton. For example, since young pollock are planktivores, large changes to pollock populations as a result of fishing could theoretically affect the carrying capacity for storm-petrels and auklets. However, zooplankton and juvenile fish abundance and distribution are thought to be influenced much more by primary productivity and oceanographic fluctuations (bottom-up factors) than predator/prey relationships (top-down factors) (see Section 4.5.10). Since the structure and intensity of the fisheries managed under PA.1 and PA.2 would be similar or reduced relative to the baseline, the effect of PA.1 and PA.2 on prey availability for planktivores is considered insignificant at the population level.

Benthic Habitat

Storm-petrels and auklets are not benthic feeders and are not expected to be affected by any changes in benthic habitat that might occur as a result of groundfish management. The PA.1 and PA.2 are considered to have no effects on these species through benthic habitat.

Cumulative Effects of PA.1 and PA.2

The past/present effects on the species in this group, including storm-petrels and most auklets, are described in Sections 3.7.7 and 3.7.18 (Tables 3.7-15 and 3.7-27) and the predicted direct and indirect effects of the groundfish fishery are described above (Table 4.9-4). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in a cumulative way. The effects considered in this analysis are listed in Table 4.5-58 and summarized below.

Mortality

- **Direct/Indirect Effects.** Incidental take of the species in this group is expected to remain sporadic in occurrence and affect relatively few individuals and is considered to be insignificant at the population level.

- **Persistent Past Effects.** Past sources of mortality that may continue to have an effect on these species include subsistence harvest, incidental take in foreign and U.S. coastal and pelagic fisheries, oil spills and other marine pollution, fox farming, and regime shifts that have caused episodes of mass starvation. Incidental take in the BSAI/GOA groundfish fisheries appears to have contributed relatively little to the mortality of these species.

- **Reasonably Foreseeable Future External Effects.** All of the mortality factors listed above in persistent past effects are likely to continue in the future except for fox farming. A similar, though unintentional, effect is the possible introduction of nest predators (i.e., rats) to seabird colonies. The contribution from chronic sources of pollution, both from terrestrial and marine sources, may contribute to future mortality.

- **Cumulative Effects.** Although a number of past and future human-caused mortality factors, including small contributions of incidental take from the groundfish fishery, have been identified for the species in this group, none of them have experienced substantial, consistent, or area-wide population declines in the recent past. The cumulative effects for these species are considered insignificant at the population level through mortality.

Changes in Food Availability

- **Direct/Indirect Effects.** The groundfish fisheries would continue to take a small amount of forage fish and invertebrate prey as bycatch. Indirect effects on zooplankton and juvenile fish abundance through changes in the abundance of target fish predators is considered minor compared to seasonal changes in primary productivity and oceanographic factors. The effect of the fishery on the abundance and distribution of seabird prey species is considered insignificant at the population level for all species in this group. While groundfish vessels contribute to overall marine pollution and disturbance, the effects of vessel hazards on seabird prey populations can not be assessed at this time.

- **Persistent Past Effects.** Factors that have affected the abundance and distribution of zooplankton and juvenile fish include bycatch in squid and forage fish fisheries, marine pollution, and the decimation of planktivorous whales by commercial whaling. These effects are considered minor compared to seasonal and oceanographic fluctuations.

- **Reasonably Foreseeable Future External Effects.** Future squid and herring fisheries as well as other net fisheries that take forage fish as bycatch may have minimal effects on prey availability for these species. Pollution is likely to affect prey in the future but specific predictions on the nature and scope of the effects, especially as they relate to the availability of prey on a scale important to the birds, can not be made at this time.

- **Cumulative Effects.** The groundfish fisheries contribute in an indirect way to human influences on planktonic prey availability, and are considered minimal compared to natural fluctuations. These cumulative effects are considered insignificant on the population level for all species in this group.

Benthic Habitat

Since these planktivorous seabirds feed at the surface or with shallow dives and their prey live in the upper and middle levels of the water column, potential changes in benthic habitat from groundfish trawls or any other fishing gear would have no discernable effect on their prey. Therefore, no cumulative effect on benthic habitat is identified for these species.

4.9.7.8 Spectacled Eiders and Steller's Eiders

Direct/Indirect Effects of PA.1 and PA.2

Incidental Take

Spectacled eiders interact very little, if at all, with the groundfish fisheries because most of the habitat for this species is located in the northern Bering Sea or in inshore areas of northwest Alaska. There is therefore very little opportunity for the groundfish fisheries to affect spectacled eiders through mortality. Although spectacled eiders have an individual species code in the Observer Program manual, no spectacled eiders have been observed to be taken in any of the fisheries since data collection began in 1993. In the most recent ESA Section 7 consultation (USFWS 2003a, USFWS 2003b), the USFWS concluded that the groundfish fisheries had negligible impacts on the population recovery or critical habitat of spectacled eiders.

The winter distribution of Steller's eiders does include areas where groundfish fisheries occur although these birds prefer shallow, nearshore waters. There is some overlap between the fisheries and Steller's eider critical habitat in the northwestern portion of Kuskokwim Bay (Kuskokwim Shoals). Only two vessels fished this area in 2001, both over 200 ft LOA so there was 100 percent observer coverage. Steller's eiders have an individual species code in the Observer Program manual but no incidental takes have been documented since 1995 (Tables 3.7-1 through 3.7-5).

Under the PA.1 and PA.2, NOAA Fisheries would continue to consult with USFWS to protect all threatened or endangered species from potential adverse effects of the groundfish fishery. PA.1 and PA.2 are not expected to change the distribution of the groundfish fisheries to the point that they overlap with the distribution of spectacled eider habitat and are therefore considered to have no effects on spectacled eiders through incidental take. Incidental take of Steller's eiders in fishing gear already approaches zero under the baseline conditions so it is unlikely that new longline or trawl mitigation methods would yield substantial benefits for the species or be implemented on their behalf. The primary danger would appear to be the risk of collisions with all vessels, especially as birds are attracted to deck lights under poor visibility conditions. Minimizing the amount of light directed out to sea may help mitigate this risk. Based on the very minimal overlap between the predicted fisheries and Steller's eider, including only the Kuskokwim Shoals area, incidental take under the PA.1 and PA.2 will likely remain at levels approaching zero and is considered to have insignificant effects on the populations of this species through incidental take.

Availability of Food

The abundance of marine invertebrate species important to the spectacled and Steller's eiders, including bivalves, snails, crustaceans, and polychaete worms, could potentially be affected by disturbance to their benthic habitat. These effects will be discussed below. The groundfish fisheries catch only negligible amounts of these species and are unlikely to affect their abundance or distribution through ecosystem level effects under the baseline conditions (see Section, 4.5.10). As discussed above, there is essentially no overlap between the groundfish trawl fisheries and spectacled eider habitat under the baseline conditions. PA.1 and PA.2 are not expected to change this situation and are considered to have no effects on spectacled eiders through prey availability. Under both PA.1 and PA.2, there would be very little overlap between the groundfish fisheries and foraging areas for Steller's eiders, so the direct take of eider prey through bycatch would be negligible. The effects of the groundfish fisheries on prey abundance and availability (through direct take rather than habitat disruption) are considered insignificant at the population level for this species.

Benthic Habitat

Gear impacts on benthic habitat used by spectacled and Steller's eiders would primarily be from bottom trawl gear although pelagic trawls and pot gear also make contact with the bottom and contribute to benthic disturbance. Trawling (and to a lesser extent other fishing gear disturbance) can reduce habitat complexity and productivity (NRC 2002). The effects of trawl gear on benthic habitat are discussed in the habitat sections of this document (Sections 3.6.4 and 4.5.6).

Based on an analysis of the Observer Program data, no overlap occurred between spectacled eider critical habitat and the groundfish fishery under the baseline conditions. As discussed above, there is essentially no overlap between the groundfish trawl fisheries and spectacled eider habitat under the baseline conditions. The PA.1 and PA.2 are not expected to change this situation and are considered to have no effects on spectacled eiders through benthic habitat changes.

Since Steller's eiders forage almost exclusively in shallow waters inshore of the groundfish fisheries, their preferred winter habitats are not subject to groundfish fishing effort. During the breeding season, the overlap of bottom trawl fisheries and Steller's eider critical habitat is also very limited, involving only a few vessels in a limited area of Kuskokwim Bay (NPFMC 2003b). The effects of this small bottom trawl fishery on Steller's eider critical habitat have not been investigated but considering the limited fishing effort and large area of critical habitat that is not fished, it is unlikely that the changes in benthic habitat resulting from this fishery would affect Steller's eiders on a population level. During Section 7 consultations with NOAA Fisheries, USFWS also concluded that the fisheries were not likely to adversely affect Steller's eider critical habitat or their food supply through bottom-contact fishing gear (USFWS 2003a). For Steller's eiders, trawl effort in their critical habitat is limited to Kuskokwim Shoals under the baseline conditions. The small amount of fishing in this area is limited by logistical considerations and lack of interest by the fleet. No changes in management under the PA.1 and PA.2 would lead to an increase use of this area or any other foraging area. Potential effects are likely to remain similar to the baseline condition, which are considered insignificant. The overall effect of the PA.1 and PA.2 on the benthic habitat of Steller's eider is considered to be insignificant at the population level.

Cumulative Effects of PA.1 and PA.2

The past/present effects on spectacled and Steller's eiders are described in Sections 3.7.9 and 3.7.10 (Tables 3.7-17 and 3.7-18) and the predicted direct and indirect effects of the groundfish fishery are described above (Table 4.9-4). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in a cumulative way. The effects considered in this analysis are listed in Table 4.5-59 and summarized below.

Mortality

- **Direct/Indirect Effects.** Incidental take of spectacled and Steller's eiders is expected to be similar to the baseline condition and is considered to be insignificant at the population level.

- **Persistent Past Effects.** Past sources of mortality that may continue to have an effect on these species include sport hunting and subsistence harvest in Russia and Alaska, incidental take in Russian and Alaskan coastal fisheries, oil spills and other marine pollution that causes physiological stress and reduces survival rates, lead shot poisoning on the nesting grounds, and collisions with vessels and other structures. Incidental take in the BSAI/GOA groundfish fisheries appears to have been very rare for Steller's eider. Both species have been afforded protection through the ESA.

- **Reasonably Foreseeable Future External Effects.** All of the mortality factors listed above in persistent past effects are likely to continue in the future. Conservation concerns focus on preventing potential impacts in critical habitat areas.

- **Cumulative Effects.** The groundfish fisheries do not contribute to direct mortality of spectacled eiders, so no cumulative effect is identified for that species. Decreased adult survival rates appear to have driven the past population decline of Steller's eiders. Known sources of direct human-caused mortality of Steller's eider, including very rare incidental take in the groundfish fisheries, do not appear to account for the past population decline in Alaska. However, several indirect factors may be contributing to decreased adult survival rates, including climate-induced changes in habitat, concentration of predators around nesting areas due to nearby human habitation, and pollution of nearshore waters from chronic and periodic sources of petroleum products (USFWS 2003a). Since the Alaska breeding population of Steller's eiders has declined dramatically in the past and has not recovered, and because several human-induced sources of mortality have been identified as potential contributing factors to this decline, including the potential for contributions to pollution and vessel collisions from the groundfish fisheries as managed under PA.1 or PA.2, the cumulative effects of mortality on Steller's eiders are considered significant adverse at the population level.

Changes in Food Availability

There is no overlap predicted between spectacled eider critical habitat and the groundfish fisheries; therefore, no cumulative effects have been identified under PA.1 or PA.2. The abundance of marine invertebrate species important to Steller's eiders, including bivalves, snails, crustaceans, and polychaete worms, could potentially be affected by disturbance to their benthic habitat. These effects will be discussed below. Although anthropogenic factors may affect eider prey in limited locations, including chronic sources of pollution near harbors, natural factors such as seasonal, tidal, and oceanographic fluctuations are considered to play a dominant role in determining the abundance and distribution of eider prey. The cumulative effects associated with the groundfish fisheries and other human activities are therefore considered to have insignificant effects on prey availability for Steller's eiders.

Benthic Habitat

- **Direct/Indirect Effects.** Bottom trawls, and to a lesser extent pelagic trawls and pot gear, disrupt benthic habitats that support the prey of eiders. Under PA.1 and PA.2, the groundfish fishery is not expected to occur in spectacled eider critical habitat or any other area that they typically use; therefore, no effects have been identified. A limited amount of bottom trawling is expected to overlap with Steller's eider critical habitat. The overall effects of PA.1 and PA.2 on Steller's eiders through potential changes in benthic habitat are considered insignificant at the population level.

- **Persistent Past Effects.** Benthic habitats important to spectacled and Steller's eiders have been affected by various trawl and pot fisheries for many years and include nearshore as well as offshore fisheries. The magnitude and longevity of the effects of these different types of fisheries have only begun to be investigated, so it is unclear what or where habitat effects are persistent, especially in regard to the indirect effects on prey species important to eiders. Natural sources of benthic habitat disruption, such as strong ocean currents, ice scouring, and foraging by gray whales and walrus, may have persistent effects in certain areas. Climate change and ocean temperature fluctuations may also play a role in altering the benthic environment.

- **Reasonably Foreseeable Future External Effects.** All future fisheries that use bottom contact fishing gear in areas used by eiders are likely to affect benthic habitat to some extent. Natural sources of benthic habitat disruption will also continue.

- **Cumulative Effects.** There is no overlap predicted between spectacled eider critical habitat and the groundfish fisheries; therefore, no cumulative effects on benthic habitat have been identified for this species. While the groundfish fisheries are predicted to have little spatial overlap with Steller's eider habitat under PA.1 or PA.2, the interaction of all human-caused and natural disturbances on benthic habitat important to Steller's eiders has not been examined with respect to their population declines in the past. The cumulative effects of benthic habitat disruptions and changes over the years as they relate to the food web important to Steller's eiders are considered to be unknown.

4.9.8 Marine Mammals Preferred Alternative Analysis

4.9.8.1 Western Distinct Population Segment of Steller Sea Lions

Direct/Indirect Effects PA.1 – Western Distinct Population Segment of Steller Sea Lions

<u>Incidental Take/Entanglement in Marine Debris</u>

The analysis used to determine changes in the level of incidental takes described in Section 4.5.8 was applied to establish the significance of incidental take and entanglement of marine mammals expected to occur under each FMP. Regarding incidental take, PA.1 is not likely to result in significant changes to the population trajectory of the western distinct population segment (western population) of Steller sea lions. An average of 8.4 Steller sea lions from the western population was estimated to have been taken incidental to groundfish fisheries from 1995-1999 (Angliss *et al.* 2001) (Table 4.5-60). The ratio of observed takes of Steller sea lions to observed groundfish catch (from 1995 to 1999) was multiplied by the new projected groundfish catch (all fisheries combined) to estimate incidental takes expected to occur over the next six years under this alternative management regime. The estimated annual incidental take level of Steller sea lions under PA.1 in all areas combined is expected to be less than ten based on expected catch in this FMP, or about one sea lion per 220,000 mt of groundfish harvested.

Incidental bycatch frequencies in the BSAI, which are typically low, reflect locations where fishing effort was highest. In the Aleutian Islands and GOA, incidental takes are often within critical habitat, though in the Bering Sea such bycatch is farther offshore and along the continental shelf. Otherwise there seems to be no apparent "hot spot" of incidental catch disproportionate with fishing effort. Therefore, it is appropriate to estimate the take ratios based on estimated catch. However, if these take rates differ between observed and unobserved vessels then these take estimates would be biased accordingly. These rates also reflect a prohibition of trawling within 10 or 20 nm of 37 rookeries which likely reduces the potential for incidental take, particularly during the breeding season when females are on feeding trips within the critical habitat area.

Entanglement of sea lions in derelict fishing gear or other marine debris does not appear to represent a significant threat to the population. From a sample of rookeries and haul-out sites in the Aleutian Islands in which 15,957 adults were observed, Loughlin *et al.* (1986) found only 11 (0.07percent) entangled in marine debris, sone of which was derelict fishing gear. Observations of sea lions at Marmot Island for several months during the same year observed two out of 2,200 adults (0.09 percent) entangled in marine debris. Between 1993 and 1997, only one fishery-related stranding was reported from the range of the western populations: a sea lion observed in August 1997 with troll gear in its mouth and down its throat (Angliss *et al.*2001). Entanglement of sea lions in derelict fishing gear or other marine debris does not appear to present a significant threat to the populations. In conclusion, incidental take and entanglement in marine debris under PA.1 is insignificant according to the criteria set for significance (Table 4.1-6).

The Marine Mammals Protection Act (MMPA) requires NOAA Fisheries (NMFS Office of Protected Resources) to assess whether human-caused mortality threatens the stability or recovery on any species of marine mammal. The MMPA defines a measurement tool fo this purpose, the potential biological removal (PBR), that is a calculated value of the maximum number of animals, not including natural mortalities, that may be removed from a stock while allowing that stock to reach or maintain its optimum sustainable population. This calculation takes into consideration the most recent population estimates, historic population trends, status of the stock in relation to historic levels (i.e., whether it is depressed or not), and potential rates of recovery. According to the most recent stock assessment, PBR for the western population of Steller sea lions is 208 animals per year (Angliss and Lodge 2002). Mortality from incidental take an entanglement in marine debris is likely to continue under PA.1 at levels that are small (less than 10 percent) relative to PBR and is therefore considered insignificant according to the criteria set for significance (Table 4.1-6).

Fisheries Harvest of Prey Species

Changes in the fishing mortality rate for Steller sea lion prey species were calculated using output from the Multi-species Management Model which projected catch rates for the various FMPs. The estimated fishing mortality rates expected to occur under each FMP management regime were compared to the baseline fishing mortality rate in order to apply the significance criteria established in Table 4.1-6 for determining the effects on marine mammal populations. The baseline fishing mortality rates for the individual BSAI and GOA groundfish fisheries, the fishing mortality rates projected to occur under each alternative FMP, and the relative difference between the baseline and alternative fishing mortality rates are shown in Table 4.5-61.

Under PA.1, the fishing mortality rate of EBS pollock is expected to increase by an average of 23 percent relative to the comparative baseline. According to the significance criteria for effects on marine mammals, the change in harvest of this key Steller sea lion prey species is considered significantly adverse. It is worth noting that the harvest rate of pollock in the EBS was abnormally low in 2002. This low harvest rate was due to the high abundance or commercially sized pollock in the EBS which resulted in a large recommended ABC for this population, By definition ABC is set annually at a level deemed to be biologically acceptable based on the status and dynamics of the population, environmental conditions, and other ecological factors (e.g., natural mortality). The baseline groundfish FMPs contain catch provisions referred to as OYs that limit the total amount of BSAI and GOA groundfish harvest. Unlike the ABC, which is applied to individual species or species groups, the OY limit applies to the entire complex of commercially important species as well as other species with lesser or no commercial importance in each management region, In 1981, the OY for total BSAI groundfish catch was set as a range from 1.4 to 2.0 million mt. In 2002, the recommended ABC for pollock in the EBS was greater than the OY ceiling and was therefore capped to stay within the OY range. Because the 2002 EBS pollock TAC was capped by the OY ceiling, F was lower than that deemed to be biologically acceptable. Therefore, in relative terms, subsequent increases in F expected to occur under PA.1 for EBS pollock may not result in significantly adverse effects to predators in terms of the biomass of prey available, despite being categorized as such under the established significance criteria. The harvest of EBS pollock under the PA.1 management regime meets the criteria of a significantly adverse impact to Steller sea lions, although the actual effects are likely insignificant due to the low fishing mortality under the baseline.

The fishing mortality rate of GOA pollock is expected to decrease by an average of 23 percent relative to the comparative baseline over the next five years under PA.1. This change in the fishing mortality rate is significantly beneficial for Steller sea lions. Fishing mortality rates are not calculated for Aleutian Islands pollock as there was no directed Aleutian Islands pollock fishery under the baseline conditions. There is no change in the projected catch of Aleutian Islands pollock between the baseline and PA.1 and therefore effects of Aleutian Islands pollock harvests are deemed to be insignificant to Steller sea lions at the population level.

Under PA.1, the BSAI Pacific cod fishing mortality rate is expected to decrease by 19 percent. This change is determined to be insignificant to Steller sea lions according to the criteria established in Table 4.5-61. Under PA.1, the GOA Pacific cod fishing mortality rate is expected to increase by 19 percent which was determined to be insignificant to Steller sea lions. Changes in Aleutian Islands Atka mackerel harvest are expected to be significantly adverse to Steller sea lions with an expected increase in the fishing mortality rate of 60 percent relative to the baseline under PA.1.

Little difference is expected relative to the baseline and among the alternatives for the harvest of other and non-target species that are prey for Steller sea lions (e.g., cephlapods and forage fish such as capelin). Changes in the harvest of these species under the various FMP alternatives were determined to be insignificant to Steller sea lions.

The comparative baseline conditions include all Steller sea lion protection measures that were adopted in 2001 (NMFS 2001a). These measures would be retained under PA.1 and include provisions to protect prey resources such as area closures, critical habitat harvest limits on prey species, gear and TAC restrictions, and a modified global harvest control rule to prohibit fishing when spawning biomass per recruit is reduced to 20% of the unfished level. With these controls, the combined harvest of prey was found to not jeopardize the continued existence of the western populations of Steller sea lions (NMFS 2001a). While ratings for harvest of individual prey species range from significantly beneficial to significantly adverse, overall harvest levels under PA.1 would be similar to the 2002 baseline conditions and are thus considered insignificant to the western population of Steller sea lions.

Spatial and Temporal Concentration of the Fishery

The criterion used to evaluate the spatial and temporal effects of the groundfish fisheries on marine mammal populations is that the FMP would be expected to result in either increased or decreased spatial and temporal concentrations in key marine mammal foraging areas and periods such that prey resources are altered to the extent that population-level effects would be expected to occur. The spatial/temporal measures under the baseline conditions were designed with the objective of reducing competitive interactions between groundfish fisheries and Steller sea lions in their key foraging areas during periods that are believed to be critical to Steller sea lions. Opportunistic sightings of Steller sea lions (sightings reported ancillary to other activities; e.g., surveys for other species, fishing, or shipping) indicate that Steller sea lions occur in offshore areas where protective measures designed to reduce fishing and sea lion interactions have not been instituted (POP 1997). The potential for competitive interactions between groundfish fisheries and Steller sea lions exists in areas that are not managed with seasonal or spatial fishery closures, yet where sea lions are known to occur. Under the baseline conditions, such potential interactions are thought to be reduced by overall groundfish harvest limits, also referred to as global controls. Additionally, groundfish fisheries have been dispersed in time and space under the baseline conditions, such that the competitive interactions with Steller sea lions are thought to be mitigated to a level that is not expected to appreciably reduce the likelihood of survival and recovery of the western population of Steller sea lions in the wild. Spatial and temporal fishing measures in PA.1 do not deviate from the baseline; thus, the effects of the spatial/temporal concentration of the fisheries under PA.1 are determined to be insignificant to Steller sea lions according to the criteria established in Table 4.1-6.

Disturbance

With regard to disturbance, existing management measures are designed to reduce nearshore disturbance of Steller sea lions. In particular, the prohibition of vessel entry within 3 nm of major rookeries avoids intentional and unintentional hazing of hauled out sea lions or those aggregated near shore. A total of 3,250 square kilometer (km^2) around 36 sites is offered this protection.

It is not clear what might constitute adverse disturbance elsewhere, such as in pelagic foraging areas. Vessel traffic, nets moving through the water column, or underwater sound production may all represent perturbations, which could affect foraging behavior, but few data exist to determine their relevance to Steller sea lions. The influence of trawl activities on Steller sea lion foraging success can not be addressed directly with existing data. Foraging could potentially be affected not only by interactions between vessels and sea lions, but also as a function of changes in fish schooling behavior, distributions or densities in response to harvesting activities. In other words, disturbance to the prey base may be as relevant a consideration as disturbance to the predator itself.

For the purposes of this analysis, it is recognized that some level of prey disturbance may occur as a fisheries effect. The impact on marine mammals who prey on fish schools is a function of both the amount of fishing activity and its concentration in space and time, neither of which may be extreme enough under the status quo to represent population level concerns. To the extent that the baseline condition imposes limits on fishing activities inside critical habitat, it is assumed some protection from these disturbance effects is currently provided. These protections occur as byproducts of other actions that either reduce fishing effort or create buffer zones to limit impacts on foraging. With these measures in place, the baseline is consistent with the underlying goal of reducing disturbance effects.

Anecdotal evidence suggests that fisheries/disturbance related events are unlikely to be of consequence to the Steller's population as a whole. For instance, vessel traffic and underwater sound production have long been features of the Bering Sea and GOA, at least over much of the twentieth century. Such circumstances have prevailed before, as well as after the decline of Steller sea lions, suggesting no obvious causal link. Steller sea lions also appear to be tolerant of at least some anthropogenic effects, recognizing their attraction to fish processing facilities and gillnets as well as their distributions in proximity to ports. Further, the eastern population of Steller sea lions is increasing, despite anthropogenic activities throughout their range on the west coast of North America and particularly in southeast Alaska. The management regime under PA.1 is not expected to result in increased disturbance to Steller sea lions relative to the baseline and are therefore rated insignificant.

Cumulative Effects PA.1 – Western Distinct Population Segment of Steller Sea Lions

The past/present effects on the western population of the Steller sea lions are described in Section 3.8.1 (Table 3.8-1) and the predicted direct/indirect effects of the groundfish fishery under PA.1 are described above (Table 4.9-5). Representative direct effects used in this analysis include mortality and disturbance with the major indirect effects bring change in prey availability and change in the spatial and temporal concentration of the fisheries (Table 4.1-6).

Mortality

- **Direct/Indirect Effects.** The level of mortality resulting from incidental take and entanglement in marine debris under PA.1 occurs at frequencies that do not have population level effects on the western population of Steller sea lions and is therefore considered insignificant.

- **Persistent Past Effects**. Substantial mortality of Steller sea lions did not occur in the fisheries until after the 1950s. The take of Steller sea lions was substantial after this time with over 20,000 animals believed to have been incidentally killed in the foreign and JV groundfish fisheries from 1966 to 1988, although data from this period is not complete (Perez and Loughlin 1991). In the BSAI groundfish trawl fisheries, incidental take has declined from about 20 per year in the early 1990s to an average of 7.8 sea lions per year from 1996-2000. The number of Steller sea lions incidentally taken by state-managed nearshore salmon gillnet fisheries and halibut longline fisheries estimated 14.5 sea lions per year in the PWS drift gillnet fisheries (Wynne et al. 1992). It is thought that shooting used to be a significant source of mortality prior listing the Steller sea lion as endangered under the ESA. Two cases of illegal shooting were prosecuted in the Kodiak area in 1998 involving two Steller sea lions from the western population (Angliss et al. 2001). The subsistence harvest in western stock has decreased from over the last ten years from 547 to 171 animals per year (1992-1998) (Angliss and Lodge 2002). Commercial harvest of sea lions for hides and meat occurred prior to 1900 and likely depleted some local populations. Over a nine year period, 1963 to 1972, more than 45,000 Steller sea lion pups were taken for commercial purposes (Merrick et al. 1987). Predation by transient killer whales and sharks has always contributed to the natural mortality of Steller sea lions, but the numbers of sea lions taken and the relative contribution of this factor to the recent population decline and lack of recovery is currently under investigation (Matkin *et al.* 2001, Matkin *et al.* 2003, Springer *et al.* 2003).

- **Reasonably Foreseeable Future External Effects**. Incidental take in the state-managed fisheries such as salmon gillnet fisheries will continue in the foreseeable future, but the numbers of Steller sea lions will likely be relatively low (less than ten per year). Entanglement and intentional shootings would be expected to continue at a similar level to the baseline condition. Pollution is unlikely to be a significant contributor to western Steller sea lion mortality due to its isolation from population centers. Predation will continue to contribute to natural mortality, but climate change and regime shifts would not be expected to have direct effects on mortality of Steller sea lions.

- **Cumulative Effects**. The cumulative effect of mortality based on the contribution of internal effects of the groundfish fishery under PA.1 and external mortality factors is considered significantly adverse for the western population of Steller sea lions. The western population of Steller sea lions has declined approximately 80 percent since the 1970s and was listed as endangered under the ESA in 1997. A number of human-caused mortality factors have been identified as potentially contributing to this decline and lack of recovery. According to current estimates, incidental take from the BSAI and GOA groundfish fisheries and other fisheries (29 individuals) and subsistence harvest (198 individuals), exceeds the PBR (208 individuals) for the western population of Steller sea lions (Angliss and Lodge 2002). In addition, natural mortality factors such as predation by transient killer whales and sharks, may be relatively more important for a depressed population and may be inhibiting the recovery of the Steller sea lion population. Since the population is still depressed from historic levels and has not recovered to the point that a recovery rate can be reliably calculate, and because overall human-caused mortality exceeds the PBR for this population, the cumulative effect of all mortality factors is considered significantly adverse for the western population of Steller sea lions. The contribution of the groundfish fisheries under PA.1 is expected to be small compared to total human-caused mortality and to be similar to the baseline level, which has been determined not to jeopardize the continued existence or recovery of the western population under the ESA (NMFS 2001a).

Prey Availability

- **Direct/Indirect Effects.** The harvest of Steller sea lion prey species by the groundfish fisheries under PA.1 is similar to the baseline condition and is expected to result in insignificant population-level effects to Steller sea lions.

- **Persistent Past Effects**. Past effects on key prey species of Steller sea lions include harvest of species that are targeted or taken as bycatch by the GOA groundfish fisheries and parallel fisheries in State of Alaska waters, and partial overlap with other state-managed fisheries. These species were targeted in the past foreign and JV groundfish fisheries. There is substantial evidence that nutritional stress played an important role in the rapid decline of the western population of Steller sea lions during the late 1970s and 1980s and one hypothesis is that the combined fisheries, perhaps in conjunction with climate and oceanographic fluctuations, greatly reduced the availability of forage fish to Steller sea lions. NMFS has issued a number of BiOps since 1991 that analyzed the key issue of whether the groundfish fisheries were contributing to the decline of sea lion populations or causing adverse impacts to their critical habitat, with most of the focus on the western population. The most recent Steller sea lion BiOp and EIS (NMFS 2001b and 2001c) explores this subject in great depth.

- **Reasonably Foreseeable Future External Effects**. State-managed fisheries such as salmon and herring are expected to continue in future years in a generally similar manner to the baseline conditions. New fisheries in State of Alaska or federal waters are not anticipated. Climate changes and regime shifts were identified as potential effects on the availability of prey, but the direction or magnitude of these changes are difficult to predict. Climate induced changes have been suspected in the decline of the western Steller sea lion population.

- **Cumulative Effects**. The cumulative effect on prey availability for Steller sea lions is based on direct, indirect, and external effects on prey and is considered conditionally significant adverse. This rating is based on the adverse effects on prey availability in the past from foreign, JV, and domestic groundfish fisheries, the state-managed salmon and herring fisheries, and indications that prey availability has been a key factor in the decline of the western population over the last several decades. This rating is conditional based on the uncertainty of whether future harvests from all fisheries will combine with natural fluctuations to affect prey availability such that the western population of the Steller sea lion continues to decline or is delayed in its recovery.

Spatial and Temporal Concentration of Fisheries

- **Direct/Indirect Effects.** The spatial and temporal concentration of the fisheries under PA.1 does not substantially deviate from the baseline condition. Thus, the effects of the spatial/temporal concentration of the fisheries under PA.1 are determined to be insignificant to Steller sea lions.

- **Persistent Past Effects**. Past foreign, JV, and domestic groundfish fisheries, as well as state-managed fisheries for salmon and herring have all attempted to maximize their catch per unit effort by concentrating their fishing at times and places where fish are most concentrated. There is substantial evidence that nutritional stress played an important role in the rapid decline of the western population of Steller sea lions during the late 1970s and 1980s and one hypothesis is that the combined fisheries caused localized depletion of forage fish. Past changes in the domestic groundfish harvest regulations have dispersed the fishing effort in time and space in order to minimize the potential for localized depletion of Steller sea lion prey. Minimizing the competitive overlap between the fisheries and Steller sea lions is the primary focus of sea lion protective measures, which constitute the baseline condition.

- **Reasonably Foreseeable Future External Effects**. The only reasonably foreseeable future factors external to the groundfish fisheries that may affect the survivability and/or reproductive success of the western Steller sea lion population include the state-managed salmon and herring fisheries, which remove Steller sea lion prey during the spring and summer months. These fisheries are expected to continue to be managed in a manner similar to recent years. No new State of Alaska or federal fisheries are anticipated at this time.

- **Cumulative Effect**. The cumulative effect of the spatial/temporal harvest of prey is based on past and future effects of the groundfish fisheries and state-managed fisheries and is considered conditionally significant adverse. Although there are several hypotheses regarding the decline and lack of recovery of Steller sea lions, localized depletion of prey due to commercial fishing is a plausible mechanism for population level effects. This rating is conditional based on the uncertainty of whether future harvests from all fisheries will combine to cause localized depletion of prey in key areas such that the western population of the Steller sea lion continues to decline or is delayed in its recovery.

Disturbance

- **Direct/Indirect Effects**. Current federal groundfish fisheries disturbance to the western population of Steller sea lions is considered insignificant under the baseline condition. Since PA.1 retains the area closures contained under the baseline, disturbance levels under this PA.1 would also be considered insignificant at the population-level.

- **Persistent Past Effects**. Past sources of disturbance on the western population of Steller sea lions include foreign, JV, and domestic groundfish fisheries, and state-managed fisheries. Commercial harvests, intentional shootings, and subsistence harvests of Steller sea lions have also been identified as disturbance sources. General vessel traffic and disturbances to the prey field from gear have regularly occurred in the past.

- **Reasonably Foreseeable Future External Effects**. Future disturbance is expected at some level from state-managed salmon and herring fisheries, as well as general fishing and non-fishing vessel traffic in Steller Sea lion foraging areas. Subsistence harvest is identified as a continuing source of disturbance to Steller sea lions. The level of disturbance is expected to be similar to the baseline conditions.

- **Cumulative Effects**. The level of disturbance to Steller sea lions resulting from internal and external effects is expected to be similar to baseline conditions, and is rated as insignificant under PA.1.

Direct/Indirect Effects PA.2 – Western Distinct Population Segment of Steller Sea Lions

Incidental Take/Entanglement in Marine Debris

Effects do not deviate from those described under PA.1 for the western population of Steller sea lions and are considered insignificant.

Fisheries Harvest of Prey Species

Under PA.2, the fishing mortality rate of EBS pollock is expected to increase by an average of 28 percent relative to the comparative baseline. According to the significance criteria for effects on marine mammals the change in the harvest of this key Steller sea lion prey species is considered to be significantly adverse (see the discussion under PA.1 regarding the aberrant fishing mortality rate in 2002, which served as the comparative baseline.) The harvest of EBS pollock under the PA.2 management regime meets the criteria of a significantly adverse impact to Steller sea lions, although the actual effect on Steller sea lions is likely not as significant in terms of the biomass of prey available, as discussed under PA.1.

The fishing mortality rate of GOA pollock is expected to decrease by an average of 23 percent relative to the comparative baseline over the next five years under PA.2. This change in F is rated as significantly beneficial under the PA.2 scenario for Steller sea lions. Fishing mortality rates are not calculated for Aleutian Islands pollock as there was no directed Aleutian Islands pollock fishery under the baseline conditions. There is no change in the projected catch of Aleutian Islands pollock between the baseline and PA.2; therefore, the effects of Aleutian Islands pollock harvests are deemed to be insignificant to Steller sea lions at the population level for this FMP.

Under PA.2, the BSAI and GOA Pacific cod fishing mortality rates are expected to decrease by 11 percent and increase six percent, respectively, over the next five years. These respective changes are determined to be insignificant to Steller sea lions. Changes in Aleutian Islands Atka mackerel harvest are expected to be insignificant to Steller sea lions under the PA.2, with a projected increase in F of 15 percent relative to the baseline. Harvest of Aleutian Islands Atka mackerel under PA.2 would be insignificant to the western population of Steller sea lions.

Little difference is expected relative to the baseline and among the alternatives for harvest of other and non-target species that are prey for Steller sea lions (e.g., cephlapods and forage fish such as capelin). Changes in the harvest of these species under the various FMP alternatives were determined to be insignificant to Steller sea lions.

Under the comparative baseline conditions, the combined harvest of prey was found to not jeopardize the continued existence of the western populations of Steller sea lions (NMFS 2001a).While ratings for harvest of individual prey species range from significantly beneficial to significantly adverse, overall harvest levels under PA.2 would be somewhat reduced from the 2002 baseline conditions and are thus considered insignificant to the western population of Steller sea lions.

Spatial and Temporal Concentration of the Fishery

The criterion used to evaluate the spatial and temporal effects of the groundfish fisheries on marine mammal populations is that the FMP would be expected to result in either increased or decreased spatial and temporal concentrations in key marine mammal foraging areas, and periods such that prey resources are altered to the extent that population-level effects would be expected to occur. The potential for competitive interaction between groundfish fisheries and Steller sea lions exists in areas that are not managed with seasonal or spatial fishery closures, yet where Steller sea lions are known to occur. Under the baseline conditions, such potential interactions are thought to be reduced by overall groundfish harvest limits, also referred to as global controls. Additionally, groundfish fisheries have been dispersed in time and space under the baseline conditions, such that the competitive interactions with Steller sea lions are thought to be mitigated to a level that is not expected to appreciably reduce the likelihood of survival and recovery of the western population of Steller sea lions in the wild. The PA.2 alternative bookend offers opportunities for additional temporal and spatial protection by adjusting current protection measures as appropriate scientific information becomes available to avoid jeopardy to ESA-listed Steller sea lions. Future protective measures would be in addition to those that exist for Steller sea lion protection under the baseline conditions and have the potential to provide beneficial effects to Steller sea lions. However, because additional spatial and temporal measures may or not be adopted and would depend on future research, no specific measures have been added or repealed under PA.2 so the spatial and temporal concentration of the fishery is not expected to significantly change relative to the baseline. PA.2 is therefore rated as insignificant for this effect.

Disturbance

Effects do not deviate from those described under PA.1 and are considered insignificant.

Cumulative Effects PA.2 – Western Distinct Population Segment of Steller Sea Lions

The past/present effects on the western population of Steller sea lions are described in Section 3.8.1 (Table 3.8-1) and the predicted direct/indirect effects of the groundfish fishery under PA.2 are described above (Table 4.9-5). Representative direct effects used in this analysis include mortality and disturbance with the major indirect effects being change in prey availability and change in the spatial/temporal concentration of the fisheries (Table 4.1-6).

Mortality

- **Direct/Indirect Effects.** With regard to incidental take and entanglement, PA.2 is likely to have insignificant effects on the population trajectory of the western population of Steller sea lions.

- **Persistent Past Effects**. Past sources of mortality are the same as discussed under PA.1.

- **Reasonably Foreseeable Future External Effects**. Reasonably foreseeable future sources of mortality are the same as discussed under PA.1.

- **Cumulative Effects**. The level of mortality resulting from the internal groundfish fisheries and external sources is expected to exceed the PBR for this population. Thus, the cumulative effects under PA.2 are rated as significantly adverse. The contribution of the groundfish fisheries is very small in comparison to the total human-caused mortality and is not considered to cause jeopardy under the ESA (NMFS 2001a).

Prey Availability

- **Direct/Indirect Effects.** Under PA.2, the federal groundfish harvest of Steller sea lion prey species is expected to be similar to the baseline condition and is rated as insignificant.

- **Persistent Past Effects**. Past effects are the same as discussed under PA.1.

- **Reasonably Foreseeable Future External Effects**. The reasonably foreseeable future effects are the same as discussed under PA.1.

- **Cumulative Effects**. Cumulative effects on the fishing mortality rate of prey species resulting from internal and external removals is considered conditionally significant adverse. This rating is conditional on whether future combined harvests of Steller sea lion prey are a key factor in the continued decline or lack of recovery of the western population of Steller sea lions.

Spatial and Temporal Effects of Harvest

- **Direct/Indirect Effects.** Under PA.2, the effects of the spatial/temporal concentration of the groundfish fisheries are determined to be similar to those under baseline conditions and are thus rated as insignificant.

- **Persistent Past Effects**. Persistent past effects are the same as those described under PA.1.

- **Reasonably Foreseeable Future External Effects**. Reasonably foreseeable future external effects are the same as described under PA.1.

- **Cumulative Effect**. The cumulative effect of the spatial/temporal harvest of prey is based on past and future effects of the groundfish fisheries and state-managed fisheries and is considered conditionally significant adverse. Although there are several hypotheses regarding the decline and lack of recovery of Steller sea lions, localized depletion of prey due to commercial fishing is a plausible mechanism for population level effects. This rating is conditional based on the uncertainty of whether future harvests from all fisheries will combine to cause localized depletion of prey in key areas such that the western population of the Steller sea lion continues to decline or is delayed in its recovery.

Disturbance

- **Direct/Indirect Effects**. The level of disturbance under PA.2 is expected to be similar to the baseline condition and is therefore considered insignificant.

- **Persistent Past Effects**. Past disturbance sources are the same as discussed under PA.1.

- **Reasonably Foreseeable Future External Effects**. The reasonably foreseeable future sources of disturbance are the same as discussed under PA.1.

- **Cumulative Effects**. The level of disturbance resulting from internal and external sources is expected to be similar to the baseline condition and is therefore considered insignificant.

4.9.8.2 Eastern Distinct Population Segment of Steller Sea Lions

Direct/Indirect Effects PA.1 – Eastern Distinct Population Segment of Steller Sea Lions

Incidental Take/Entanglement in Marine Debris

With regard to incidental take, PA.1 is not likely to result in significant changes to the population trajectory of the eastern distinct population segment (eastern population) of Steller sea lions. No Steller sea lions from the eastern population were taken incidentally by groundfish fisheries from 1995-1999 (Angliss *et al.* 2001) (Table 4.5-60). In this context, incidental take refers to animals which are deceased or have injuries that are expected to result in death. Because no animals from the eastern population have been taken incidentally by groundfish fisheries, changes in catch resulting from PA.1 are not expected to result in an increase in the level of incidental takes.

Entanglement of Steller sea lions from the eastern population in derelict fishing gear or other materials seems to occur at frequencies that do not have significant effects on the population. Thus, incidental take and entanglement in marine debris under PA.1 is insignificant according to the significance criteria (Table 4.1-6).

Fisheries Harvest of Prey Species

BSAI groundfish fisheries are not likely to have large impacts on the prey availability of the eastern population of Steller sea lions, as there is little overlap with this population and fisheries which harvest Steller sea lion prey species. Only fisheries in the GOA would be expected to affect the eastern population of Steller sea lions. Average fishing mortality rates of GOA pollock and Pacific cod under PA.1 are expected to decrease by 23 percent and increase by 19 percent, respectively, relative to the comparative baseline over the next five years. Changes in the fishing mortality rates expected to occur under PA.1 are significantly beneficial for GOA pollock and insignificant for Pacific cod harvests.

Little difference is expected relative to the baseline and among the alternatives for harvest of other, non-target species that are prey for Steller sea lions (e.g., cephlapods and forage fish such as capelin). Changes in the harvest of these species under the various FMP alternatives were determined to be insignificant to Steller sea lions.

The combined harvest of prey species for the eastern population of Steller sea lion under PA.1 is expected to be similar or less than the baseline conditions and have insignificant population-level effects on the eastern population of Steller sea lions.

Spatial and Temporal Concentration of the Fishery

The groundfish fisheries have been dispersed in time and space under the baseline conditions, such that the competitive interactions with Steller sea lions are thought to be mitigated to a level that is not expected to appreciably reduce the likelihood of survival and recovery of the eastern population of Steller sea lions. The spatial and temporal concentration of the fishery under PA.1 is not expected to change significantly relative to the baseline and is therefore rated as having insignificant effects on Steller sea lions.

Disturbance

PA.1 retains the area closures contained under the baseline. The management regime under PA.1 is not expected to result in increased disturbance to Steller sea lions relative to the baseline. The effects of disturbance are rated insignificant under the PA.1 management scenario.

Cumulative Effects PA.1 – Eastern Distinct Population Segment of Steller Sea Lions

The past/present effects on the eastern population of the Steller sea lion are described in Section 3.8.1 (Table 3.8-1) and the predicted direct/indirect effects of the groundfish fishery under PA.1 are described above (Table 4.9-5). Representative direct effects used in this analysis include mortality and disturbance with the major indirect effects being change in prey availability and change in spatial/temporal concentration of the fisheries (Table 4.1-6).

Mortality

- **Direct/Indirect Effects**. With regard to incidental take and entanglement, PA.1 is not likely to result in significant changes to the population trajectory of the eastern population of Steller sea lions.

- **Persistent Past Effects.** It is thought that shooting used to be a significant source of mortality prior to listing the Steller sea lion as threatened on the ESA. NOAA Fisheries, Alaska Enforcement Division has successfully prosecuted two cases of illegal shooting involving four Steller sea lions from the eastern population (Angliss *et al.* 2001). It is not known to what extent illegal shooting continues in the eastern population, but stranding of Steller sea lions with bullet holes still occurs. Predator control programs associated with mariculture facilities in British Columbia accounts for a mean of 44 animals killed per year from the eastern population (Angliss *et al.* 2001). The subsistence harvest in the eastern population of the Steller sea lion is very small and consists of an average of two Steller sea lions taken per year from southeast Alaska (1992-1997) (Angliss and Lodge 2002). Commercial harvest of Steller sea lions for hides and meat occurred prior to 1900 and likely depleted local populations. Over a nine year period (1963 to 1972) more than 45,000 Steller sea lion pups were taken for commercial purposes (Merrick *et al.* 1987). The proportion of these from the eastern population are unknown. Steller sea lions are incidentally taken in low numbers by commercial fisheries other than groundfish fisheries, including some state-managed salmon drift and set gillnet fisheries and the salmon troll fishery in southeast Alaska (mean of 1.25 and 0.2, respectively) (Angliss *et al.* 2001). Small numbers of Steller sea lions from the eastern population are taken outside of southeast Alaska in groundfish fisheries (0.45 per year in Washington, Oregon, and California) and set gillnet fisheries in northern Washington State (0.2 per year) (Angliss *et al.* 2001). The PBR for this population is 1,396 and current human caused mortality is 45.5, substantially less than ten percent of the PBR.

- **Reasonably Foreseeable Future External Effects.** Incidental take in the state-managed fisheries such as salmon gillnet and troll fisheries will continue in the foreseeable future but the numbers of Steller sea lions will likely be relatively low (less than ten per year). Groundfish fisheries in Washington, Oregon and California and salmon set gillnets fisheries will continue to take small numbers from this population. Entanglement and intentional shootings would be expected to continue. Pollution is likely more of a factor for this population due to its closer association with population centers. Climate changes and regime shifts would not be expected to have direct effects on mortality of Steller sea lions.

- **Cumulative Effect.** The level of take resulting from internal effects of the groundfish fisheries and external mortality effects are expected to have a negligible impact on the eastern population of Steller sea lions. These combined effects are considered insignificant since the overall human-caused mortality does not approach the PBR for this population. Although this population is listed as threatened under the ESA, the population has been increasing over the last 20 years. The contribution of the groundfish fisheries is very small in comparison to the total human-caused mortality and is not determined to cause jeopardy under the ESA (NMFS 2001a).

<u>Effects of Prey Availability</u>

- **Direct/Indirect Effects.** The fishing mortality rate of Steller sea lion prey species under PA.1 is similar to baseline conditions and is not expected to result in population-level effects.

- **Persistent Past Effects**. Past effects on key prey species of Steller sea lions include harvest of species that are targeted or taken as bycatch by the GOA groundfish fisheries and parallel fisheries in State of Alaska waters, and partial overlap with other state-managed fisheries. These species were also targeted in the past foreign and JV groundfish fisheries. NOAA Fisheries issued a number of BiOps since 1991 that analyzed the key issue of whether the groundfish fisheries were contributing to the decline of sea lion populations or causing adverse impacts to their critical habitat, although most of the focus was on the western population. The most recent Steller sea lion BiOp and EIS (NMFS 2001b and 2001c) explores this subject in great depth.

- **Reasonably Foreseeable Future External Effects**. State-managed fisheries such as salmon and herring are expected to continue in future years in a generally similar manner to the baseline conditions. New fisheries in State of Alaska or federal waters are not anticipated. Climate changes or regime shifts were identified as potentially having adverse effects of availability of prey, but the direction or magnitude of these changes are difficult to predict. Climate induced change has been suspected in the decline of the western population Steller sea lion, but effects of climate change or regime shifts on the eastern population of the Steller sea lion are largely unknown.

- **Cumulative Effects**. The cumulative effects of prey availability on the eastern population of the Steller sea lion are considered to be insignificant at the population level. The eastern population of Steller sea lions has been increasing steadily over the last 20 years so prey availability is not considered to be limiting the recovery of the population.

<u>Spatial and Temporal Concentration of the Fishery</u>

- **Direct/Indirect Effects.** The spatial and temporal concentration of the fisheries under PA.1 is not expected to deviate from the baseline and is therefore determined to be insignificant to the eastern population of Steller sea lions.

- **Persistent Past Effects.** Past effects of spatial and temporal harvest of prey were identified for foreign, JV, federal and domestic groundfish fisheries and state-managed fisheries for salmon and herring. Past changes in the groundfish harvest have dispersed the fishing effort in time and space in order to minimize effects on Steller sea lions. Minimizing the competitive overlap between the fisheries and Steller sea lions is the primary focus of sea lion protective measures, which remain in effect under PA.1.

- **Reasonably Foreseeable Future External Effects.** State-managed fisheries such as salmon set and drift gillnet fisheries, salmon troll fisheries and herring fisheries are expected to continue in future years in a manner similar to the baseline conditions.

- **Cumulative Effects**. The cumulative effect of the spatial and temporal harvest of prey based on both internal effects of the groundfish fishery and external effects, such as the state-managed fisheries, is likely to remain similar to the baseline condition, which has occurred while the population has increased steadily, and is therefore considered insignificant for the eastern population of Steller sea lions.

<u>Disturbance</u>

- **Direct/Indirect Effects**. The disturbance levels on Steller sea lions under the PA.1 are expected to be similar to the baseline condition and are not expected to have a population-level effect. Therefore, PA.1 is considered insignificant. Protection measure around rookeries and haul-outs will continue under PA.1.

- **Persistent Past Effects.** Past disturbance was identified from foreign, JV, and federal domestic groundfish fisheries, and state-managed salmon and herring fisheries. General vessel traffic has also contributed to the disturbance level on this population. Intentional shooting has likely been a disturbance factor in past years.

- **Reasonably Foreseeable Future External Effects**. State-managed fisheries and vessel traffic will likely continue in the future at a level similar to the baseline conditions. Disturbance from subsistence harvest is not a issue for this population.

- **Cumulative Effects**. The cumulative effects on disturbance levels resulting from internal and external sources are expected to be similar to baseline conditions and are not likely to have a population-level effect. Therefore, disturbance under PA.1 is considered insignificant.

Direct/Indirect Effects PA.2 – Eastern Distinct Population Segment of Steller Sea Lions

Incidental Take/Entanglement in Marine Debris

Effects do not deviate from those described under the PA.1 bookend and are considered insignificant.

Fisheries Harvest of Prey Species

BSAI groundfish fisheries are not likely to have large impacts on the prey availability of the eastern population of Steller sea lions, as there is little overlap with this population and fisheries which harvest Steller sea lion prey species. Only fisheries in the GOA would be expected to affect the eastern population of Steller sea lions. Average fishing mortality rates of GOA pollock under PA.2 are expected to decrease 29 percent relative to the comparative baseline over the next five years. Average fishing mortality rates of GOA Pacific cod are expected to increase by six percent relative to the comparative baseline over the next five years. The changes in the fishing mortality rate expected to occur under PA.2 are significantly beneficial for GOA pollock and insignificant for Pacific cod harvests.

Little difference is expected relative to the baseline and among the alternatives for harvest of other and non-target species that are prey for Steller sea lions (e.g., cephlapods and forage fish such as capelin). Changes in the harvest of these species under the FMP alternatives were determined to be insignificant to Steller sea lions. The combined harvest of Steller sea lion prey species under PA.2 is expected to result in insignificant population-level effects on the eastern population of the Steller sea lions.

Spatial and Temporal Concentration of the Fishery

The spatial and temporal measures in PA.2 were designed with the objective of reducing competitive interactions between groundfish fisheries and Steller sea lions. The potential for competitive interaction between groundfish fisheries and Steller sea lions exists in areas that are not managed with seasonal or spatial fishery closures, yet where sea lions are known to occur. Under the baseline conditions, such potential interactions are thought to be reduced by overall groundfish harvest limits, also referred to as global controls. Additionally, groundfish fisheries have been dispersed in time and space under the baseline conditions, such that the competitive interactions with Steller sea lions are thought to be mitigated to a level that is not expected to appreciably reduce the likelihood of survival and recovery of the eastern population of Steller sea lions in the wild. PA.2 offers opportunities for additional temporal and spatial protections which would offer increased protection in areas determined to be important for Steller sea lions. These protective measures would be in addition to those that exist for Steller sea lion protection under the baseline conditions and have the potential to provide beneficial effects to Steller sea lions. However, because additional spatial and temporal measures may or not be adopted and would depend on future research, no specific measures have been added or repealed under PA.2 so the spatial and temporal concentration of the fishery is not expected to significantly change relative to the baseline. PA.2 is therefore rated as insignificant for this effect.

Disturbance

Effects do not deviate from those described under the PA.1 bookend and are considered insignificant.

Cumulative Effects PA.2 – Eastern Distinct Population Segment of Steller Sea Lions

For the eastern population of the Steller sea lions, the analysis and conclusions regarding cumulative effects for mortality, prey availability, spatial and temporal concentration of the fishery, and disturbance are the same as discussed under PA.1.

4.9.8.3 Northern Fur Seals

Direct/Indirect Effects PA.1 – Northern Fur Seals

Incidental Take/Entanglement in Marine Debris

The incidental take of northern fur seals is uncommon in the groundfish fisheries. The last recorded mortality in any Alaskan groundfish fishery occurred in 1996, when the take rate was one animal per 1,862,573 mt of groundfish harvested. Observer records from 1990 to 1999 indicate that direct interactions with groundfish vessels occurred only in the BSAI trawl fishery, despite observer placement in pot, longline and trawl fisheries in both the BSAI and GOA. In the BSAI trawl fishery, the average annual take rate (1995 to 1999) was 0.6. This level of take is inconsequential to population trends.

Northern fur seal entanglement in marine debris is more common than any other species of marine mammal in Alaskan waters (Laist 1987, 1997, Fowler 1987). Fowler (1987) concluded that mortality of northern fur seals from entanglement in marine debris contributed significantly to declining trends in the Pribilof Islands during mid to late 1970s and early 1980s. The contribution of intentional discard of net debris from Alaskan groundfish fisheries vessels is thought to have declined over the past decade. However, consistent numbers of seals entangled in packing bands on St. Paul Island may reflect disposal of these materials in proximity to the islands. Recent data from satellite-tracked drifters deployed in the Bering Sea suggests a "trapped" circulation pattern around the Pribilof Islands (Stabeno *et al.* 1999) which may retain marine debris in the nearshore environment. An increase in the number of Antarctic fur seals (*Arctocephalus gazella*) entangled in polypropylene packing bands was observed at Bird Island, South Georgia, in the late 1980s as these materials came into common usage by at-sea processing vessels (Croxall *et al.* 1990). Involuntary sources of marine debris, as in loss of gear, are diminishing as fishery cooperative systems develop (such as in the BSAI offshore pollock allocation). That is, as the pace of fisheries is slowed, there is less incentive to risk capital equipment. Data do not yet exist to assess the rates at which various gear types are lost or discarded to result in risk to fur seals, especially in regard to fishery or nation of origin. In consideration of progress in stemming the loss and discard of net fragments and other plastic debris by domestic commercial fisheries, the extent to which the current FMP could change the rate of fur seal entanglement in marine debris is considered to be low. There seem to be few options, given the likelihood that sources beyond the control of fisheries managers (i.e., foreign fisheries, international shipping, and shoreside refuse) constitute significant sources of discard. According to these factors and projected catch levels under PA.1, incidental takes and entanglements of northern fur seals are expected to occur incidental to groundfish fisheries at levels that are not expected to result in population-level effects. Increased harvest rates under this management alternative are not large enough for expected take levels to increase relative to the baseline. Therefore, this effect is rated insignificant under PA.1 as it is under baseline conditions.

Fisheries Harvest of Prey Species

The diet of northen fur seals includes a wide range of fish species, with less apparent dependence on Pacific cod and Atka mackerel compared to Steller sea lions. However, both adult and juvenile pollock occur in the diet of northern fur seals and consumption rates vary according to the abundance of different age classes of pollock in the foraging environment (Swartzman and Haar 1983, Sinclair *et al*. 1996). Because fur seals are opportunistic foragers, the presence of strong year-classes results in a disproportionately high percentage of that age class of pollock in the fur seal diet. Evaluation of the effects of harvest of prey species on northen fur seals, focuses less on removals of Pacific cod and Atka mackerel and more broadly on removals of pollock and small schooling fishes. Northen fur seals forage at shallow to mid-water depths of 0 to 820 ft (0-250 m), both near shore and in pelagic regions of their migratory range. Female and young male fur seals generally consume both juvenile and adult small-sized (2 to 8 inches) schooling fishes and squids although diet varies across oceanographic subregions along heir migration routes and around breeding location in the Pribilof Islands. In the eastern Bering Sea, primary prey species include pollock and pacific cod, but deep sea smelts, lanternfish, and squids are also major components. Studies based on scat analyses have indicated that the pollock and Pacific cod consumed by fur seals tend to be smaller than those selected by the target fisheries; however, data from stomach collections from the 1960s through the 1980s indicate that fur seals often consume adult pollock. Recent studies using bio-chemical methods to study the diet of northen fur seals suggest that the diet of deep diving fur seals in water over the continental shelf includes adult pollock (Kurle and Worthy 2000, Goebel 2002).

Under PA.1, the fishing mortality rate of EBS pollock is expected to increase by an average of 23 percent relative to the comparative baseline. Assuming that adult pollock are a key prey species of the northern fur seal, this change in the harvest is rated significantly adverse according to the significance criteria for effects on marine mammals. However, the actual effect of this increased harvest rate, in terms of biomass available, is likely insignificant due to the abnormally low fishing mortality under the comparative baseline (see the discussion regarding the aberrant fishing mortality rate of EBS pollock in 2002 in Section 4.9.8.1.)

Catches of squid and small schooling fish (e.g., fish designated in the forage fish assemblage) in the groundfish fisheries of the BSAI and GOA are low, generally less than 1,000 mt per year. While precise biomass estimates for these groups do not exist, the exploitation rate on these groups in the groundfish fisheries is thought to be very low. For instance, squid biomass in the Bering Sea may be as large as 4 million mt, based on marine mammal food habits, daily ration, and abundance data (Sobolevsky 1996). Similarly, with respect to small schooling fishes, consumption of capelin in the GOA by arrowtooth flounder alone may be as large as 300,000 mt per year (Livingston 1994). Assuming that these crude projections of squid and capelin biomass at least approximate the order of magnitude of the true population levels, then the fisheries removals would amount to only a fraction of one percent of those populations. Fisheries for pollock and Pacific cod do not target fish younger than 3 years of age (Ianelli *et al.* 1999, Dorn *et al.* 1999, Thompson and Dorn 1999, Thompson and Zenger 1994, Fritz 1996). Catches of pollock smaller than 30 centimeters (cm) are small, and thought to be only 1 to 4 percent of the number of one- and two-year olds each year in the EBS and GOA (Fritz 1996).

While fisheries do harvest prey of northern fur seals (i.e., pollock and Pacific cod), the harvest rates of those species in the size range consumed by fur seals tend to be low. Furthermore, the fraction of the northern fur seal diet composed of those species is a smaller fraction of the overall diet as compared, for instance, to Steller sea lions. The overall harvest of northern fur seal prey species is likely to be similar to the baseline condition and is therefore determined to be insignificant under PA.1.

Spatial and Temporal Concentration of the Fishery

Spatial and temporal fishing measures in PA.1 do not deviate from the baseline, thus the effects of the spatial/temporal concentration of the fisheries under the PA.1 are determined to be insignificant to northern fur seals according to the criteria established in Table 4.1-6. However, effects to northern fur seals from spatial/temporal concentration of the fisheries under the strategy defined as the baseline for this environmental analysis were rated conditionally significant adverse in the Steller sea lion SEIS (NMFS 2001b). Therefore, while the spatial/temporal effects of PA.1 are insignificant relative to the baseline, the baseline has been described as having potential adverse effects on northern fur seals.

In recent years, fishing effort for pollock has increased in nearshore areas around the Pribilof Islands (NMFS 2003) where northern fur seals are known to forage. The greatest potential for temporal overlap between northern fur seals and the pollock fishery in the eastern Bering sea is July through November. Under the baseline, pollock fisheries were extended in order to slow the pace of the fishery and may now occur from June through October. This disperses the harvest over a longer time period than in previous seasons, thereby reducing temporal concentration of the fisheries. However, this change also extends the fisheries into the summer months when fur seals are concentrated near the Pribilof Island rookeries and may thus increase the likelihood of localized effects in foraging areas near the Pribilofs (NMFS 2001b). Seasonally, the highest bycatch of small pollock occurs during the summer (May-July) when spawning aggregations have dispersed and pollock are generally less segregated by size (Fritz 1996). Given the expected temporal dispersal of the fisheries under PA.1 and the steadily increasing biomass trends for pollock, the magnitude of harvest and bycatch of species/size classes important to fur seals during the breeding season is not expected to cause localized depletion of prey to the point that the fur seal population as a whole will be affected. Therefore, the spatial/temporal concentration of the fishery under PA.1 is determined to be insignificant to northern fur seals.

Disturbance

Disturbance from the baseline level of fishing activities has not been implicated as a potential cause for the population decline of northern fur seals. PA.1 is expected to produce similar levels of disturbance as the baseline which are unlikely to have population-level effects and are therefore considered insignificant according to the significance criteria established in Table 4.1-6.

Cumulative Effects PA.1 – Northern Fur Seals

A summary of the effects of the past/present with regards to the northern fur seal are presented in Section 3.8.2. (Table 3.8-2). The predicted direct/indirect effects of the groundfish fishery under PA.1 are described above (Table 4.9-5). Representative direct effects used in this analysis include mortality and disturbance. Indirect effects include availability of prey an spatial and temporal concentration of the fisheries (Table 4.1-6).

Mortality

- **Direct/Indirect Effects**. Under PA.1, incidental take and entanglement is not expected to have a population-level effect and is rated as insignificant.

- **Persistent Past Effects**. Past effects of mortality on fur seal population include commercial harvest of young males up to 1985, harvest of females between 1956 and 1968, incidental take in the JV fisheries, foreign fisheries, and annual subsistence harvest on the Pribilof Islands. Commercial harvest of fur seals peaked in 1961 with over 126,000 animals, but was halted in 1985. The harvest of female fur seal on the Pribilof Islands, as many as 300,000 between 1956 and 1968, likely contributed to the decline of the population in the late 1970s and early 1980s (York and Kozloff 1987). This precipitous decline resulted in its depleted status under the MMPA. Entanglements may have contributed significantly to declining trends of the population during the late 1970's (Fowler 1987). Since the cessation of commercial harvest in 1985, fur seal number have steadily declined (NMFS 1993, Angliss and Lodge 2002). The contribution of the earlier harvest of fur seal to the subsequent decline is uncertain, since it has been nearly 20 years since commercial harvest was ended. Subsistence harvests have been one of the major contributors to fur seal mortality in recent years. From 1986 to 1996, the average annual subsistence take was 1,605 from St. Paul and St. George Islands. From 1995 to 2000 this average take dropped to 1,340 seals per year, which represents about 8 percent of the PBR for this species.

- **Reasonably Foreseeable Future External Effects**. These effects include incidental take from foreign fisheries outside the U.S. EEZ where fur seal are widely dispersed. State-managed fisheries take small numbers of fur seals, including the PWS drift gillnet fisheries, Alaska Peninsula and Aleutian Islands salmon gillnet fisheries, and the Bristol Bay salmon fisheries (Angliss *et al.* 2001). Subsistence will continue to be a major source of mortality in the future, but is limited to the Pribilof Islands. Levels of take are expected to be well below ten percent of the PBR for this species. Short-term and long-term climate changes are not considered a direct mortality factor for this species.

- **Cumulative Effects**. The cumulative effects of mortality resulting from internal and external effects are considered insignificant due to the large size of the fur seal population and the low levels of take, which are well below the PBR for this species. The contribution of the groundfish fisheries is very small and approaches zero.

Availability of Prey

- **Direct/Indirect Effects.** The effects of the groundfish fisheries under PA.1 include the removal of northern fur seal forage; however, the size of the fish removed is an important factor in determining whether competitive overlap with fisheries would occur. Overall, the harvest of northern fur seal prey species is rated as insignificant since the harvest rates of those species in the size range consumed by fur seals tend to be low.

- **Persistent Past Effects.** Effects of groundfish harvest in the past has likely occurred from overlap of prey species and fish targeted by the foreign and JV fisheries in the BSAI as well as the State of Alaska and federal fisheries. Climatic and oceanic fluctuations are suspected in past changes in the abundance and distribution of prey.

- **Reasonably Foreseeable Future External Effects**. Effects of fisheries on prey species harvest in the future are expected to include a small overlap in prey species with the state-managed fisheries in nearshore areas. Climate changes and regime shifts could influence prey species abundance and distribution. Climate effects are largely unknown, but could potentially have adverse effects on the availability of prey.

- **Cumulative Effects**. The cumulative effect of prey availability from both the internal contribution of the groundfish fisheries and external effects on prey such as other fisheries and possibly long-term climate change is considered conditionally significant adverse. This rating is based on the fact that the population declined substantially in the past for unknown reasons and that decreased prey availability is a plausible mechanism that could have contributed to the decline. Since the causal link between the population decline and the cumulative effects of all past fisheries on prey availability has not been established, the potentially adverse cumulative effects on northern fur seal through this mechanism are considered conditional.

Spatial/Temporal Concentration of Harvest

- **Direct/Indirect Effects**. The effects of the spatial and temporal concentration of the fisheries under PA.1 are determined to be insignificant to northern fur seals as they do not deviate from the spatial and temporal measures under the baseline conditions.

- **Persistent Past Effects**. Effects of past fisheries on prey availability are primarily from the foreign and JV fisheries and the state and federal domestic fisheries in the BSAI. There has been concern with regard to displaced/increased fishing effort that is encroaching into nearshore areas of the Pribilof Islands resulting in increased overlap with fur seal foraging habitat. The proportion of the total June-October pollock catch in fur seal foraging habitat increased from an average of 40 percent in 1995-1998 to 69 percent in 1999-2000 (NMFS 2001b). There is a particular concern for the potential impact of this increased fishing pressure on lactating females from St. George Island where catch rates were consistently higher than in areas used by females from St. Paul (Robson *et al.* 2004).

- **Reasonably Foreseeable Future External Effects**. Effects of the spatial and temporal harvest of prey species is primarily from the foreign and federal domestic fisheries outside the EEZ due to the extensive range of the fur seal. State-managed fisheries have very limited overlap with fur seal prey. Climate change was identified as a potential factor in spatial and temporal effects on prey.

- **Cumulative Effects**. The cumulative effect of the spatial/temporal harvest of prey based on the presence of internal and external factors is considered conditionally significant adverse. This rating is based on the fact that the population declined substantially in the past for unknown reasons and that localized depletion of prey is a plausible mechanism that could have contributed to the decline. Since the causal link between the population decline and the cumulative effects of all past fisheries on localized depletion of prey has not been established, and there is uncertainty regarding whether future fisheries harvests will contribute to the decreasing population trend, the potentially adverse cumulative effects on northern fur seal through this mechanism are considered conditional.

Disturbance

- **Direct/Indirect Effects.** Levels of disturbance are not expected to depart substantially from those which occurred to northern fur seals under the baseline conditions. Therefore, the effects of disturbance on northern fur seals are expected to be insignificant under PA.1.

- **Persistent Past Effects**. Persistent past effects on fur seal disturbance include commercial groundfish fisheries harvest by JV fisheries, foreign and federal domestic fisheries, and to a lesser extent, the subsistence harvest of fur seals on the Pribilof Islands. It is unknown whether these past activities have persisted to the present, but the ongoing fisheries continue to result in some level of disturbance to fur seals while they are in the BSAI region. Recent spatial and temporal measures associated with Steller sea lion protective measures have increased the overlap of fishing activity and northern fur seal foraging habitat (NMFS 2001b).

- **Reasonably Foreseeable Future External Effects**. Future disturbance effects on fur seals were identified as state-managed fisheries, general vessel traffic, and subsistence activities on the Pribilof Islands.

- **Cumulative Effects**. The cumulative effects of disturbance from internal and external factors are considered insignificant because there is little to indicate adverse effects occurring on the population level.

Direct/Indirect Effects PA.2 – Northern Fur Seal

Incidental Take/Entanglement in Marine Debris

Effects do not deviate from those described under PA.1 bookend and are considered insignificant.

Fisheries Harvest of Prey Species

Under PA.2, the fishing mortality rate of EBS pollock is expected to increase by an average of 34 percent relative to the comparative baseline. According to the significance criteria for effects on marine mammals the change in the harvest is rated significant assuming that adult pollock are a key northern fur seal prey species (see the discussion regarding the aberrant fishing mortality rate of EBS pollock in 2002 in Section 4.9.8.1).

While fisheries do harvest prey of northern fur seals (i.e., pollock and Pacific cod), the harvest rates of those species in the size range consumed by fur seals tend to be low. Furthermore, the fraction of the northern fur seal diet composed of those species is a smaller fraction of the overall diet as compared, for instance, to Steller sea lions. The overall harvest of northern fur seal prey species was rated insignificant under PA.2.

Spatial and Temporal Concentration of the Fishery

PA.2 includes provisions for future scientific research intended to help refine spatial/temporal protection measures that further reduce impacts of the fisheries on Steller sea lions. While past sea lion protection measures may have increased fishery impacts on northern fur seals by redirecting the fisheries into places and times that overlap with fur seal foraging habitat, PA.2 also includes a management objective to minimize impacts on non-ESA-listed species of marine mammals. Development of new spatial/temporal protection measures would therefore need to be a balance between protecting the interests of different species, including fur seals. Because additional spatial/temporal measures may or not be adopted and would depend on future research, no specific measures have been added or repealed under PA.2. For this analysis, it will be assumed that the spatial and temporal concentration of the fishery will be similar to the baseline or will be modified in such a way as to be relatively beneficial to prey fields of marine mammals in general. The spatial/temporal concentration of the fishery under PA.2 is therefore rated as having insignificant effects on northern fur seal.

Disturbance

Effects do not deviate from those described under the PA.1 bookend and are considered insignificant.

Cumulative Effects PA.2 – Northern Fur Seal

For northern fur seals, the analysis and conclusions regarding cumulative effects for mortality, prey availability, spatial and temporal concentration of the fishery, and disturbance are the same as discussed under PA.1.

4.9.8.4 Harbor Seals

Direct/Indirect Effects PA.1 – Harbor Seals

Incidental Take/Entanglement in Marine Debris

According to projected catch levels, incidental takes and entanglements of harbor seals incidental to groundfish fisheries under PA.1 are not expected to result in population-level effects. Increased harvest rates under this management FMP may result in the increased take of one harbor seal relative to the baseline, for a total estimated average of less than five animals per year. This level of incidental take would not result in changes to the population trajectory for this species. Therefore, takes and entanglements of harbor seals incidental to groundfish fisheries are determined to be insignificant according to the criteria established in Table 4.1-6.

Fisheries Harvest of Prey Species

The major prey of harbor seals in Alaskan waters include fish from the following families: Gadidae, Clupeidae, Cottidae, Pleuronectidae, Salmonidae, Osmeridae, Hexagrammidae, and Trichodontidae. Octopus and gonatid squid are also important. However, overlaps with commercial groundfish fisheries occur primarily with reference to pollock, Atka mackerel, and Pacific cod, which may constitute grounds for indirect interactions, particularly in the GOA and Aleutian Islands. However, the basis for concern is less pronounced than those noted for Steller sea lions, or even for northern fur seals, so that the overall effects are likely to be lower as well. Pollock, Atka mackerel, and Pacific cod constitute approximately 12, 9, and 8 percent, respectively, of harbor seal diet in the Aleutian Islands and Bering Sea (Perez 1990). In the GOA, pollock, octopus and capelin were reported by Pitcher and Calkins (1979) as the most important prey, while Pacific cod was less important and Atka mackerel were absent in the sample. Ashwell-Erickson and Elsner (1981) estimated that harbor seals and spotted seals combined consume approximately 81,600 mt of pollock per year, compared to current Bering Sea pollock biomass estimates (1998) of over 9 million mt. Pollock removals by fisheries are less than 10 percent of the biomass estimate, suggesting that in terms of volume, the unharvested fraction, under baseline conditions, is sufficient to satisfy harbor seal foraging needs.

Under PA.1, the fishing mortality rate of EBS pollock is expected to increase by an average of 23 percent relative to the comparative baseline. According to the significance criteria for the effects on marine mammals, the change in the harvest of this key harbor seal prey species is rated significant (see the discussion regarding the comparative baseline fishing mortality rate in Section 4.9.8.1.) The harvest of EBS pollock under the PA.1 management regime meets the criteria of a significantly adverse impact to harbor seals, but the actual effect in terms of biomass available is likely insignificant due to the unusually low fishing mortality under the baseline.

The fishing mortality rate of GOA pollock is expected to decrease by an average of 23 percent under the PA.1 bookend relative to the comparative baseline over the next five years and rated insignificant at the population level for harbor seals. Under the PA.1, the BSAI Pacific cod fishing mortality rate is expected to decrease by 19 percent, which is determined to be insignificant to harbor seals according to the criteria established in Table 4.1-6. Changes in Aleutian Islands Atka mackerel harvest under the PA.1 bookend is expected to be significantly adverse to harbor seals with a 61 percent increase in F relative to the baseline.

Little difference is expected relative to the baseline and among the alternatives for harvest of other and non-target species that are prey for harbor seals (e.g., cephlapods and forage fish such as capelin). Changes in the harvest of these species under the various FMP alternatives were determined to be insignificant to harbor seals.

Although there is overlap in species/size classes taken by the groundfish fisheries and harbor seal prey, harbor seals also consume a large amount of other prey species. Overall, the combined harvest of harbor seal prey species under PA.1 is not expected to increase substantially from the baseline condition or to result in population-level effects and is therefore considered insignificant.

Spatial and Temporal Concentration of the Fishery

The effects of the spatial and temporal concentration of the fisheries under PA.1 are determined to be insignificant to harbor seals as they do not deviate from the spatial and temporal measures under the baseline conditions.

Disturbance

The potential for disturbance effects caused by vessel traffic, fishing gear, or noise appears limited for harbor seals. These animals are common in inshore waters subjected to considerable levels of anthropogenic disturbances, typical of ports and shipping lanes. Interactions with groundfish fishing gear, such as trawl nets, also appears limited, based on the rare incidence of takes in the groundfish fisheries. Finally, given the near shore distribution of harbor seals, their overlap with fishing activities is more limited than in the case of either Steller sea lions or northern fur seals. Disturbance of harbor seals under PA.1 is not expected to increase relative to the baseline and is rated insignificant.

Cumulative Effects PA.1 – Harbor Seals

A summary of the effects of the past/present with regards to the harbor seal are presented in Section 3.8.4 (Table 3.8-4). The predicted direct/indirect effects of the groundfish fishery under PA.1 are described above (Table 4.9-5). Representative direct effects used in this analysis include mortality and disturbance. Indirect effects include availability of prey and spatial and temporal concentration of the fisheries (Table 4.1-6).

Mortality

- **Direct/Indirect Effects**. Incidental take and entanglements of harbor seals expected to occur incidentally in the groundfish fisheries under PA.1 are not expected to result in a population-level effect and are considered insignificant.

- **Persistent Past Effect**. Residual effects on local populations from State of Alaska predator control programs (1950s to 1972) and commercial hunts (1963 to 1972) may still exist in some areas, although there are no data on these factors. Foreign and JV groundfish fisheries in the 1960s and 1970s have likely contributed to some level of direct harbor seal mortality from entanglement in gear, but based on the near shore distribution of harbor seals, there was likely minimal direct interaction and mortality. From 1990 to 1996, minimum estimates of harbor seals taken incidentally in groundfish gear in the Bering Sea were four per year and less than one per year in the GOA. In southeast Alaska, four harbors seals are estimated to be killed each year on longlines. Harvest of harbor seals for subsistence purposes is likely the highest cause of anthropogenic mortality for this species, since the cessation of commercial harvests in the early 1970s. Between 1992 and 1998, the state-wide subsistence harvest of harbor seals from all stocks ranged between 2,546 and 2,854 animals, the majority of which are taken in southeast Alaska (Wolfe and Hutchinson-Scarbrough 1999). Harvest of the Bering Sea stock of harbor seals is approximately 161 animals, 42 percent of PBR for this species. For the GOA stock, the subsistence harvest is at approximately 91 percent of the PBR for this stock. For the southeast stock, subsistence harvest is at approximately 83 percent of PBR.

- **Reasonably Foreseeable Future External Effects**. Incidental take of harbor seal in state-managed fisheries such as salmon set and drift gillnet fisheries would be expected to continue at the present low rate. Subsistence take is expected to continue to be the greatest source of human controlled mortality with a relatively high percentage of the PBR in both the GOA and southeast Alaska stock, with a lower take in the BSAI region. Climate changes are not likely factors in the direct mortality of harbor seal, although there would likely be indirect effects.

- **Cumulative Effects**. The combined effects of mortality resulting from internal effects and external sources are determined to be insignificant. The human-caused mortality for all harbor seals is below the PBR for each stock and, therefore, population-level effects are unlikely.

Availability of Prey

- **Direct/Indirect Effects**. The combined harvest of harbor seal prey species under PA.1 is not expected to result in a population-level effect and is considered insignificant.

- **Persistent Past Effects**. Availability of prey for harbor seal in the past has likely been adversely affected by foreign, JV, and federal domestic groundfish fisheries and state-managed salmon and herring fisheries since the fish targeted by these fisheries are prey of the harbor seal. Climates changes regime shifts could have possibly been factors in fluctuations of prey availability in the past.

- **Reasonably Foreseeable Future External Effects**. State-managed salmon and herring fisheries are identified as potential adverse effects on harbor seal prey availability. Climate change regime shifts will continue to be contributing factors, although the effects can be either beneficial or adverse, depending on the direction and magnitude of the change.

- **Cumulative Effects**. The combination of internal effects of the groundfish fisheries and other external fisheries on prey availability were determined to be conditionally significant adverse. This rating is based on the fact that the population has declined substantially in the past for unknown reasons and that decreased prey availability is a plausible mechanism that could have contributed to the decline. Since the causal link between the population decline and the cumulative effects of all past fisheries on prey availability has not been established, the potentially adverse cumulative effects on harbor seals through this mechanism are considered conditional.

Spatial and Temporal Concentration of the Fishery

- **Direct/Indirect Effects.** The effects of PA.1 on the reproductive success and survivability of harbor seals resulting from the spatial and temporal concentration of the fisheries are rated as insignificant.

- **Persistent Past Effects.** Effects on harvest concentration in the past has likely occurred due to overlap of harbor seal prey species and fish targeted in areas fished by the foreign and JV fisheries in the BSAI, as well as the State of Alaska and federal fisheries. Climatic and oceanic fluctuations are not considered to be factors in past changes.

- **Reasonably Foreseeable Future External Effects**. Future changes in the spatial/temporal harvest could cause competitive overlap in prey species with the state-managed fisheries in nearshore areas, such as salmon and herring. Since these fisheries generally occur in the nearshore areas in comparison to other groundfish fisheries, overlap is more pronounced than with the groundfish fisheries. Effects of climate changes regime shifts on prey species may affect prey abundance and distribution.

- **Cumulative Effects**. The cumulative effect of the spatial/temporal harvest of prey from internal effects of the groundfish fisheries and external effects of other fisheries is considered to be conditionally significant adverse, based primarily on past effects and contributions from state-managed fisheries. This rating is based on the fact that the population has declined substantially in the past for unknown reasons and that localized depletion of prey is a plausible mechanism that could have contributed to the decline. Since the causal link between the population decline and the cumulative effects of all past fisheries on localized depletion of prey has not been established, the potentially adverse cumulative effects on harbor seals through this mechanism are considered conditional.

Disturbance

- **Direct/Indirect Effects.** Disturbance levels under PA.1 are expected to be remain similar to the baseline condition and are rated as insignificant.

- **Persistent Past Effects**. Past disturbances on harbor seals include foreign, JV, and federal domestic groundfish fisheries, and to a lesser extent, the subsistence harvest of harbor seal. It is unknown whether these past effects have persisted into the present population, but the ongoing fisheries activities and subsistence continue to result in some level of disturbance to harbor seal.

- **Reasonablely Foreseeable Future External Effects**. State-managed fisheries, general vessel traffic and subsistence activities would be expected to continue to create some level of disturbance to harbor seal in the foreseeable future.

- **Cumulative Effects**. Cumulative effects were identified for disturbances resulting from internal sources and external factors such as other fisheries. Effects are expected to be similar to the baseline conditions and are considered insignificant.

Direct/Indirect Effects PA.2 – Harbor Seals

Incidental Take/Entanglement in Marine Debris

Effects do not deviate from those described under the PA.1 bookend and are considered insignificant.

Fisheries Harvest of Prey Species

Under PA.2, the fishing mortality rate of EBS pollock is expected to increase by an average of 23 percent relative to the comparative baseline. According to the significance criteria for the effects on marine mammals, the change in the harvest of this key harbor seal prey species is considered to be significant. The harvest of EBS pollock under the PA.2 management regime meets the criteria of a significantly adverse impact to harbor seals, but the actual effect is likely insignificant due the unusually low fishing mortality under the baseline.

The fishing mortality rate of GOA pollock is expected to decrease by an average of 29 percent under the PA.2 bookend relative to the comparative baseline over the next five years, which is determined to be significantly beneficial to harbor seals. Under PA.2, the BSAI Pacific cod fishing mortality rate is expected to increase by 11 percent, which is determined to be insignificant to harbor seals according to the criteria established in Table 4.1-6. Changes in Aleutian Islands Atka mackerel harvest under the PA.2 bookend is expected to be insignificant to harbor seals with a 15 percent increase in F relative to the baseline.

Little difference is expected relative to the baseline and among the alternatives for harvest of other and non-target species that are prey for harbor seals (e.g., cephlapods and forage fish such as capelin). Changes in the harvest of these species under the various alternatives were determined to be insignificant to harbor seals. Overall, the combined harvest of harbor seal prey species under PA.2 is expected to be similar to the baseline and to result in insignificant population-level effects.

Spatial and Temporal Concentration of the Fishery

The PA.2 bookend offers opportunities for additional temporal and spatial protections relative to the baseline condition and may be more precautionary in regards to prey availablity. Under PA.2, additional protection for Steller sea lions, such as fishing closures and areas closed under MPAs or no-take preserves, would potentially offer increased protection to harbor seal foraging areas. These protective measures would be in addition to those that exist for Steller sea lion protection under the baseline conditions, and have the potential to provide beneficial effects to harbor seals based on the assumption that they may result in improvements to the prey field. For this analysis, it will be assumed that the spatial and temporal concentration of the fishery will be similar to the baseline or will be modified in such a way as to be relatively beneficial to marine mammals in general. PA.2 is therefore rated as insignificant for this effect.

Disturbance

Effects do not deviate from those described under the PA.1 bookend and are considered insignificant.

Cumulative Effects PA.2 – Harbor Seals

For harbor seals, the analysis and conclusions regarding cumulative effects for mortality, prey availability, spatial and temporal concentration of the fishery, and disturbance are the same as discussed under PA.1.

4.9.8.5 Other Pinnipeds

Direct/Indirect Effects PA.1 – Other Pinnipeds

Incidental Take/Entanglement in Marine Debris

The incidental take rates in commercial fisheries for ice seals, walrus and northern elephant seals are very low. Mean annual mortality of all ice seals combined from 1995 - 1999 was estimated to be 1.8 animals based on NMFS observers on board BSAI groundfish trawl, longline, and pot fishing vessels (Angliss *et al.* 2001) (Table 4.5-60). These rates constitute levels approaching zero according to NMFS standards (Angliss *et al.* 2001) and are not expected to affect the population trajectories of the species included in this category. The take rate walrus and elephant seal qualifies as an insignificant level, approaching zero by NMFS standards (Forney *et al.* 2000) and is not expected to affect population trajectory of these species. Entanglement in marine debris is likewise rare for these species and is considered to have insignificant effects. Of the Federally-managed fisheries in Alaska, only the EBS and Aleutian Islands pollock fishery would be likely to have an impact on ice seals and walrus, because of their northern distribution in the Bering Sea. Because of their distribution in Alaska in the GOA and south of the Aleutian Islands (Stewart and DeLong 1994, LeBoeuf *et al.* 2000), northern elephant seals would be likely to be affected only by the GOA and Aleutian Islands pollock and cod fisheries. Due to the low level of documented interactions between other pinnipeds and the groundfish fisheries, incidental takes and entanglements of other pinnipeds occurring in the groundfish fisheries under PA.1 are determined to be insignificant according to the criteria established in Table 4.1-6.

Fisheries Harvest of Prey Species

With the exception of spotted seals, the food habits of the ice seals do not overlap with commercial fisheries targets. Bearded seals consume primarily benthic prey including crabs and clams as well as shrimps and Arctic cod (Kosygin 1966, 1971, Lowry *et al.* 1981a, 1981b). Ringed seals eat Arctic cod, saffron cod, smelt, herring, shrimps, amphipods and euphausiids (Fedoseev 1984, Johnson *et al.* 1966, Lowry *et al.* 1980, McLaren 1958). Ribbon seal diet has been characterized as intermediate between ringed and bearded seals (Shustov 1965). Spotted seals include pollock in their diet when feeding in the central Bering Sea (Bukhtiyarov *et al.* 1984), but their use of that resource in the EBS and Aleutian Islands is unknown. Spotted seal diet in Bristol Bay, the Priblof Islands and the eastern Aleutian Islands is likewise unknown, but if similar to harbor seals in those areas, it is likely to be diverse and may include a small percentage of commercially important species. Fishery harvests of ice seal prey species are expected to be minimal under PA.1 and are therefore determined to be insignificant.

The Pacific walrus diet is composed almost exclusively of benthic invertebrates (97 percent), particularly bivalve molluscs. Fish ingestion has been considered incidental to their normal feeding behavior (Fay and Stoker 1982). Therefore, groundfish removals would have an insignificant effect on walrus prey abundance.

The diet of northern elephant seals in the GOA is unknown; however, this species is known to be a deep diver. This behavior suggests that their foraging may be partitioned by depth from most groundfish fishing activities. The effects of groundfish harvests under PA.1 on prey species for northern elephant seals is determined to be unknown.

Spatial and Temporal Concentration of the Fishery

Due to the limited potential for competitive overlap to occur between other pinnipeds and the groundfish fisheries, the spatial and temporal concentrations of the fisheries are expected to have insignificant effects on species in this category under PA.1.

Disturbance

Disturbance of other pinnipeds under the PA.1 management regime is not expected to change relative to the baseline, which is considered of negligible effect, and is rated as insignificant.

Cumulative Effects PA.1 – Other Pinnipeds

A summary of the effects of the past/present with regards to other pinnipeds are presented in Section 3.8.3 and Section 3.8.5 through Section 3.8.9 (Tables 3.8-3, 3.8-5 through 3.8-9). The predicted direct/indirect effects and cumulative effects under PA.1 are described in Table 4.9-5.

Mortality

- **Direct/Indirect Effects**. Population-level effects are not expected to result from incidental take and entanglement for any of the species in this group under the PA.1. Therefore, PA.1 is rated as insignificant for the mortality of other pinnipeds.

- **Persistent Past Effects**. Past external effects on the populations of other pinnipeds includes low levels of incidental take in the foreign, JV, and domestic groundfish fisheries and low levels of take in the state-managed fisheries (see Sections 3.8.3, and 3.8.5 through 3.8.9). Subsistence is the major human-caused external factor for mortality. Subsistence annual harvest rates include 5,265 spotted seal, 6,788 bearded seal, 100 ribbon seal, 9,567 ringed seal, 1,000 walrus, and zero elephant seal.

- **Reasonably Foreseeable Future External Effects**. State-managed fisheries will likely continue to take very small numbers of seals in this group. Subsistence take of these marine mammals will likely continue at a similar rate to the baseline conditions.

- **Cumulative Effect**. The combined effects of mortality within the other pinniped group resulting from internal effects of the groundfish fisheries and external effects, such as subsistence harvest, are considered insignificant. For spotted, ringed, bearded, and ribbon seals, PBRs cannot be calculated. Walrus take is below PBR and population level effects are unlikely. Elephant seal populations are expanding so overall mortality is considered insignificant. Contributions of the groundfish fisheries to overall mortality is very small.

Abundance of Prey

- **Direct/Indirect Effects.** Except for elephant seals, where the amount of prey overlap is unknown, there is very little overlap of species taken in the groundfish fisheries with prey of the pinnipeds in this group and the effects of fisheries harvest on prey species are determined to be insignificant under PA.1.

- **Persistent Past Effects**. Past effect on spotted seal include foreign, JV, and domestic groundfish fisheries and state-managed fisheries for salmon and herring. For the other ice seals, elephant seals and walrus, no persistent past effects were identified due to the lack of overlap with the groundfish fisheries.

- **Reasonably Foreseeable Future External Effects**. Future effects were identified for state-managed fisheries for the spotted seal. Climate changes may be either beneficial or adverse factors for ice seals due to the potential climatic effects on the extent of ice cover in the Bering Sea and associated indirect effects on the abundance and distribution of prey.

- **Cumulative Effects**. The cumulative effect of all fisheries on the abundance of prey for pinnipeds is considered insignificant for all species. Spotted seals have some overlap of prey with the groundfish fisheries but the harvest of prey by the fisheries is not expected to have population level effects. The amount of groundfish fishery overlap with elephant seals is unknown but, since the elephant seal population is expanding, food does not appear to be limiting so cumulative effects on prey availability are considered insignificant. The amount of prey overlap with the other pinniped species is very limited and is considered insignificant for all species in this group.

Spatial and Temporal Concentration of Fisheries

- **Direct/Indirect Effects**. Spatial and temporal fishing measures under PA.1 do not deviate from the baseline, which has insignificant effects on pinniped species.

- **Persistent Past Effects**. Persistent past effect on spotted seal include foreign, JV, and domestic groundfish fisheries and state-fisheries. None are identified for the other pinniped species.

- **Reasonably Foreseeable Future External Effects**. State-managed fisheries within the range of spotted seal would be expected to be conducted in the future in a manner similar to the baseline conditions. Future effects of spatial and temporal concentration of fisheries on ice seals and walrus would not be expected.

- **Cumulative Effects.** The spatial/temporal concentration of the groundfish fishery and all other fisheries is considered to have an insignificant cumulative effect on pinniped prey due to limited seasonal overlap. Population-level effects are unlikely for any of the species in this group.

Disturbance

- **Direct/Indirect Effects**. Levels of disturbance similar to the baseline are expected under PA.1 and are considered insignificant.

- **Persistent Past Effects.** Past sources of disturbance on spotted seals have been from the foreign, JV, and the federal domestic groundfish fisheries in the BSAI and state-managed fisheries for salmon. Overlap of fisheries is minimal for most of species. The primary source of external disturbance to the other pinniped category would be related to the subsistence harvest.

- **Reasonably Foreseeable Future Effects**. State-managed fisheries could be expected to continue at a level similar to the baseline condition. Disturbance from subsistence harvest activities in future years would be expected to be similar to the baseline conditions.

- **Cumulative Effect**. The combined effects of disturbance levels resulting from internal and external effects are found to be insignificant for all species based on very limited overlap with the fisheries and the lack of evidence that disturbance has a population-level effect for any of these species.

Direct/Indirect Effects PA.2 – Other Pinnipeds

For species within the other pinniped group, the analysis and conclusions regarding direct/indirect effects for incidental take and entanglement in marine debris, fisheries harvest of prey species, spatial and temporal concentration of the fishery, and disturbance are the same as discussed under PA.1.

Cumulative Effects PA.2 – Other Pinnipeds

For species within the other pinniped group, the analysis and conclusions regarding cumulative effects for mortality, prey availability, spatial and temporal concentration of the fishery, and disturbance are the same as discussed under PA.1.

4.9.8.6 Transient Killer Whales

Direct/Indirect Effects PA.1 – Transient Killer Whales

Incidental Take/Entanglement in Marine Debris

With regard to incidental take, PA.1 is not likely to result in significant changes to the population trajectory of killer whales. Six commercial fisheries in Alaska that could have interacted with transient killer whales from the western and GOA stock were monitored for incidental take by fishery observers from 1990 to 1999. Of the observed fisheries (BSAI and GOA groundfish trawl, pot, and longline), killer whale mortalities occurred only in the Bering Sea groundfish trawl and longline fisheries (Angliss *et al.* 2001) (Table 4.5-60). In addition to mortalities caused by entanglement, killer whales are susceptible to injury or mortality through vessel strikes. One killer whale was reported to be killed when it struck the propeller of a BSAI groundfish trawl vessel in 1998 (Angliss and Lodge 2002). The mean annual mortality of killer whales incidental to groundfish fisheries from 1995 to 1999 was estimated to be 1.4 whales (Angliss *et al.* 2001). It is not known what proportion of these whales were transients versus residents. Increased harvest rates under PA.1 may result in the increased take of less than one killer whale relative to the baseline, for a total estimated average of less than two animals per year. Interactions which result in the entanglement of killer whales in fishing gear are rare and are not expected to have population-level effects. Therefore, takes and entanglements of killer whales incidental to groundfish fisheries under PA.1 are determined to be insignificant according to the criteria established in Table 4.1-6.

Fisheries Harvest of Prey Species

The diet of transient killer whales consists of marine mammals. The diet of transient killer whales consists of marine mammals. Since the groundfish fisheries kill very few marine mammals through incidental take, the direct effects of groundfish fisheries on the abundance of transient killer whale prey species are determined to be insignificant under PA.1.

Spatial and Temporal Concentration of the Fishery

The spatial/temporal concentration of the groundfish fisheries does not directly affect the distribution of marine mammals. Therefore, the direct effects of the fisheries on transient killer whale prey are determined to be insignificant under FMP 1.

Disturbance

PA.1 retains the area closures contained under the baseline. The management regime under PA.1 is not expected to result in increased disturbance to killer whales relative to the baseline and is rated insignificant.

Cumulative Effects PA.1 – Transient Killer Whales

The past/present effects on the transient killer whales are described in Section 3.8.22 (Table 3.8-22) and the predicted direct/indirect effects of the groundfish fishery under PA.1 are described above (Table 4.9-5). Representative direct effects used in this analysis include mortality and disturbance, with the major indirect effects being the change in the prey availability and the change in the spatial/temporal concentration of the fisheries (Table 4.1-6).

Mortality

- **Direct/Indirect Effects**. With regard to incidental take and entanglement, PA.1 is not likely to result in changes to the population trajectory of transient killer whales and is considered insignificant.

- **Persistent Past Effects**. Mortality has been documented in the JV, domestic groundfish and state-managed fisheries, and intentional shootings have been known to occur. Past incidental take in the groundfish fisheries is less than two animals per year, but its not known if these animals were transients or residents. In addition to mortalities caused by entanglement, killer whales are susceptible to injury or mortality through vessel strikes. The EVOS resulted in the loss of half of the individual killer whales from the AT1 pod in PWS (Matkin *et al.* 1999). This distinct group of whales is being evaluated for recognition as a separate stock and protection as a depleted stock under the MMPA. Contaminant levels in whales in this group were found to be many times higher than others killer whales (Matkin *et al.* 1999).

- **Reasonably Foreseeable Future External Effects**. Future mortality is expected from external factors such as state-managed fisheries, intentional shooting, and marine pollution, particularly persistent organic pollutants such as DDT and PCBs (Matkin *et al.* 2001).

- **Cumulative Effects**. Cumulative effects of mortality resulting from internal effects of the groundfish fisheries and external factors are determined to be insignificant. The exception to this finding is in the AT1 transient group in PWS. The cumulative effects of mortality on this group were determined to be significantly adverse due to the past external effects of the EVOS and the subsequent population decline of the AT1 transient group.

<u>Prey Availability</u>

- **Direct/Indirect Effects**. Since the groundfish fisheries kill very few marine mammals through incidental take, the direct effects of groundfish fisheries on the abundance of transient killer whale prey species are determined to be insignificant.

- **Persistent Past Effects**. Since marine mammals are the primary prey of transient killer whales, all of the factors that have been identified as affecting the abundance or distribution of cetaceans, pinnipeds, and sea otters are pertinent in this context. These factors include commercial and subsistence harvest, intentional shootings, incidental take in all fisheries, marine pollution, climate change, and regime shifts. In addition, there is the potential for past indirect effects of fisheries on the abundance of Steller sea lions, fur seals, and harbor seals, all of which are important prey species for transient killer whales. Declines in harbor seals in PWS after the EVOS could have affected the AT1 group of transient killer whales through their food supply (Matkin *et al.* 1999).

- **Reasonably Foreseeable Future External Effects**. Future external effects on prey species important to transient killer whales would include state-managed fisheries to a small extent and subsistence harvest of the various marine mammals.

- **Cumulative Effects**. The cumulative effects on different marine mammal species are varied, with some populations declining substantially while others increase. Although some individual whales may specialize on particular prey species, the ability of these top predators to switch prey and forage over vast areas is believed to decrease the importance of any one species or stock of marine mammal prey. The overall availability of prey does not appear to be having population level effects on transient killer whales and therefore the cumulative effect is considered insignificant.

<u>Spatial and Temporal Concentration of the Fishery</u>

- **Direct/Indirect Effects**. The spatial/temporal concentration of the groundfish fisheries does not directly affect the distribution of marine mammals. Therefore, the direct effects of the fisheries on transient killer whale prey are determined to be insignificant.

- **Persistent Past Effects.** All persistent past effects that have been identified for cetaceans, pinnipeds, and sea otters are pertinent in this context. These factors include the potential contribution of the spatial/temporal concentration of past fisheries to have caused localized depletion of prey for Steller sea lions, harbor seals, and northern fur seals with consequent population-level effects on those species.

- **Reasonably Foreseeable Future External Effects**. The future spatial/temporal concentration of external fisheries could have indirect effects on the abundance and distribution of marine mammals that are important prey for transient killer whales.

- **Cumulative Effects**. The cumulative effects of the spatial/temporal concentration of fisheries on different marine mammal species result in changes to the abundance and distribution of prey to transient killer whales. Since transient killer whales. are able to switch prey and forage over vast areas, the potential localized depletion of any one species or stock of marine mammal prey is unlikely to have population level effects on the killer whales. The cumulative effect of the spatial and temporal harvest of fish from all fisheries does not appear to be having population level effects on transient killer whales and is therefore considered insignificant.

Disturbance

- **Direct/Indirect Effects**. Levels of disturbance to killer whales are expected to be similar to baseline conditions and are expected to be insignificant.

- **Persistent Past Effects**. Some levels of disturbance have likely occurred from foreign, JV, and domestic groundfish fisheries, and state-managed fisheries. Vessel traffic external to the fisheries has contributed to overall disturbance of these animals. Effects of the level of disturbance on transient killer whales is largely unknown.

- **Reasonably Foreseeable Future External Effects**. External effects of state-managed fisheries and other vessel traffic on disturbance will likely occur in future years at a level similar to the baseline.

- **Cumulative Effects**. Cumulative effects of disturbance levels on transient killer whales resulting from internal and external factors are considered insignificant and are not likely to have any population-level effects.

Direct/Indirect Effects PA.2 – Transient Killer Whales

For transient killer whales, the analysis and conclusions regarding direct/indirect effects for incidental take and entanglement in marine debris, fisheries harvest of prey species, spatial and temporal concentration of the fishery, and disturbance are the same as discussed under PA.1.

Cumulative Effects PA.2 – Transient Killer Whales

For the transient killer whales, the analysis and conclusions regarding cumulative effects for mortality, prey availability, spatial and temporal concentration of the fishery, and disturbance under PA.2 are the same as discussed under PA.1.

4.9.8.7 Other Toothed Whales

Direct/Indirect Effects PA.1 – Other Toothed Whales

Incidental Take/Entanglement in Marine Debris

Incidental takes attributed to the fisheries and entanglement in fishing gear and marine debris occur at low levels and are thought to be insignificant to toothed whale populations. The highest incidental take rate for any cetacean is that of Dall's porpoise. From 1995 to 1999 an average of 8.8 Dall's porpoise were estimated to have been taken incidental to groundfish fishing activities. The majority of these were taken in BSAI trawl fisheries while 1.6 and 1.2 animals were taken in BSAI longline and GOA trawl fisheries respectively. Three harbor porpoise moralities were observed incidental to BSAI groundfish trawl fisheries from 1995 to 1998. The mean annual mortality of Pacific white-sided dolphins incidental to groundfish fisheries from 1995 to 1999 was estimated to be less than one animal with reported takes occurring only in the BSAI longline fishery (Angliss *et al.* 2001) (Table 4.5-60). The estimated mean annual mortality of beluga whales, endangered sperm whales, and beaked whales incidental to groundfish fisheries was zero from 1995 to 1999.

Ten non-lethal interactions with endangered sperm whales have been documented in the GOA longline fishery targeting sablefish in management zones 640 and 650 (Hill *et al.* 1999). Two of the three entanglements reported between 1997 and 2000 resulted in release of the animal without serious injury. The extent of the injuries to the third animal was not known though it was alive at the time of release. No sperm whale mortalities have been observed or reported in the BSAI/GOA groundfish fisheries since observers began collecting data in 1990 (Angliss and Lodge 2002).

In the observed fisheries (BSAI and GOA groundfish trawl, pot, and longline), killer whale mortalities occurred only in the Bering Sea groundfish trawl and longline fisheries (Angliss *et al.* 2001). The mean annual mortality of killer whales incidental to groundfish fisheries from 1995 to 1999 was estimated to be 1.4 whales (Angliss *et al.* 2001). It is not known what proportion of these whales were transients versus residents. Interactions which result in the entanglement of killer whales in fishing gear are rare and are not expected to have population-level effects.

The level of incidental takes and entanglement of toothed whales from groundfish fishing under PA.1 is expected to be rare and is not expected to affect the population trajectories of any species, and is therefore insignificant at the population level.

Fisheries Harvest of Prey Species

The effects of the fisheries on toothed whale prey are largely constrained by differences between their prey and the fisheries harvest targets. PA.1 is not expected to increase the level of competitive interactions for prey from the baseline condition and is therefore determined to have insignificant effects on prey of toothed whales.

The beluga whale stocks along the western coast of Alaska from Bristol Bay north, and in Cook Inlet are generally restricted to shallow coastal and estuarian habitats not used by commercial groundfish fisheries. Their diet is predominantly salmonids and small schooling fishes such as eulachon and capelin. These species are taken only in small quantities as bycatch in the groundfish fisheries. Thus, it is unlikely that fishery interactions exist between beluga whales and Alaskan groundfish fisheries.

Similarly, Pacific white-sided dolphins are not commonly observed north of the Aleutian Islands, and appear to be seasonal visitors in parts of the GOA and southeast Alaska. The main body of their population is more commonly found in the central North Pacific Ocean (Ferrero and Walker 1996). With regard to diet, Pacific white-sided dolphins and Dall's porpoise feed mainly on cephalopods and small schooling fishes such as myctophids. These species are taken only in small quantities as bycatch in the groundfish fisheries.

The remaining species consume a wide variety of both fish and invertebrate species, but overlap with commercially important species is limited in most cases. Beaked whales, a diverse group unto itself, are poorly known, but available information suggests that they prey on benthic and epibenthic species including squid, skates, rattails, rockfish, and octopus. Harbor porpoise diet in Alaskan waters is also poorly understood, although forage consumed by stocks in the Pacific Northwest and their tendency toward near shore distribution suggest that they probably consume a variety of coastal species. None of these species are taken in significant quantities in the groundfish fisheries.

Sperm whale diet overlaps with commercial fisheries targets more than any other species in this group, but the degree of overlap is at least partly due to direct interactions with longline gear. In addition to consuming primarily medium to large sized squids, they also consume salmonids, rockfish, lingcod and skates, and in the GOA they have been observed feeding off longline gear targeting sablefish and halibut. The interaction with commercial longline gear does not appear to have an adverse impact on sperm whales since no mortalities have been observed. On the contrary, the whales appear to have become more attracted to these vessels in recent years as reliable and easy sources of food.

Most information regarding resident killer whale consumption of commercially important groundfish results from observations of whales depredating longlines as they are retrieved in locations ranging from the southeastern Bering sea to PWS. In the waters between Unimak Pass and the Priblof Islands, killer whales regularly strip sablefish and Greenland turbot from longlines. Consumption of other groundfish species by resident killer whales not interacting with gear is largely unknown. In general, they are opportunistic feeders with diets that differ both regionally and seasonally. Nishiwaki and Handa (1958) examined killer whale stomach contents from the North Pacific and found squid, fish, and marine mammals. The importance of these prey items in the BSAI or GOA groundfish management areas is uncertain, but there is no evidence to suggest exclusive reliance on commercially important groundfish species.

Spatial and Temporal Concentration of the Fishery

As stated above, groundfish fisheries have little competitive overlap with toothed whales. The spatial and temporal concentration of the fisheries under PA.1 are expected to be similar to the comparative baseline conditions, which are considered to have insignificant effects on endangered sperm whales and other toothed whales at the population level.

Disturbance

Disturbance of endangered sperm whales and other toothed whales under the PA.1 management regime is not expected to change relative to the baseline and is rated insignificant.

Cumulative Effects PA.1 – Other Toothed Whales

The past/present effects on the other toothed whale group are described in Sections 3.8.19 through 3.8.21 and Sections 3.8.23 through 3.8.25 (Tables 3.8-19 through 3.8-25) and the predicted direct/indirect effects of the groundfish fishery under the PA.1 are described above (Table 4.9-5). Representative direct effects used in this analysis include mortality and disturbance with the major indirect effects of availability of prey and spatial and temporal concentration of the fisheries (Table 4.1-6).

Mortality

- **Direct/Indirect Effects**. The level of mortality for endangered sperm whales and other toothed whale species related to groundfish fishing activities is rare and is not expected to affect the population trajectories of any of these species. Therefore PA.1 is rated as insignificant at the population level.

- **Persistent Past Effects**. Persistent past effects on species within the other toothed whale group include incidental take and entanglement in foreign, JV, Federal domestic groundfish fisheries and state-managed fisheries, and subsistence hunting on beluga whales. The decline of the Cook Inlet beluga population is thought to have been the result of subsistence harvests, which ranged from 21 to 123 animals per year between 1993 and 1998. Only one beluga was harvested in 2001 by hunters from the Native village of Tyonek and one beluga was harvest in 2002 by the Cook Inlet community hunters. Belugas are incidentally taken by the state-managed salmon gillnet fisheries in Bristol Bay and Cook Inlet. However, one beluga was reported to be taken from the EBS in 1996 and seven were reported taken in Bristol Bay in 2000. In the BSAI and GOA groundfish fisheries, no mortality or serious injuries to belugas have been observed. Harbor porpoise have not been taken in the observed groundfish fisheries over a ten year period between 1990 to 1998 (Angliss *et al.* 2001). Salmon gillnet fisheries in southeast Alaska take approximately three individuals per year. Dall porpoise mean annual mortality was 6.0 for the Bering Sea groundfish trawl fishery, 1.2 for the GOA groundfish trawl fishery, and 1.6 for the Bering Sea groundfish longline fishery. The Alaska Peninsula/Aleutian Island salmon drift gillnet fishery has a higher take of Dall's Porpoise, with an estimated 28 porpoises in one year (1990). Thousands of Pacific white-sided dolphins were killed annually between 1978 and 1991 in the high seas driftnet fisheries, which no long occur (Angliss *et al.* 2001). One Pacific white-sided dolphin was taken in the BSAI trawl fishery and one in the BSAI longline fishery during the same time span (Angliss *et al.* 2001). State-managed salmon gillnet fisheries take approximately two dolphins per year.

  Approximately 258,000 sperm whales in the North Pacific were harvested by commercial whalers between 1947 and 1987. The highest counts occurred in 1968 when 16,357 sperm whales were harvested after which the population became severely depleted. Sperm whale interactions with longline fisheries operating in the GOA are known to occur and may be increasing in frequency. Sperm whales have been known to prey on sablefish caught on commercial longline gear in the GOA. Only three entanglements have been reported in the GOA longline fishery.

  For killer whales, the combined mortality from the observed groundfish fisheries was 1.4 whales per year (Angliss *et al.* 2001). While it is most likely that whales interacting with fisheries are from resident pods (since they eat fish), no genetic testing has been done on whales incidentally taken in the groundfish fisheries to ascertain whether they were from resident or transient stocks.

For beaked whales (Baird's, Cuvier's, or Stejneger's), no incidental take or entanglement in the BSAI and GOA groundfish trawl, longline, and pot fisheries has been documented (Hill and DeMaster 1999).

- **Reasonably Foreseeable Future External Effects.** Foreign fisheries outside the EEZ and state-managed fisheries were identified as potential sources of mortality in the future. Several of the toothed whale species range outside of the BSAI and GOA during the winter months. Subsistence take of some stocks of beluga whales would be expected to occur in the future. Other species are not taken for subsistence purposes.

- **Cumulative Effect**. Cumulative effects of mortality resulting from internal and external factors are considered insignificant for all non ESA-listed species due to the low level of incidental take in the groundfish fisheries and limited external human-caused mortality.

  For the endangered sperm whale, the cumulative effect was also considered insignificant because the very low level of incidental take in the groundfish fisheries and very limited human-caused mortality from external sources is not expected to delay the recovery of sperm whale populations.

Prey Availability

- **Direct/Indirect Effects**. The groundfish fishery under PA.1 is not expected to increase the level of competitive interactions for toothed whale prey from the baseline condition and is therefore considered to have insignificant effects on toothed whale prey..

- **Persistent Past Effects**. Although this group preys on a wide variety of fish species, past effect on the availability of prey for this group are identified for fisheries in general, and include the foreign, JV, and federal domestic groundfish fisheries, and the state-managed fisheries for salmon and herring. The diversity of diet in this whale group results in limited overlap for most species with the possible exception of sperm whales and resident killer whales.

- **Reasonably Foreseeable Future External Effects**. State-managed fisheries were identified as external factors having a potential effect on prey for these species in the future. Climate and regime shifts are identified, but the direction and magnitude of these effects are difficult to predict.

- **Cumulative Effects**. The ability of these whale species to forage over wide areas and on a variety of prey species moderates any potential impacts from fisheries competition. Cumulative effects on prey availability were identified for this group, including a very limited contribution from the groundfish fishery, but the degree of fishery harvest and bycatch of prey important to these whale species is not expected to have population-level effects on any species, including the endangered sperm whale, and is therefore considered insignificant.

Spatial and Temporal Concentrations of the Fisheries

- **Direct/Indirect Effects**. Spatial and temporal fishing measures under PA.1 do not deviate from the baseline, which do not appear to be causing localized depletion of prey for any species of toothed whale, and are thus determined to be insignificant.

- **Persistent Past Effects**. The spatial/temporal concentration of foreign, JV, and domestic groundfish fisheries and the state-managed fisheries are believed to have had minimal effects on the abundance and distribution of toothed whale prey.

- **Reasonably Foreseeable Future External Effects**. State-managed fisheries are expected to continue in manner similar to the baseline conditions. Effects of future fishing activities on toothed whale prey are expected to be minimal.

- **Cumulative Effects**. The ability of toothed whales to forage over wide areas and on a variety of prey species moderates any potential impacts from localized depletion of prey from the spatial/temporal concentration of fisheries. Cumulative effects on prey abundance and distribution, including a very limited contribution from the groundfish fishery, are not expected to have population-level effects on any species, including the endangered sperm whale, and are therefore considered insignificant..

Disturbance

- **Direct/Indirect Effects**. Disturbance levels resulting from the groundfish fishery under PA.1 are determined to be insignificant at the population level.

- **Persistent Past Effects**. Past potential disturbance effects on species in this group include foreign, JV, and federal domestic groundfish fisheries; however, there is little indication of a adverse effect at this level of disturbance. General vessel traffic likely contributes to disturbance to these species.

- **Reasonably Foreseeable Future External Effects**. Increases in the general marine vessel traffic and continued fishing activity in the state-managed fisheries were identified as potential sources of disturbance.

- **Cumulative Effects**. The cumulative effect of disturbance from both internal and external factors is found to be insignificant for endangered sperm whales and other toothed whale species based on the lack of evidence that disturbance has a population-level effect for any of these species. For sperm whales, there is growing evidence that the whales are attracted to fishing vessels as reliable and easy sources of food.

Direct/Indirect Effects PA.2 – Other Toothed Whales

For species within the other toothed whales group, the analysis and conclusions regarding direct/indirect effects for incidental take and entanglement in marine debris, fisheries harvest of prey species, spatial and temporal concentration of the fishery, and disturbance are the same as discussed under PA.1.

Cumulative Effects PA.2 – Other Toothed Whales

For species within the other toothed whales group, the analysis and conclusions regarding cumulative effects for mortality, prey availability, spatial and temporal concentration of the fishery, and disturbance under PA.2 are the same as discussed under PA.1.

4.9.8.8 Baleen Whales

Direct/Indirect Effects PA.1 – Baleen Whales

Incidental Take/Entanglement in Marine Debris

Take of baleen whales incidental to groundfish fishing activities is rare. A single fin whale mortality was reported in the GOA pollock trawl fishery operating south of Kodiak Island and Shelikof Strait in autumn 1999. Humpback whales are occasionally taken in the Bering Sea pollock trawl fishery through entanglement in fishing gear. The extent of interaction between bowhead whales and the groundfish fishery is not known. Rope entanglement injuries and deaths as well as ship-strike injuries appear to be rare. The extent of interaction between gray whales and the groundfish fishery is not known, but some entanglement in gear does occur. Since 1989, no incidental takes of right whales are known to have occurred in the North Pacific.

With respect to incidental take and entanglement in marine debris incidental to groundfish fisheries, PA.1 is not expected to result in significant effects on the population trajectories of any baleen whales, does not conflict with the goals of any recovery plan for endangered whales, and is thus insignificant according to the criteria established in Table 4.1-6.

Fisheries Harvest of Prey Species

Most baleen whale species such as blue, fin, sei, and northern right whale feed primarily on copepods, euphausiids and amphipods. Gray whales feed mostly on epibenthic and benthic invertebrates, while humpbacks and minke whales have a more diverse diet including euphausiids, Atka mackerel, sand lance herring, and capelin. The BSAI and GOA groundfish fisheries do not target these prey items (with the exception of Atka mackerel) and take very small amounts of these prey species as bycatch. Neither the abundance nor distribution of zooplankton are substantially influenced by commercial fishing operations. While a few species of baleen whales do consume herring and juvenile pollock (e.g., humpback and fin whales), changes in removal patterns of these prey species under PA.1 would not be expected to impact their availability to whales, which can forage over vast areas and throughout the water column. The groundfish fisheries under FMP 1 are therefore unlikely to impact baleen whales through competition for prey, including the endangered blue, fin, bowhead, humpback, sei and northern right whales.

Spatial and Temporal Concentration of the Fishery

Spatial and temporal fishing measures under PA.1 do not deviate from the baseline, which does not cause localized depletion of prey for baleen whales, and are therefore determined to be insignificant to both the endangered and non ESA- listed baleen whales according to the criteria established in Table 4.1-6.

Disturbance

The effects of disturbance caused by vessel; traffic, or sound production on baleen whales in the GOA and BSAI are largely unknown. With regard to vessel traffic, most baleen whales appear tolerant, at least as suggested by their reactions at the surface. Observed behavior ranges from attraction to course modification or maintenance of distance from the vessel. Reaction to gear, such as pelagic trawls is unknown, although the rarity of incidental takes suggests either partitioning, or avoidance. Given their distribution throughout the fishing grounds, at least some individuals may be expected to occasionally avoid contact with vessels or fishing gear, which would constitute a reaction to a disturbance. Assuming these instances occur, the effects are likely to be temporary.

Coincident to fishing activity, as well as vessel transit, is the routine use of various sonar devices. The sounds produced by these devices may be audible to baleen whales and suggest disturbance sources. For instance, wintering humpback whales have been observed reacting to sonar pulses by moving away (Maybaum 1990, 1993), although few other cases of reaction have been documented. Given the continued occupation fo the fishing rounds by these animals. And their generally positive population trends, disturbance from sonar, if it occurs in the BSAI or GOA does not appear to have population-level effects. Disturbance of both endangered and non ESA-listed baleen whales under the PA.1 management regime is not expected to change relative to the baseline and is therefore rated insignificant.

Cumulative Effects PA.1 – Baleen Whales

The past/present effects on the other baleen whale group are described in Section 3.8.11 to Section 3.8.18 (Tables 3.8-11 through 3.8-18), and the predicted direct/indirect effects of the groundfish fishery under the PA.1 are described above (Table 4.9-5). Representative direct effects used in this analysis include mortality and disturbance with the major indirect effects of availability of prey and spatial and temporal concentration of the fisheries (Table 4.1-6).

<u>Mortality</u>

- **Direct/Indirect Effects**. The low level of take and entanglement of baleen whales projected to occur under the PA.1 is considered insignificant at the population level.

- **Persistent Past Effects.** Commercial whaling in the last century has had lingering effects on most of the baleen whales in this group, with the possible exception of the minke whale. These include the endangered blue whales, fin whales, sei whales humpback whales, northern right whales and the non-ESA listed gray whale. Subsistence whaling has also affected several of the baleen whales in the past. Gray whales are harvested both in Alaska and in Russia and have a 5-year quota of 620 whales. The 1968-1993 average take for Russian and Alaska Natives combined was 159 whales per year. Bowhead whales are harvested under International Whaling Commission quotas which allow up to 67 strikes per year although actual strikes have been less than the quota since 1978. A single fin whale mortality was reported in the GOA pollock trawl fishery operating south of Kodiak Island and Shelikof Strait in autumn 1999. Fin whales were reported in this region year-round, most often in the summer and autumn (POP 1997). Humpback whales are present year-round in Alaska waters but are most frequently reported during the summer and autumn. In 1997, a dead humpback was found entangled in netting and trailing orange buoys near the Bering Strait. It is often difficult to determine if the entanglement occurred with active or derelict gear, or to identify the fishery the derelict gear originated from. Two mortalities (October 1998 and February 1999) were reported by observers in the Bering Sea pollock trawl fishery operating near Unimak Pass. The extent of interactions between bowhead whales and the groundfish fishery are not known. Bowhead whales are present in the Bering Sea during winter and early spring but are usually associated with ice-covered regions. Rope entanglement injuries and deaths as well as ship-strike injuries appear to be rare. Of 236 bowhead whales examined from the Alaskan subsistence harvest (from 1976 to 1992), three had visible ship-strike injuries from unknown sources and six had ropes attached or scars from fishing gear (primarily pot gear), one found dead was entangled in ropes similar to those used with fishing gear in the Bering Sea (Philo *et al.* 1992). Since 1992, additional bowhead whales have been observed entangled in pot gear or with scars from ropes. The extent of interactions between gray whales and the groundfish fishery are not known. Rope entanglement injuries and deaths as well as ship-strike injuries appear to be rare. Since 1997, five entanglements (mostly in pot gear) and one ship strike mortality have been reported in Alaska waters. Since 1989, no incidental takes of right whales are known to have occurred in the North Pacific. Gillnets were implicated in the death of a right whale off the Kamchatka Peninsula (Russia) in October of 1989. Because the right whale population is believed to be very small, any mortality incidental to commercial fisheries would be considered to be significant. Based on the lack of reported mortalities of endangered right whales, the estimated annual mortality rate incidental to commercial fisheries is zero whales per year from this stock.

- **Reasonably Foreseeable Future External Effects.** Foreign fisheries outside the EEZ and state-managed fisheries are expected to continue to take small numbers of baleen whales in the coming years. Entanglement in fishing gear will continue to effect baleen whales throughout their ranges. Subsistence use of gray whales and bowhead will continue to be the largest source of human-caused mortality.

- **Cumulative Effects**. Cumulative effects of mortality resulting from internal effects of the fishery and contributions from external factors are considered conditionally significant adverse for fin, humpback, and northern right whales due to past effects on their population, potential for interactions with fisheries, and their endangered status. Right whales are very rare so even one human-caused mortality could be considered significant. Given the overlap of their preferred habitat with the BSAI fisheries, the chances of future adverse interactions with fishing gear are more than negligible. The adverse rating for these three species is conditional on whether future take or entanglement substantially affects their rates of recovery. Cumulative effects are found to be insignificant for the endangered blue, bowhead, and sei whales. These species rarely interact with the fisheries so population-level effects are not anticipated. Mortality is also considered insignificant for non-ESA-listed minke and gray whales. Population-level effects are not expected for either of these species.

<u>Prey Availability</u>

- **Direct/Indirect Effects**. The effects of PA.1 are determined to have an insignificant effect on baleen whale prey species due the lack of competitive overlap in prey species targeted by the fisheries.

- **Persistent Past Effects**. Persistent past effects on availability of prey were not identified due to the lack of competitive overlap in prey species targeted.

- **Reasonably Foreseeable Future External Effects**. Future external effects were identified as state-managed fisheries such as herring, which are preyed on by humpback whales and fin whales. Other species are not expected to be impacted through their prey.

- **Cumulative Effects**. Cumulative effects on prey availability resulting from internal effects of the fisheries and contributions from external factors are insignificant primarily due to the limited overlap of prey species within the fisheries.

Spatial and Temporal Concentration of the Fishery

- **Direct/Indirect Effects**. Spatial and temporal concentrations under the PA.1 do not deviate substantially from the baseline, thus the effects of the spatial and temporal concentration of the fisheries under PA.1 are determined to be insignificant.

- **Persistent Past Effects**. Persistent past effects associated with spatial/temporal concentration of the fisheries were not identified.

- **Reasonably Foreseeable Future External Effects**. State-managed fisheries would be expected to contribute to the change in the spatial/temporal concentration of some prey species within the baleen whales group.

- **Cumulative Effects**. Cumulative effects on the spatial and temporal concentration of harvest of baleen whale prey resulting from internal effects of the fishery and contributions from external factors are considered insignificant for endangered and non-ESA listed species in this group due to the limited overlap of prey species within the fisheries.

Disturbance

- **Direct/Indirect Effects**. Levels of disturbance similar to the baseline condition are expected under PA.1 and are considered insignificant.

- **Persistent Past Effects**. Some level of disturbance has likely occurred from foreign, JV, and domestic groundfish fishing, and state-managed fisheries along with general vessel traffic. For some species, such as the gray whale and bowhead whale, subsistence activities have contributed to disturbance of these animals.

- **Reasonably Foreseeable Future External Effects**. State-managed fisheries and general vessel traffic, from recreational boating and whale watching to commercial vessels, would be expected to continue in future years, as well as subsistence activities.

- **Cumulative Effects**. Cumulative effects of disturbance resulting from internal and external sources are determined to be similar to the baseline condition and not likely to result in a population-level effect for any of the species in this group. Therefore, the cumulative effect is considered to be insignificant for both endangered and non ESA-listed baleen whales.

Direct/Indirect Effects PA.2 – Baleen Whales

For species within the baleen whales group, the analysis and conclusions regarding direct/indirect effects for incidental take and entanglement in marine debris, fisheries harvest of prey species, spatial and temporal concentration of the fishery, and disturbance are the same as discussed under PA.1.

Cumulative Effects PA.2 – Baleen Whales

For the baleen whale group, the analysis and conclusions regarding cumulative effects for mortality, prey availability, spatial and temporal concentration of the fishery, and disturbance under PA.2 are the same as discussed under PA.1.

4.9.8.9 Sea Otters

Direct/Indirect Effects PA.1 – Sea Otters

Incidental Take/Entanglement in Marine Debris

Sea otter interactions with fishing gear, either passive or active are infrequent. Laist (1997) reported that sea otter entanglement in marine debris is rare. Likewise, incidental takes in fishing gear occur at a rate too low to cause population level effects. While the PBRs for the three sea otter stocks in Alaska were 871 (southeast), 2,095 (southcentral) and 5,699 (southwest), mortalities incidental to commercial fishing were zero, less than one, and less than two per year, respectively (Angliss and Lodge 2002).

In southwest Alaska, the North Pacific Groundfish Observer Program reported eight kills in the Aleutian Islands black cod pot fishery in 1992. No other sea otter kills were reported by NOAA observers in the region from 1990 to 1996. In the 2000 *List of Fisheries,* sea otters were added to the BSAI groundfish trawl as a species recorded as taken in this fishery. The USFWS is currently pursuing information regarding the extent of that possible interaction. The total fishery caused mortality and serious injury for the Alaska sea otter is considered to be insignificant (i.e., will not affect population trajectories). The effects on sea otters under the PA.1 are considered insignificant, with respect to incidental catch and entanglement in marine debris.

Fisheries Harvest of Prey Species

The effect of PA.1 on sea otters is limited by differences between their prey and the species targeted and taken as bycatch by the fisheries.. Sea otters consume a wide variety of prey species, including annelid worms, crabs, shrimp, mollusks (e.g., chitons, limpets, snails, clams, mussels, and octopus), sea urchins, and tunicates. Occasionally, groundfish (e.g., sablefish, rock greenling, and Atka mackerel) may also be consumed, but invertebrates are considered the predominant elements of their diet (Kenyon 1969, USFWS 1994). Given the minor importance of groundfish in their diet, fishery harvests under PA.1 are not expected to have significant effects on the abundance of sea otter prey relative to the baseline and are therefore determined to be insignificant for sea otters.

Spatial and Temporal Concentration of the Fishery

The grounds for suggesting competition for forage between sea otters and commercial fisheries is weak despite the species broad geographical distribution in the GOA and the Aleutian Islands. Sea otters inhabit waters of the open coast, as well as bays and the inside passages of southeastern Alaska. Since their primary prey items are found on the bottom in the littoral zone, to depths of 50 m, the majority of otters feed within one km of the shore (Kenyon 1969). In areas where shallow waters extend far offshore (e.g., Unimak Island), sea otters have been reported as far as 16 km offshore. They are often seen resting and diving for food in and near kelp beds (Kenyon 1969). Because of this habitat preference for shallow areas, they do not overlap spatially with groundfish fisheries. Since the spatial and temporal concentration of the fisheries under PA.1

is expected to be similar to the baseline, which does not appear to affect the localized abundance of sea otter prey, PA.1 is considered to be insignificant for this effect on sea otters.

Disturbance

As noted for many of the other marine mammals, the effects of disturbance caused by vessel traffic, fishing operations, or sound production on sea otters in the GOA and BSAI are expected to be insignificant. Sea otters exhibit considerable tolerance for vessel traffic, and in some cases are attracted to small boats (Richardson *et al.* 1995). Sea otters may be more tolerant of underwater sound relative to other species, owing to the greater amount of time they spend at the surface. Levels of disturbance under PA.1 are expected to be similar to the baseline level and are therefore considered insignificant for sea otters.

Cumulative Effects PA.1 – Sea Otters

The past/present effects on the sea otter are described in Section 3.8.10 (Table 3.8-10) See Table 4.9-5 for a summary of the direct/indirect and cumulative effects. Representative direct effects used in this analysis include mortality and disturbance with the major indirect effects being the change in prey availability and the change in the spatial/temporal concentration of the fisheries (Table 4.1-6).

Mortality

- **Direct/Indirect Effects**. The effects of incidental take and entanglement on sea otters under PA.1 are considered insignificant.

- **Persistent Past Effects.** Commercial exploitation for pelts had a large impact on sea otters dating from the mid-1700s to the late 1800s, causing them to become nearly extinct (Bancroft 1959, Lensink 1962). Protective measures instituted in 1911 have allowed remnant groups to increase and reoccupy much of the historic sea otter range in Alaska (Kenyon 1969, Estes 1980). Residual effects from this early harvest likely persist in several areas. Alaska Natives have hunted sea otters for pelts and meat throughout history. Current harvest levels represent nine percent of PBR for the southwestern stock, 15 percent of PBR for the southcentral stock, and 35 percent of PBR for southeast stock. (USFWS 2002a. 2002b, and 2002c). In 1992, fisheries observers reported eight sea otters taken incidentally by the Aleutian Island black cod pot fishery. During that year, only a third of the fisheries were observed, yielding an estimate of 24 otters killed in cod pot gear. No other sea otter takes were reported from observed fisheries in the range of the southwest stock from 1993 through 2000. In 1997, one sea otter was self-reported to be taken in the BSAI groundfish trawl fishery (USFWS 2002a, 2002b, and 2002c). Oil spills, such as the EVOS, can result in substantial mortality of sea otters. Sea otter numbers have declined dramatically from the Alaska Peninsula to the Bering Sea and this stock is being considered for listing under the ESA.

- **Reasonably Foreseeable Future External Effects.** Low-levels of incidental take in commercial and subsistence fisheries, subsistence hunting, and periodic mortalities from oil spills are likely to continue in the future. Population level effects from killer whale predation may continue in the southwest Alaska stock, depending on the recovery of alternate prey and behavior of transient killer whales.

- **Cumulative Effects**. The cumulative effects of mortality from all sources are different for different stocks of sea otters. The populations of the southeast and southcentral stocks of sea otters appear to be stable or increasing and are not expected to have additional mortality pressure in the future. These stocks are considered to have insignificant cumulative effects from mortality. The rapid decline of the southwest Alaska stock does not appear to be the result of food shortages, disease, or toxic contamination and is likely the result of increased predation by transient killer whales following the collapse of their preferred sea lion prey population in the 1980s (Estes *et al.* 1998). Since the mechanism(s) of the population decline is still under investigation, the cumulative effect on the southwest stock is considered to be conditionally significant adverse for mortality.

Prey Availability

- **Direct/Indirect Effects.** The effects of the PA.1 on sea otters is limited by differences between their prey and the fisheries harvest targets. As such, the effects of harvest of key prey species in groundfish fisheries are determined to be insignificant for sea otters.

- **Persistent Past Effects**. The federal groundfish fisheries have had little effect on the availability of prey in the past due to the limited overlap in prey species of the sea otter and the fish targeted by the groundfish fisheries. There is some minor overlap in state-managed crab fisheries of sea otter prey.

- **Reasonably Foreseeable Future External Effects.** State-managed crab fisheries that take crab from shallow waters are identified as external effects. The overlap primarily occurs in inshore areas or offshore areas with relatively shallow water.

- **Cumulative Effects**. Cumulative effects on prey availability resulting from internal effects of the groundfish fisheries and external factors, such as the crab fisheries, are determined to be insignificant due to the very limited overlap of these fisheries and the sea otter forage species.

Spatial and Temporal Concentration of the Fisheries

- **Direct/Indirect Effects**. Despite the species broad geographical distribution in the GOA and the Aleutian Islands, they do not generally overlap spatially with groundfish fisheries. Therefore, the effects of the spatial and temporal concentration of the fisheries are insignificant for sea otters.

- **Persistent Past Effect**. The limited spatial overlap of groundfish fisheries and other fisheries in the past have limited their interaction with sea otter prey. Past effects of spatial/temporal concentration have likely been in very specific areas and associated with state-managed crab fisheries.

- **Reasonably Foreseeable Future External Effects**. State-managed crab fisheries are likely to continue into the future at a level similar to the baseline conditions.

- **Cumulative Effects**. The cumulative effect of the spatial/temporal harvest of prey in the internal and external fisheries is considered to be insignificant due their limited spatial overlap with sea otter habitat. These fisheries are unlikely to have population-level effects.

Disturbance

- **Direct/Indirect Effects**. Baseline levels of disturbance caused by vessel traffic, fishing operations, or sound production on sea otters in the GOA and BSAI are considered to be insignificant. Levels of disturbance under the PA.1 are expected to be similar to the baseline; therefore, the effects of disturbance on sea otters are expected to be insignificant.

- **Persistent Past Effects**. Past disturbance levels are primarily related to vessel traffic from fisheries and other vessels and disturbance associated with subsistence harvest of sea otters.

- **Reasonably Foreseeable Future External Effects.** State-managed fisheries are expected to continue at a level similar to the baseline conditions. Commercial vessel traffic within sea otter habitat in future years would also be expected to be similar the baseline.

- **Cumulative Effects**. Cumulative effects of disturbance on sea otters resulting from internal effects of the groundfish fisheries and external effects of other fisheries are considered insignificant and are unlikely to result in a population-level effect. Contribution of the groundfish fisheries to the overall cumulative effect is minor.

Direct/Indirect Effects PA.2 – Sea Otters

For sea otters, the analysis and conclusions regarding direct/indirect effects for incidental take and entanglement in marine debris, fisheries harvest of prey species, spatial and temporal concentration of the fishery, and disturbance are the same as discussed under PA.1.

Cumulative Effects

For sea otters, the analysis and conclusions regarding cumulative effects for mortality, prey availability, spatial and temporal concentration of the fishery, and disturbance under PA.2 are the same as discussed under PA.1.

4.9.9 Socioeconomic Preferred Alternative Analysis

This policy alternative would seek to accelerate the existing precautionary management measures through rights-based management and ecosystem-based management principles and, where appropriate and practicable, increase habitat protection and impose additional bycatch constraints. This section contains both quantitative and qualitative analysis of select economic and social effects of PA.1 and PA.2.

In general, the quantitative economic outcomes of this management policy appear nearly identical to those projected under Alternative 1. No significant differences between the two management policies are projected, at least in the variables for which changes are captured by the projection model. Most of the differences between the policies occur in variables that have not been quantified in the analysis such as product prices, harvesting and processing capacity, average costs, and fishing vessel safety.

4.9.9.1 Harvesting and Processing Sectors

The model and analytical framework used in the analysis of the effects of PA.1 on the harvesting and processing sectors are described in Section 4.1.7.

Table 4.9-6 summarizes projected impacts of PA.1 on harvesting and processing sectors. The numbers in the table reflect the five-year average of outcomes projected for 2003 to 2007. As a result of a projected increase in the TAC for Pacific cod in the BSAI and GOA, harvests of this species are estimated to increase by 36 percent, from 218,000 mt to 297,000 mt. Changes in the harvests of other groundfish species are not expected to be significant, nor are changes in total groundfish wholesale value of output, groundfish employment, and groundfish payments to labor.

4.9.9.1.1 Catcher Vessels

Direct/Indirect Effects of PA.1

Groundfish Landings By Species Group

A comparison of the five-year average of outcomes projected for the 2003-2007 period to 2001 catcher vessel conditions reveals that under PA.1 there would be few significant changes in overall retained harvests of groundfish relative to the comparative baseline. As a result of a projected increase in the TAC for Pacific cod in the BSAI and GOA, retained catches of this species are expected to increase by about 54 percent. In addition, an increase in the TAC for sablefish and rockfish will result in a significant increase in the retained harvests of these species. Retained harvests of pollock and flatfish are not expected to change significantly. This leads to direct/indirect effects ratings of insignificant/significantly beneficial for groundfish landings by species group under PA.1.

Ex-Vessel Value

The total ex-vessel value of groundfish landed by catcher vessels is expected to increase relative to the comparative baseline, but not significantly. Increased Pacific cod harvests by the smaller trawl catcher vessels and pot catcher vessels account for much of the increase in groundfish ex-vessel value. Longline vessels are expected to benefit from the increased catches of sablefish and rockfish.

Employment and Payments to Labor

Total groundfish employment and payments to labor by catcher vessels are expected to increase under PA.1, but not significantly.

Impacts on Excess Capacity

A conditionally significant decrease in excess capacity in the harvesting sectors is expected under this FMP relative to the comparative baseline, leading to a conditionally significant beneficial direct/indirect effect rating. The significance of the decrease is conditional because it is uncertain to what extent PA.1 would extend rights-based management to additional groundfish fisheries. One of the primary reasons for expanding the use of rights-based management is to prevent the build-up of excess harvesting and processing capacity or reduce excess capacity that already exists (NMFS 2001a). Excess capacity both contributes to and is the result of the race for fish, with its associated potential adverse impacts on profitability, product quality, and safety. Rights-based systems, whether they allocate shares of the catch to individuals or groups, are incentive adjusting methods in that they attempt to control capacity by creating economic incentives for owners of vessels to decrease their use of labor and capital rather than by directly regulating the level of fishing effort.

The implementation of additional individual or group-based (e.g., community or cooperative) quota systems that end the race for fish and allow transfer of quota shares would be expected to lead to some consolidation of quota to fewer vessels. The degree of consolidation will vary depending on the level of excess capacity, economies of scale and scope in harvesting, and rules that restrict transfer and accumulation of quota shares (NMFS 2001a). Similar consolidation could occur with expanded use of cooperatives or community quota programs. Some excess capacity, in the sense of an ability of vessels and processors to catch and harvest a TAC in less time than a maximum season length would allow, can be expected to persist regardless of what type of additional rights-based measures are put in place. This is generally the case for a number of reasons. It is often not economically efficient to operate at maximum possible production levels, there are typically certain times of the year when it is more efficient and profitable to harvest and process fish, and alternative uses for fishing and processing capital are limited (NMFS 2001a).

Average Costs

A conditionally significant decrease in average costs is expected under this FMP relative to the comparative baseline, leading to a conditionally significant beneficial direct/indirect effect rating. The significance of the decrease in average costs is conditional because it is uncertain to what extent PA.1 would extend rights-based management to additional groundfish fisheries. Increased rationalization of the fisheries would be expected to reduce the costs of harvesting. Individual vessels will have the opportunity to select the least cost combination of fishing inputs. At the industry level, costs will fall because production is expected to shift over time toward the most cost-effective harvesting operations. Fixed costs will be reduced by consolidating harvesting operations and retiring or selling-off vessels. The cost savings will depend both on the constraints put on the transfer and consolidation of harvesting rights and on the level of excess capacity prior to implementation of remedial measures.

Fishing Vessel Safety

A conditionally significant increase in fishing vessel safety is expected under this FMP relative to the comparative baseline, leading to a conditionally significant beneficial direct/indirect effect rating. The significance of the increase in fishing vessel safety is conditional because it is uncertain to what extent PA.1 would extend rights-based management to additional groundfish fisheries. Rights-based systems of any kind are expected to improve safety by reducing the pressure to fish under dangerous conditions (NMFS 2001a). The race for fish creates incentives to fish farther from shore or in areas and seasons with more hazardous weather conditions, and requires crew members to work for long stretches with little rest or sleep. Rights-based systems should slow down the pace of fishing and reduce the financial penalty incurred by opting to cease fishing under unsafe conditions. The most important benefit of improved safety will be a decrease in fishery related injuries and loss of life. Other benefits include savings from not having to replace lost vessels and gear. Finally, significant improvements in safety, if they occur, should result in decreased insurance costs for the industry (NMFS 2001a).

At the same time, it is important to recognize that rationalized fisheries do not necessarily guarantee improvements in safety for fishermen. Under an IFQ program, for example, market opportunities or biological conditions (e.g., spawning aggregations) may still encourage fishermen to fish at times or in places that are unsafe.

For a summary of the direct/indirect effects on catcher vessels under PA.1, please see Table 4.9-6.

Cumulative Effects of PA.1

This section assesses the potential for the direct/indirect effects to interact with persistent past effects and other reasonably foreseeable future events, resulting in a cumulative effect. The persistent past effects on catcher vessels are presented in detail in Section 3.9 (Table 3.9-125), and the predicted direct/indirect effects are described above. Representative indicators for direct/indirect effects include groundfish landings by species group, groundfish ex-vessel value, employment, payments to labor, excess capacity, average costs, and fishing vessel safety.

Groundfish Landings By Species Group

- **Direct/Indirect Effects**. An insignificant change in retained harvest of groundfish relative to the comparative baseline is projected under PA.1, with the exception of sablefish and rockfish, which are likely to increase significantly.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. These contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Given the current downward trends in the commercial salmon and crab fisheries, catcher vessels that rely on a mix of groundfish, salmon, and crab may experience a reduction in harvest levels. However, this cumulative effect may not result in significant changes in groundfish landings under PA.1. An increase in TAC for Pacific cod in the BSAI and GOA is expected (54 percent), as well as for sablefish and rockfish. Harvests of pollock and flatfish are not expected to change significantly. Overall, the reductions in other fisheries, in combination with some increases in certain groundfish landings by species group, are expected to result in insignificant cumulative effects under PA.1. Other economic development activities and other sources of municipal and state revenue are not expected to contribute to cumulative effects on groundfish landings by species group. While climate change may result in potential increases or decreases in fish populations as explained in more detail in Section 4.9.1, these changes are not expected to have significant cumulative effects on groundfish landings by species group.

Ex-Vessel Value

- **Direct/Indirect Effects**. The total ex-vessel value of groundfish landed by catcher vessels is not expected to increase significantly under PA.1.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market, which contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Changes in revenue streams that affect the ability of communities to provide municipal services, fund capital projects, borrow money, and retire or service debt have the greatest potential for cumulative effects on landing tax revenues from non-groundfish fisheries (such as salmon, crab, and halibut). During recent years, state municipal revenue sharing, power cost equalization, and contribution to education programs have been decreasing. Marginal increases in ex-vessel value (9 percent) that are predicted for PA.1 may mitigate some of the declines in other fisheries. For these reasons, insignificant cumulative effects on ex-vessel value are expected to result from PA.1.

Employment and Payments to Labor

- **Direct/Indirect Effects**. Changes in ex-vessel value relative to the baseline under PA.1 are insignificant.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. These contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. The current reductions in the salmon and crab fisheries, and the fact that many fishermen rely on participation in multiple fisheries may elevate the importance of participation in the groundfish fisheries. The increase, although slight, in groundfish employment (9 percent) under PA.1, is likely to mitigate some of the reductions in other fisheries. Similarly, payments to labor are projected to increase slightly (9 percent) under PA.1, thereby mitigating some of the reductions in other fisheries. These other fisheries are not expected to contribute to cumulative effects on payments to labor in the groundfish fisheries. Therefore, cumulative effects on employment and payments to labor are expected to be insignificant under PA.1.

Impacts on Excess Capacity

- **Direct/Indirect Effects**. Changes in excess capacity are likely to be conditionally significant beneficial under PA.1.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. These contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Under PA.1, the extent to which rights-based management would be implemented in groundfish fisheries is uncertain. Should rights-based management be extended to other groundfish fisheries, excess capacity would be expected to be reduced in those fisheries. Excess capacity currently exists in non-groundfish fisheries to a certain extent as well, and may continue to exist unless management measures are taken to reduce it. Assuming that rights-based management is implemented in additional groundfish fisheries, a conditionally significant beneficial cumulative effect is likely for excess capacity under this FMP (see Appendix F-8).

Average Costs

- **Direct/Indirect Effects**. Conditionally significant beneficial effects are expected to occur for average costs under PA.1.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. These contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Average costs in the groundfish fisheries are often associated or shared with other fisheries. Fixed costs are somewhat independent of the fisheries in that loan payments and general office and accounting expenses remain at a certain amount while ex-vessel value and product value are variable. Should costs in other fisheries increase or decrease, vessels that are dependent on multiple fisheries are often sensitive to these changes. The extent to which rights-based management would be expanded is uncertain. Should rationalization programs be implemented average costs would be reduced. Thus, a conditionally significant beneficial cumulative effect is projected for PA.1 as a result of rights-based management that could be implemented.

Fishing Vessel Safety

- **Direct/Indirect Effects**. Conditionally significant beneficial effects are predicted under PA.1.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. These contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Vessel safety is primarily a function of the race for fish, and of distance to fishing areas and sea conditions relative to vessel size. Should rights-based management be expanded under PA.1, vessel safety could improve due to the end of the race for fish and less pressure to fish under dangerous conditions. Closures implemented in other fisheries may affect vessel safety in the groundfish fisheries, though these closures are not expected to result in a significant cumulative effect on vessel safety. Thus, a conditionally significant beneficial cumulative effect on fishing vessel safety is projected for PA.1 as a result of rights-based management that could be implemented.

Direct/Indirect Effects of PA.2

Table 4.9-6 summarizes projected impacts of PA.2 on harvesting and processing sectors. The numbers in the table reflect the five-year average of outcomes projected for 2003 to 2007. As a result of a projected increase in the TAC for Pacific cod in the BSAI and GOA, harvests of this species are estimated to increase by 29 percent, from 218,000 mt to 281,000 mt. Changes in the harvests of other groundfish species are not expected to be significant, nor are changes in total groundfish wholesale value of output, groundfish employment, and groundfish payments to labor.

Groundfish Landings By Species Group

A comparison of the five-year average of outcomes projected for the 2003-2007 period to 2001 catcher vessel conditions reveals that under PA.2, there would be a number of significant changes in overall retained harvests of groundfish relative to the comparative baseline. As a result of a projected increase in the TAC for Pacific cod in the BSAI and GOA, retained catches of this species are expected to increase by about 49 percent. The implementation of a more conservative TAC for sablefish and rockfish (components of the A-R-S-O species group) will result in a significant reduction in the retained harvests of these species. Retained harvests of pollock and flatfish are not expected to change significantly. Bycatch of non-target species and PSC is expected to decrease with incentives included in rationalization programs.

Reducing PSC limits for herring, crab, halibut, and salmon in the BSAI could impact the temporal nature of many fisheries. Fisheries which currently close seasonally because they exceed seasonal PSC limits could have even shorter seasons and possibly harvest less of the TAC if PSC limits are reduced. However, other measures implemented under PA.2 such as increased rationalization may lead to a reduction in prohibited species bycatch rates and thereby lessen the constraints of PSC limits on groundfish fisheries, regardless of whether or not the limits are reduced.

Ex-Vessel Value

The ex-vessel value of groundfish landed by catcher vessels is expected to increase relative to the comparative baseline, but not significantly. Increased Pacific cod harvests by the smaller trawl catcher vessels and pot catcher vessels account for much of the increase in groundfish ex-vessel value. Longline vessels are expected to experience a significant reduction in ex-vessel value due to the decrease in catches of rockfish and sablefish.

Employment and Payments to Labor

Total groundfish employment and payments to labor by catcher vessels are expected to decrease under PA.2, but not significantly. Longline vessels account for most of the decrease in employment and payments to labor.

Impacts on Excess Capacity

The comprehensive rationalization program that would be implemented under PA.2 is expected to result in a significant decrease in excess capacity in the harvesting and processing sectors relative to the comparative baseline, leading to a significantly beneficial direct/indirect effect rating. One of the primary reasons for expanding the use of rights-based management is to prevent the build-up of excess harvesting and processing capacity or reduce excess capacity that already exists (NMFS 2001a). Excess capacity both contributes to, and is the result of, the race for fish, with its associated potential adverse impacts on profitability, product quality, and safety. Rights-based systems, whether they allocate shares of the catch to individuals or groups, are incentive adjusting methods, in that they attempt to control capacity by creating economic incentives for owners of vessels to decrease their use of labor and capital rather than by directly regulating the level of fishing effort.

The implementation of additional IFQ programs that end the race for fish and allow transfer of quota shares would be expected to lead to some consolidation of quota to fewer vessels. The degree of consolidation will vary depending on the level of excess capacity, economies of scale and scope in harvesting, and rules that restrict transfer and accumulation of quota shares (NMFS 2001a). Similar consolidation could occur with expanded use of cooperatives or CDQ programs. Some excess capacity, in the sense of an ability of vessels and processors to catch and harvest the TAC in less time than a maximum season length would allow, can be expected to persist regardless of what type of additional rights-based measures are put in place. This is generally the case for a number of reasons. It is often not economically efficient to operate at maximum possible production levels; there are typically certain times of the year when it is more efficient and profitable to harvest and process fish; and alternative uses for fishing and processing capital are limited (NMFS 2001a).

Average Costs

Possible increased area closures to protect habitat as well as restrictions on bottom trawling for pollock are likely to increase average costs. The comprehensive rationalization program is expected to significantly reduce costs, leading to conditionally significant adverse/significantly beneficial direct/indirect effects ratings. The significance of the increase in average costs is conditional because it is uncertain to what extent PA.2 would create marine protected areas and no-take reserves to protect habitat. If additional area closures are implemented, the spatial displacement of fishing effort could be large for some bottom trawl fisheries. Operating costs would be expected to increase as vessels must travel further to fish, and gross revenue may decline as vessels may be required to fish in less productive areas.

Restrictions on bottom trawling for pollock are likely to increase average costs. It is reasonable to assume that, subject to regulatory constraints, harvesters target catch with the gear that maximizes its value either by increasing the value (quality) of the fish or by decreasing the harvesting cost or both. To the extent that the historical fishing gear was used because it has the lowest cost per unit of catch, the prohibition on bottom trawling for pollock in the GOA would result in increased cost per unit of catch for those fishing vessels that switch to pelagic trawling. Moreover, these vessels would have to purchase new gear and learn to use it. For vessels that use bottom trawl gear exclusively, the conversion necessary to fish with pelagic trawl gear would be substantial in some cases. In addition to new trawl gear, the conversion could include a more powerful engine, new gear handling equipment on deck, and new electronics.

Increased rationalization is expected to reduce the costs of harvesting. Individual vessels will have the opportunity to select the least cost combination of fishing inputs. At the industry level, costs will fall because production is expected to shift over time toward the most cost effective harvesting operations. Fixed costs will be reduced by consolidating harvesting operations and retiring or selling off vessels. The cost savings will depend both on the constraints put on the transfer and consolidation of harvesting rights and on the level of excess capacity prior to implementation of remedial measures.

Fishing Vessel Safety

A significant improvement or a conditionally significant reduction in fishing vessel safety could occur under PA.2 relative to the comparative baseline, leading to a significantly beneficial/conditionally significant adverse direct/indirect effects ratings. The significance of the decrease in vessel safety is conditional because it is uncertain to what extent PA.2 would close additional areas as MPAs or no-take reserves. Furthermore, the net effect of the various measures on fishing vessel safety is uncertain. The comprehensive rationalization program is expected to promote vessel safety by eliminating the race for fish. On the other hand, the spatial closures to protect habitat, if implemented, will limit the areas available for fishing and are likely to force vessels to operate farther from shore and in less than optimal weather conditions.

The implementation of rights-based systems under this FMP is expected to improve safety by reducing the pressure to fish under dangerous conditions (NMFS 2001a). The race for fish creates incentives to fish in areas and seasons with more hazardous weather and sea conditions and requires crew members to work for long stretches with little rest or sleep. Rights-based systems should slow down the fishing and reduce the financial penalty incurred by opting to stop fishing under unsafe conditions. The most important benefit of improved safety will be a decrease in fishery related injuries and loss of life. Other benefits include savings from not having to replace lost vessels and gear. Finally, significant improvements in safety, if they occur, should result in decreased insurance costs for industry (NMFS 2001a). At the same time, it is important to recognize that rationalized fisheries do not necessarily guarantee improvements in safety for fishermen. Under an IFQ program, for example, market opportunities may still encourage fishermen to fish at times or in places that are unsafe.

However, the additional area closures to protect habitat that may be implemented under PA.2 could result in vessels fishing farther from a port. This would decrease fishing vessel safety. Smaller catcher vessels based out of the Alaska Peninsula, Aleutian Islands, and Kodiak communities may be especially exposed to additional risks. These effects could be mitigated somewhat if individual fishing quotas were set aside for smaller vessels to fish in certain nearshore areas.

For a summary of the direct/indirect effects on catcher vessels under PA.2, please see Table 4.9-6.

Cumulative Effects of PA.2

This section assesses the potential for the direct/indirect effects to interact with persistent past effects and other reasonably foreseeable future events, resulting in a cumulative effect (Table 4.9-6). The persistent past effects on catcher vessels are presented in detail in Section 3.9 (Table 3.9-125) and the predicted direct/indirect effects are described above. Representative indicators for direct/indirect effects include groundfish landings by species group, groundfish ex-vessel value, employment, payments to labor, excess capacity, average costs, and fishing vessel safety.

<u>Groundfish Landings By Species Group</u>

- **Direct/Indirect Effects**. Insignificant cumulative effects are predicted under PA.2 for most species except for Pacific cod which is expected to increase significantly. The implementation of a more conservative TAC for sablefish and rockfish (components of the A-R-S-O species group) will result in a significant reduction in the retained harvests of these species.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. These contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Although there are currently reductions in the commercial salmon and crab fisheries, the predicted increases in retained harvest of Pacific cod (49 percent) may help mitigate that effect. Reductions in harvest of the A-R-S-O complex (29 percent) are projected to be significant but could be mitigated by the large increases in Pacific cod. Changes in other economic development activities and other sources of municipal and state revenue are expected to be mitigated by the increase in retained Pacific cod harvests. Overall, cumulative effects on groundfish landings by species group are projected to be insignificant under PA.2.

Ex-Vessel Value

- **Direct/Indirect Effects**. The total ex-vessel value of groundfish landed by catcher vessels is not expected to increase significantly under PA.2. Longline vessels are expected to experience a significant reduction in ex-vessel value due to the decrease in catches of rockfish and sablefish.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. These contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. While marginal changes in ex-vessel value in other fisheries may occur in the future, these changes are not expected to cumulatively affect groundfish ex-vessel value significantly. Other economic development activities and other sources of municipal and state revenue are not expected to have a significant cumulative effect on ex-vessel value under PA.2.

Employment and Payments to Labor

- **Direct/Indirect Effects**. Changes in employment and payments to labor relative to the baseline under PA.2 are insignificant.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. These contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Given the current reductions in the salmon and crab fisheries, and the fact that many fishermen often participate in multiple fisheries, fewer fishermen may be able to support their participation in the groundfish fisheries as a result of these reductions. However, the opposite result may occur where more harvesters are competing for groundfish employment as a result of reductions in other fisheries. Though these changes may occur, they are not expected to result in significant cumulative effects on groundfish employment under PA.2. Payments to labor in other fisheries are not expected to contribute to cumulative effects on payments to labor in the groundfish fisheries. Therefore, cumulative effects on payments to labor are projected to be insignificant.

Impacts on Excess Capacity

- **Direct/Indirect Effects**. Changes in excess capacity are likely to be significantly beneficial under PA.2.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. These contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Under PA.2, the comprehensive rationalization program would significantly reduce excess capacity. Although excess capacity would still remain in other fisheries such as salmon and crab, the program implemented under PA.2 would have such a strong effect that the benefits would far outweigh the effects of overcapacity in other fisheries (see Appendix F-8).

Average Costs

- **Direct/Indirect Effects**. Significantly beneficial or conditionally significant adverse effects are expected to occur for average costs under PA.2.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. These contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Average costs in the groundfish fisheries are often associated or shared with other fisheries. Fixed costs are somewhat independent of the fisheries in that loan payments and general office and accounting expenses remain at a certain amount while ex-vessel value and product value are variable. As described above, area closures affect average costs through increases or decreases in transit time to fishing areas. If additional closures are implemented under PA.2 to protect habitat, these closures would increase average costs by causing fishermen to travel farther to harvest fish. On the other hand, comprehensive rationalization is likely to significantly reduce average costs. Cost savings depend on the constraints put on the transfer and consolidation of harvesting rights and the level of excess capacity that might still remain in other fisheries. Therefore, significantly adverse or beneficial cumulative effects are possible under PA.2.

Fishing Vessel Safety

- **Direct/Indirect Effects**. Significantly beneficial or conditionally significant adverse effects are predicted for fishing vessel safety under PA.2.

- **Persistent Past Effects**. The persistent past effects include foreign fisheries exploitation, over-harvesting, expansion or development of commercial services and marine infrastructure in coastal communities, development of JV fisheries leading to the development of domestic fish harvesting and processing capacity, increased global demand for seafood, the collapse of Atlantic cod in the 1990s, and the development of the Japanese surimi market. These contributed to increased demand for groundfish species (see Section 4.5.9).

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Vessel safety is primarily a function of the race for fish, and of distance to fishing areas and sea conditions relative to vessel size. Under PA.2, vessel safety could improve due to the end of the race for fish and rationalization. However, possible additional area closures implemented under PA.2, plus any closures implemented in other fisheries, may adversely affect vessel safety causing vessels to travel farther and in potentially dangerous weather conditions. Therefore, significantly beneficial or adverse cumulative effects are possible under PA.2.

4.9.9.1.2 Catcher Processors

Direct/Indirect Effects of PA.1

Groundfish Landings By Species Group

Comparison of the five-year average of outcomes projected for the 2003-2007 period to 2001 catcher processor conditions reveals that under PA.1 there would be few significant changes in overall groundfish catches relative to the comparative baseline. As a result of a projected increase in the TAC for Pacific cod in the BSAI and GOA, catches of this species are expected to increase by about 30 percent. Catches of pollock, flatfish, and A-R-S-O species are not expected to change significantly.

Groundfish Gross Product Value

The overall wholesale product value of groundfish outputs of catcher processors is expected to increase relative to the comparative baseline, but not significantly. Increased Pacific cod harvests by head-and-gut trawl catcher processors, pot catcher processors, and longline catcher processors account for much of the increase in product value. The harvest of Pacific cod by surimi trawl catcher processors and fillet trawl catcher processors is limited by AFA sideboard measures that restrict the participation of AFA-eligible vessels in other groundfish fisheries to some level of historic participation.

Employment and Payments to Labor

Total groundfish employment and payments to labor by catcher processors are expected to increase under PA.1, but not significantly.

Product Quality and Product Utilization Rate

A conditionally significant increase in product quality and product utilization rates is expected under this FMP relative to the comparative baseline, leading to a conditionally significant beneficial direct/indirect effect rating. The significance of the increase in product quality and utilization is conditional because it is uncertain to what extent PA.1 would extend rights-based management to additional groundfish fisheries. The race for fish creates incentives to maximize profits per unit of fishing time rather than per unit of fish. Consequently, it may induce wasteful practices or reduce the incentives to increase recovery rates if those increases are costly either in out-of-pocket costs or opportunity costs of time. Even when increased or full utilization is profitable in terms of the value and costs of product, there may be an implicit cost due to storage space limitations that will force more frequent unloading.

For the most part, rights-based systems should give individuals and groups the incentive to get the maximum value out of each unit of catch. Consequently, product quality and utilization rates are expected to increase under this FMP bookend should rights-based management be extended to additional fisheries. Some increases in value can be expected as a result of the improved quality that can be achieved by more careful harvesting and handling practices. In a race for fish these time-consuming practices may be neglected because the opportunity costs are too high. For example, vessels may choose to make shorter tows to reduce the crushing of fish in the codend or may spend more time searching for larger, more valuable fish. The value of production will increase because processors have the time and incentive to make products of higher value, and to retain fish they had previously discarded. For example, in rationalized fisheries head-and-gut trawl catcher processors may be more likely to retain male rock sole and small yellowfin sole because retention of those fish would no longer put vessels at a competitive disadvantage compared to vessels that discard.

Excess Capacity

As with catcher vessels, a conditionally significant decrease in excess capacity in the harvesting and processing sectors is expected under this FMP relative to the comparative baseline, leading to a conditionally significant beneficial direct/indirect effect rating. The decrease in excess capacity depends on the extent to which PA.1 extends rights–based management to additional groundfish fisheries.

Average Costs

As with catcher vessels, a conditionally significant decrease in average costs is expected under this FMP relative to the comparative baseline, leading to a conditionally significant beneficial direct/indirect effect rating. The decrease in average costs depends on the extent to which PA.1 extends rights-based management to additional groundfish fisheries.

Fishing Vessel Safety

As with catcher vessels, a conditionally significant increase in fishing vessel safety is expected under this FMP relative to the comparative baseline, leading to a conditionally significant beneficial direct/indirect effect rating. The increase in fishing vessel safety depends on the extent to which PA.1 extends rights-based management to additional groundfish fisheries.

For a summary of the direct/indirect effects on catcher processors under PA.1, please see Table 4.9-6.

Cumulative Effects of PA.1

This section assesses the potential for the direct/indirect effects to interact with persistent past effects and other reasonably foreseeable future events, resulting in a cumulative effect (Table 4.9-6). The persistent past effects on catcher processors are presented in detail in Section 3.9 (Table 3.9-125), and the predicted direct/indirect effects are described above. Representative indicators for direct/indirect effects include groundfish landings by species group, groundfish gross product value, employment, payments to labor, excess capacity, product quality, product utilization rate, average costs, and fishing vessel safety.

<u>Groundfish Landings By Species Group</u>

- **Direct/Indirect Effects**. Overall, insignificant effects are expected for retained harvests of groundfish species except for Pacific cod which is expected to result in significant increases of the number of landings (30 percent).

- **Persistent Past Effects**. For details on persistent past effects, see Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue and are described in detail in Section 4.5.9.1.

- **Cumulative Effects**. Given the current downward trends in the commercial salmon and crab fisheries, catcher processors that rely on a mix of groundfish, salmon, and crab may experience a reduction in harvest levels. However, this cumulative effect may not result in significant changes in groundfish landings under PA.1. An increase in TAC for Pacific cod in the BSAI and GOA is expected (30 percent). Overall, reductions in other fisheries, in combination with some increases in certain groundfish landings by species group, are expected to result in insignificant cumulative effects under PA.1. Other economic development activities and other sources of municipal and state revenue are not expected to contribute to cumulative effects on groundfish landings by species group. While climate change may result in potential increases or decreases in fish populations as explained in more detail in Section 4.9.1, these changes are not expected to have significant cumulative effects on groundfish landings by species group.

<u>Groundfish Gross Product Value</u>

- **Direct/Indirect Effects**. The gross product value is not expected to result in significant changes from the baseline.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Changes in revenue streams that affect the ability of communities to provide municipal services, fund capital projects, borrow money, and retire or service debt have the greatest potential for cumulative effects on landing tax revenues from groundfish and non-groundfish fisheries (such as salmon, crab, and halibut). During recent years, state municipal revenue sharing, power cost equalization, and contribution to education programs have been decreasing. Marginal increases in gross product value (6 percent) that are predicted for PA.1 may mitigate some of the current declines in other fisheries. For these reasons, insignificant cumulative effects on gross product value are expected to result from PA.1.

Employment and Payments to Labor

- **Direct/Indirect Effects**. Insignificant changes in employment and payments to labor are predicted for catcher processors under PA.1.
- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.
- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue. Details on these future external effects are listed at the beginning of Section 4.5.9.
- **Cumulative Effects**. The current reductions in the salmon and crab fisheries, and the fact that many fishermen rely on participation in multiple fisheries may elevate the importance of participation in the groundfish fisheries. The increase, although slight, in groundfish employment (7 percent) under PA.1, is likely to mitigate some of the reductions in other fisheries. Similarly, payments to labor are projected to increase slightly (6 percent) under PA.1, thereby, mitigating some of the reductions in other fisheries. These other fisheries are not expected to contribute to significant cumulative effects on payments to labor in the groundfish fisheries. Therefore, cumulative effects on employment and payments to labor are expected to be insignificant under PA.1.

Product Quality and Product Utilization Rate

- **Direct/Indirect Effects**. Conditionally significant beneficial effects in product quality and product utilization rates are expected under PA.1 relative to the baseline.
- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.
- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).
- **Cumulative Effects**. Advances in technology have improved product quality and utilization for various fisheries throughout the world. The end of the race for fish has made significant differences in product quality and utilization; however, any continuation of this harvest strategy in fisheries may hinder some of these improvements. To the extent that rights-based management is extended to other fisheries under PA.1, increases in product quality and utilization are expected. Furthermore, increases in product quality and utilization are likely in the long-term given the trend towards improved fishing and preservation techniques. Thus, conditionally significant beneficial cumulative effects are projected under PA.1.

Impacts on Excess Capacity

- **Direct/Indirect Effects**. Conditionally significant beneficial effects in excess capacity are expected under PA.1 relative to the baseline.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Although excess capacity still remains in other fisheries as well as the groundfish fishery, measures such as LLP and an end to the race for fish help mitigate this effect (see Appendix F-8). Cumulative effects are conditionally significant beneficial because to the extent that a rights-based management regime is extended to other groundfish fisheries under PA.1, excess capacity would be reduced.

Average Costs

- **Direct/Indirect Effects**. Conditionally significant beneficial effects in average costs are expected under PA.1 relative to the comparative baseline.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Average costs in the groundfish fisheries are often associated or shared with other fisheries. Fixed costs are somewhat independent of the fisheries in that loan payments and general office and accounting expenses remain at a certain amount, while ex-vessel value and product value are variable. Catcher processors that are dependent on multiple fisheries are often sensitive to changes in other fisheries. Assuming rights-based management extends to other groundfish fisheries under PA.1, average costs would be reduced. Thus, conditionally significant beneficial cumulative effects are predicted on excess capacity under PA.1.

Fishing Vessel Safety

- **Direct/Indirect Effects**. Conditionally significant beneficial effects for fishing vessel safety are expected under PA.1.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Vessel safety is primarily a function of the race for fish, distance to fishing areas and sea conditions relative to vessel size. Additional closures that may result from other fisheries management measures may increase the risk to fishermen; however, these effects are not expected to be significant under PA.1. The extent to which rights-based management is implemented under PA.1 will affect vessel safety. As there are no predicted increases in area closures under PA.1, and assuming rights-based management is extended to other groundfish fisheries, cumulative effects on vessel safety are conditionally significant beneficial compared to the baseline condition.

Direct/Indirect Effects of PA.2

Groundfish Landings By Species Group

A comparison of the five-year average of outcomes projected for the 2003-2007 period to 2001 catcher processor conditions reveals that under PA.2 there would be few significant changes in overall groundfish catches relative to the comparative baseline. As a result of a projected increase in the TAC for Pacific cod in the BSAI and GOA, catches of this species are expected to increase by about 22 percent. The implementation of a more conservative TAC for sablefish and rockfish (components of the A-R-S-O species group) will result in a significant reduction in the retained harvests of these species. Retained harvests of pollock and flatfish are not expected to change significantly. Bycatch of non-target species and PSC is expected to decrease with incentives included in rationalization programs.

Groundfish Gross Product Value

The overall wholesale product value of groundfish outputs of catcher processors is expected to increase relative to the comparative baseline, but not significantly. Increased Pacific cod harvests by head-and-gut trawl catcher processors, pot catcher processors, and longline catcher processors account for much of the increase in product value. The harvest of Pacific cod by surimi trawl catcher processors and fillet trawl catcher processors is limited by AFA sideboard measures that restrict the participation of AFA-eligible vessels in other groundfish fisheries to some level of historic participation.

Employment and Payments to Labor

Total groundfish employment and payments to labor by catcher processors are expected to increase under PA.1, but not significantly.

Product Quality and Product Utilization Rate

A significant improvement or a conditionally significant reduction in product quality and utilization rates could occur under PA.2 relative to the comparative baseline, leading to significantly beneficial and conditionally significant adverse direct/indirect effects ratings. The significance of the decrease in product quality and utilization is conditional because it is uncertain to what extent PA.2 would establish additional area closures to protect habitat. Furthermore, the net effect of the various measures on fishing vessel product quality and utilization is uncertain.

The implementation of a comprehensive rights-based management program will tend to improve product quality and utilization rates. The race for fish creates incentives to maximize profits per unit of fishing time rather than per unit of fish. Consequently, it may induce wasteful practices or reduce the incentives to increase recovery rates if those increases are costly either in out-of-pocket costs or opportunity costs of time. Even when increased or full utilization is profitable in terms of the value and costs of product, there may be an implicit cost due to storage space limitations that will force more frequent unloading. For the most part, rights-based systems should give individuals and groups the incentive to get the maximum value out of each unit of catch. Some increases in value can be expected as a result of the improved quality that can be achieved by more careful harvesting and handling practices. In a race for fish these time-consuming practices may be neglected because the opportunity costs are too high. For example, vessels may choose to make shorter tows to reduce the crushing of fish in the codend or may spend more time searching for larger, more valuable fish. The value of production will also increase because processors have the time and incentive to make products of higher value, where previously they had focused on products that could be produced quickly or with lower quality fish. For instance, we might expect to see more fillet production in place of round or headed-and-gutted product.

On the other hand, the additional area closures that are implemented under PA.2 may contribute to lower product quality. However, this effect is not likely to offset the gains from rationalization. It is reasonable to assume that, subject to regulatory constraints, harvesters target catch in areas that maximizes its value either by increasing the quality of the fish or by decreasing the harvesting cost or both. Consequently, a measure that prohibits vessels from using historical fishing grounds may result in a decline in product quality (e.g., fish may be smaller or a less uniform size).

Excess Capacity

As with catcher vessels, the comprehensive rationalization program that would be implemented under PA.2 is expected to result in a significant decrease in excess capacity in the harvesting and processing sectors relative to the comparative baseline, leading to a significantly beneficial direct/indirect effect rating. Because the number of catcher processors that are not AFA-eligible out number the vessels that are AFA-eligible, the reduction in excess capacity resulting from rationalization should be significant.

Average Costs

As with catcher vessels, possible increased area closures to protect habitat as well as restrictions on bottom trawling for pollock are likely to increase average costs. The comprehensive rationalization program is expected to significantly reduce costs, leading to conditionally significant adverse/significantly beneficial direct/indirect effects ratings. The significance of the increase in average costs is conditional because it is uncertain to what extent PA.2 would create MPAs and no-take reserves to protect habitat. Furthermore, the net effect of the various measures on average costs is uncertain.

Fishing Vessel Safety

As with catcher vessels, a significant improvement or a conditionally significant reduction in fishing vessel safety could occur under PA.2 relative to the comparative baseline, leading to conditionally significant adverse and significantly beneficial direct/indirect effects ratings. The significance of the decrease in vessel safety is conditional because it is uncertain to what extent PA.2 would close additional areas as MPAs or no-take reserves. Furthermore, the net effect of the various measures on fishing vessel safety is uncertain. The comprehensive rationalization program is expected to promote vessel safety by eliminating the race for fish. On the other hand, the spatial closures to protect habitat, if implemented, will limit the areas available for fishing and are likely to force vessels to operate farther from shore and in less than optimal weather conditions.

For a summary of the direct/indirect effects on catcher processors under PA.2, please see Table 4.9-6.

Cumulative Effects of PA.2

This section assesses the potential for the direct/indirect effects to interact with persistent past effects and other reasonably foreseeable future events, resulting in a cumulative effect (Table 4.9-6). The persistent past effects on catcher processors are presented in detail in Section 3.9 (Table 3.9-125) and the predicted direct/indirect effects are described above. Representative indicators for direct/indirect effects include groundfish landings by species group, groundfish gross product value, employment, payments to labor, excess capacity, product quality, product utilization rate, average costs, and fishing vessel safety.

Groundfish Landings By Species Group

- **Direct/Indirect Effects**. Overall, insignificant changes in groundfish harvests are expected under PA.2; however, significant increases in Pacific cod and significant decreases in sablefish and rockfish are predicted for this FMP.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue and are described in detail in Section 4.5.9.

- **Cumulative Effects**. As stated under PA.1, the current downward trends in the commercial salmon and crab fisheries are adversely affecting catcher processors that rely on a mix of fisheries harvests. However, this cumulative effect may not result in significant changes in groundfish landings under PA.2. An increase in TAC for Pacific cod in the BSAI and GOA is expected (22 percent). Harvests of pollock and flatfish are not expected to change significantly. Overall, the reductions in other fisheries, in combination with some increases in certain groundfish landings by species group, are expected to result in insignificant cumulative effects under PA.2. Other economic development activities and other sources of municipal and state revenue are not expected to contribute to cumulative effects on groundfish landings by species group.

Groundfish Gross Product Value

- **Direct/Indirect Effects**. The gross product value is not expected to result in significant changes from the baseline.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. As described under PA.1, insignificant cumulative effects on groundfish gross product value are expected to result from PA.2.

Employment and Payments to Labor

- **Direct/Indirect Effects**. Insignificant changes in employment and payments to labor are predicted for catcher processors under PA.2.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Total employment and payments to labor are expected to increase under PA.2. As with catcher vessels, reductions in the salmon and crab fisheries, and the reliance many fishermen have on participation in multiple fisheries may elevate the importance of participation in the groundfish fisheries. The increase, although slight, in groundfish employment (5 percent) under PA.2 may mitigate some of the reductions in other fisheries. Similarly, payments to labor are also projected to increase slightly (5 percent) under PA.2. Catcher processors that participate in the halibut fishery may be less sensitive to reductions in salmon and crab. Therefore, cumulative effects on employment and payments to labor are expected to be insignificant under PA.2.

Product Quality and Product Utilization Rate

- **Direct/Indirect Effects**. A significantly beneficial or conditionally significant adverse effect on product quality and product utilization rates is possible under PA.2.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Advances in technology have improved product quality and utilization for various fisheries throughout the world. The end of the race for fish has made significant differences in product quality and utilization; however, the additional closures that may be implemented under this FMP may result in a decline in product quality (e.g., fish may be smaller or a less uniform size). Overall, significant beneficial or adverse cumulative effects are possible for product quality and utilization under PA.2.

Impacts on Excess Capacity

- **Direct/Indirect Effects**. A significantly beneficial effect in excess capacity is expected under PA.2 relative to the baseline. Excess capacity is predicted to decrease significantly.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. As with PA.1, comprehensive rationalization in the groundfish fishery will help reduce excess capacity. Although excess capacity still remains in other fisheries as well as the groundfish fishery, measures such as LLP and an end to the race for fish help mitigate this effect (see Appendix F-8). Assuming that these programs continue in other fisheries and are expanded in the groundfish fisheries under PA.2, significant beneficial cumulative effects are expected for excess capacity.

Average Costs

- **Direct/Indirect Effects**. Various measures under PA.2 are likely to both increase and decrease average costs. The net effect of PA.2 on average costs is unknown (see the direct/indirect effects discussion in this section).

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. As described in more detail under PA.1, average costs in the groundfish fisheries are often associated or shared with other fisheries and include both fixed costs and variable costs. The effects of comprehensive rationalization under this FMP are likely to reduce costs. However, area closures affect average costs through increases in transit time to fishing areas. It is uncertain to what extent PA.2 would establish additional area closures. Therefore, significantly beneficial or adverse cumulative effects are possible under PA.2.

Fishing Vessel Safety

- **Direct/Indirect Effects**. Significant beneficial or conditionally significant adverse effects for fishing vessel safety are possible under PA.2. The net effect of this FMP on vessel safety is uncertain (see the direct/indirect effects discussion in this section).

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Vessel safety is primarily a function of the race for fish, distance to fishing areas, and sea conditions relative to vessel size. Under PA.2, vessel safety could improve due to the end of the race for fish and rationalization. However, possible additional area closures implemented under PA.2, plus any closures implemented in other fisheries, may adversely affect vessel safety causing vessels to travel farther and in potentially dangerous weather conditions. Therefore, significant beneficial or adverse cumulative effects on vessel safety are possible under PA.2.

4.9.9.1.3 Inshore Processors and Motherships

Direct/Indirect Effects of PA.1

Groundfish Landings By Species Group

A comparison of the five-year average of outcomes projected for the 2003-2007 period to 2001 inshore processor and mothership conditions reveals that under PA.1 there would be few significant changes in overall groundfish catches relative to the comparative baseline. As a result of a projected increase in the TAC for Pacific cod in the BSAI and GOA, catches of this species are expected to increase by about 50 percent. In addition, an increase in the TAC for sablefish and rockfish (components of the A-R-S-O species group) will result in a significant increase in the harvests of these species. Harvests of pollock and flatfish are not expected to change significantly.

Groundfish Gross Product Value

The wholesale product value of groundfish processed by inshore processors and motherships is expected to increase relative to the comparative baseline, but not significantly. Increased deliveries of Pacific cod to Bering Sea pollock shore plants, Alaska Peninsula, and Aleutian Islands shore plants, Kodiak shore plants, and floating inshore processors account for much of the increase in groundfish product value. Southeast Alaska shore plants and southcentral Alaska shore plants are expected to benefit from the increased catches of sablefish and rockfish.

Employment and Payments to Labor

Total groundfish employment and payments to labor by inshore processors and motherships are expected to increase under PA.1, but not significantly.

Product Quality and Product Utilization Rate

As with catcher processors, a conditionally significant increase in product quality and product utilization rates is expected under this FMP relative to the comparative baseline, leading to a conditionally significant beneficial direct/indirect effect rating. The significance of the increase in product quality and utilization is conditional because it is uncertain to what extent PA.1 would extend rights-based management to additional groundfish fisheries. With additional fisheries operating under rights-based management rather than the race for fish, inshore processors will likely be able to slow their overall throughput and focus on obtaining the highest value per fish rather than the most fish per unit of time.

Excess Capacity

A conditionally significant decrease in excess capacity in the harvesting and processing sectors is expected under this FMP relative to the comparative baseline, leading to a conditionally significant beneficial direct/indirect effect rating. The decrease in excess capacity depends on the extent to which PA.1 extends rights-based management to additional groundfish fisheries. In contrast to the harvesting sector; however, rights-based management measures can increase the excess capacity of inshore processors in the short run. For example, when the IFQ program was established for the sablefish and halibut longline fisheries additional fresh-market processors and buyers entered the fisheries. In addition, existing processors that had increased capacity to cope with the fish gluts that occurred under race for fish found that they had more capacity than was necessary under the slower-paced IFQ fisheries. In contrast, in the BSAI pollock fishery under the AFA, processing capacity increases were specifically limited by restricting entry into the pollock fishery and sideboard restrictions imposed on AFA catcher vessels. In the long-run; however, excess processing capacity is expected to significantly diminish in rationalized fisheries.

Average Costs

As with catcher vessels, a conditionally significant decrease in average costs is expected under this FMP relative to the comparative baseline, leading to a conditionally significant beneficial direct/indirect effect rating. The decrease in average costs depends on the extent to which PA.1 extends rights-based management to additional groundfish fisheries.

Increased rationalization is expected to reduce the costs of processing. Individual processing facilities will have the opportunity to select the least cost combination of processing inputs. At the industry level, costs will fall because production is expected to shift over time toward the most cost effective processing operations. Fixed costs will be reduced by consolidating processing operations and retiring or selling-off processing equipment. The cost savings will depend both on the constraints put on the transfer and consolidation of harvesting and processing rights and on the level of excess capacity prior to implementation of remedial measures.

For a summary of the direct/indirect effects on inshore processors and motherships under PA.1 (Table 4.9-6).

Cumulative Effects of PA.1

This section will assess the potential for the direct/indirect effects to interact with persistent past effects and other reasonably foreseeable future events, resulting in a cumulative effect (Table 4.9-6). The persistent past effects on inshore processors and motherships are presented in detail in Section 3.9 (Table 3.9-125) and the predicted direct/indirect effects are described above. Representative indicators for direct/indirect effects include groundfish landings by species group, groundfish gross product value, employment, payments to labor, excess capacity, product quality, product utilization rate, average costs, and fishing vessel safety.

Groundfish Landings By Species Group

- **Direct/Indirect Effects**. Overall, retained harvests of groundfish species are expected to be insignificant except for Pacific cod, which are expected to have significant effects.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue and are described in detail in Section 4.5.9.

- **Cumulative Effects**. Inshore plants and motherships that rely on a mix of groundfish, salmon, and crab may experience a reduction in harvest levels. Those that process halibut may be less sensitive to these reductions in other fisheries. The combination of increases in halibut, reductions in salmon and crab and relatively stable projections (except for significant increases in Pacific cod) for groundfish, may result in insignificant cumulative effects under PA.1. Other economic development activities and other sources of municipal and state revenue are not expected to contribute to cumulative effects on groundfish landings by species group. While climate changes may result in potential increases or decreases in fish populations (see Section 4.9.1), these changes are not expected to result in significant cumulative effects on groundfish landings by species group.

Groundfish Gross Product Value

- **Direct/Indirect Effects**. The gross product value is expected to increase, but not significantly from the baseline.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Changes in revenue streams that affect the ability of communities to provide municipal services, fund capital projects, borrow money, and retire or service debt have the greatest potential for cumulative effects on landing tax revenues from groundfish and non-groundfish fisheries (such as salmon, crab, and halibut). During recent years, state municipal revenue sharing, power cost equalization, and contribution to education programs have been decreasing. Marginal increases in gross product value (7 percent) that are predicted for PA.1 may mitigate some of the declines in other fisheries. For these reasons, insignificant cumulative effects on ex-vessel value are expected to result from PA.1.

Employment and Payments to Labor

- **Direct/Indirect Effects**. Employment and payments to labor are expected to increase but not significantly under PA.1.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Processors that rely on salmon and crab may continue to experience reductions in employment and payments to labor. Groundfish employment and labor income projections under PA.1 are not significant (7 percent) but may mitigate some of the reductions due to salmon and crab. Processors may experience increases if they process halibut and groundfish due to recent increases in the halibut fishery. The combination of reductions and increases in these multiple fisheries are likely to result in insignificant cumulative effects on employment and payments to labor are expected under PA.1.

Product Quality and Product Utilization Rate

- **Direct/Indirect Effects**. A conditionally significant increase in product quality and utilization rate are expected under PA.1 relative to the baseline.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. As with catcher processors, advances in technology have improved product quality and utilization for various fisheries throughout the world. The end of the race for fish has made significant differences in product quality and utilization; however, any continuation of this harvest strategy in fisheries may hinder some of these improvements. Overall, increases in product quality and utilization are likely in the long-term given the trend towards improved fishing and preservation techniques. Thus, conditionally significant beneficial cumulative effects are projected under PA.1.

Impacts on Excess Capacity

- **Direct/Indirect Effects**. A conditionally significant beneficial effect in excess capacity is expected under PA.1 relative to the baseline. Capacity is expected to decrease.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Although excess capacity still remains in other fisheries as well as the groundfish fishery, measures such as LLP and an end to the race for fish help mitigate this effect (see Appendix F-8). Should rights-based management extend to additional groundfish fisheries, excess capacity would be further reduced. Therefore, a conditionally significant beneficial cumulative effect is expected to occur for excess capacity under this FMP, particularly if other fisheries do not change their licensing programs.

Average Costs

- **Direct/Indirect Effects**. A conditionally significant beneficial effect in average costs are expected under PA.1 relative to the comparative baseline. Average costs are expected to decrease.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. As described under catcher vessels and catcher processors, average costs in the groundfish fisheries are often associated or shared with other fisheries and include both fixed and variable costs. Vessels that are dependent on multiple fisheries are often sensitive to changes in costs in other fisheries. As rights-based management may be extended to other fisheries under PA.1, a conditionally significant beneficial cumulative effect on average costs in the groundfish fisheries is expected.

Direct/Indirect Effects of PA.2

Groundfish Landings By Species Group

A comparison of the 5-year average of outcomes projected for the 2003-2007 period to 2001 inshore processor and mothership conditions reveals that under PA.2 there would be a number of significant changes in overall harvests of groundfish relative to the comparative baseline. As a result of a projected increase in the TAC for Pacific cod in the BSAI and GOA, catches of this species are expected to increase by about 44 percent. The implementation of a more conservative TAC for sablefish and rockfish (components of the A-R-S-O species group) will result in a significant reduction in the harvests of these species. Harvests of pollock and flatfish are not expected to change significantly. Bycatch of non-target species and PSC is expected to decrease with incentives included in rationalization programs.

Groundfish Gross Product Value

The overall wholesale product value of groundfish processed by inshore processors and motherships is expected to increase relative to the comparative baseline, but not significantly. Increased deliveries of Pacific cod to short plants in the Bering Sea (pollock), Alaska Peninsula, Aleutian Islands, Kodiak, and floating inshore processors account for much of the increase in groundfish product value. Decreased deliveries of rockfish and sablefish will have a significant adverse impact on the product value of shore plants southeast and southcentral Alaska. The product value of shore plants in the Alaska Peninsula, the Aleutian Islands, and Kodiak will be adversely affected by this decrease, but less so.

Employment and Payments to Labor

Total groundfish employment and payments to labor by inshore processors and motherships are expected to increase under PA.2, but not significantly.

Product Quality and Product Utilization Rate

As with catcher processors, a significant improvement or a conditionally significant reduction in product quality and utilization rates could occur under PA.2 relative to the comparative baseline. The net effect of the various measures on product quality and utilization is uncertain. The implementation of a comprehensive rights-based management program will tend to improve product quality and utilization rates. However, a large portion of the product currently produced by inshore processors and motherships is already produced in rationalized fisheries (e.g., sablefish longline fishery and BSAI pollock fishery). Furthermore, the additional area closures considered under PA.2 may cause product quality to decrease. Pacific cod and Alaska pollock are fragile fish whose quality deteriorates rapidly the longer the time from harvest to processing. As such, any factors that will increase the length of time to processing will, in general, lower the quality of the product produced. To the extent that PA.2 results in catcher vessels traveling farther distances from (inshore) processors, and thereby lengthening the time between harvest and processing, the quality of surimi, fillets, and roe will be adversely affected.

Excess Capacity

As with catcher vessels and catcher processors, the comprehensive rationalization program that would be implemented under PA.2 is expected to result in a significant decrease in excess capacity in the processing sectors relative to the comparative baseline in the long-term. In the short-term, however, a comprehensive rationalization may create excess capacity that would continue during the transition from the race for fish to rights-based management.

Average Costs

The net effect of PA.2 on average costs relative to the baseline is uncertain. If implemented, the area closures to protect habitat are likely to contribute to higher average costs for processors. On the other hand, a comprehensive rationalization program is expected to contribute to lower average costs. This leads to conditionally significant adverse and significant beneficial direct/indirect effects ratings for average costs under PA.2.

Although it is uncertain to what extent PA.2 would establish additional area closures to protect habitat, this FMP could include measures that result in considerable spatial displacement of fishing effort. The result could be substantial increases in average costs. However, an expanded rationalization program is expected to reduce the costs of processing. Individual processing facilities will have the opportunity to select the least cost combination of processing inputs. At the industry level, costs will fall because production is expected to shift over time toward the most cost effective processing operations. Fixed costs will be reduced by consolidating processing operations and retiring or selling off processing equipment. The cost savings will depend both on the constraints put on the transfer and consolidation of harvesting and processing rights and on the level of excess capacity prior to implementation of remedial measures.

Cumulative Effects of PA.2

This section will assess the potential for the direct/indirect effects to interact with persistent past effects and other reasonably foreseeable future events, resulting in a cumulative effect (Table 4.9-6). The persistent past effects on catcher vessels are presented in detail in Section 3.9 (Table 3.9-125) and the predicted direct/indirect effects are described above. Representative indicators for direct/indirect effects include groundfish landings by species group, groundfish gross product value, employment, payments to labor, excess capacity, product quality, product utilization rate, average costs, and fishing vessel safety.

Groundfish Landings By Species Group

- **Direct/Indirect Effects**. Projected increases in Pacific cod are expected under PA.2; however, sablefish and rockfish will decrease significantly. Pollock and flatfish harvests are not expected to change significantly.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue and are described in detail in Section 4.5.9.1.

- **Cumulative Effects**. Current downward trends in the commercial salmon and crab fisheries may put pressure on processors who do not rely on mixed harvests. Those processors that rely on groundfish and halibut catch may experience some increases in landings under PA.2. The significant increases in Pacific cod and the current increasing trends in halibut may counteract the reductions in other fisheries. Insignificant cumulative effects on groundfish landings are expected to result under PA.2. Other economic development activities and other sources of municipal and state revenue are not expected to contribute to cumulative effects on groundfish landings by species group. While climate change may result in potential increases or decreases in fish populations as explained in more detail in Section 4.9.1, these changes are not expected to have significant cumulative effects on groundfish landings by species group.

Groundfish Gross Product Value

- **Direct/Indirect Effects**. The gross product value is expected to increase from the baseline, but not significantly. Decreased deliveries of rockfish and sablefish will have a significant adverse impact on the product value of shore plants in southeast and southcentral Alaska. The product value of shore plants in the Alaska Peninsula, Aleutian Islands, and Kodiak will be adversely affected by this decrease but less so than southeast and southcentral Alaska.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. As described with catcher processors, changes in revenue streams that affect the ability of communities to provide municipal services, fund capital projects, borrow money, and retire or service debt have the greatest potential for cumulative effects on landing tax revenues from groundfish and non-groundfish fisheries (such as salmon, crab, and halibut). During recent years, state municipal revenue sharing, power cost equalization, and contribution to education programs have been decreasing. Marginal increases in gross product value (4 percent) that are predicted for PA.2 may mitigate some of the declines in other fisheries. For these reasons, insignificant cumulative effects on ex-vessel value are expected to result from PA.2.

Employment and Payments to Labor

- **Direct/Indirect Effects**. Insignificant effects are predicted for catcher processors under PA.2.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. The current reductions in the salmon and crab fisheries, and the fact that many fishermen rely on participation in multiple fisheries may elevate the importance of the groundfish and halibut fisheries. The increase, although slight, in groundfish employment (5 percent) under PA.2 is likely to mitigate some of the reductions in other fisheries. Similarly, payments to labor are projected to increase slightly (4 percent) under PA.2, thereby mitigating some of the reductions in other fisheries. Changes in other fisheries are not expected to contribute to cumulative effects on payments to labor in the groundfish fisheries. Therefore, cumulative effects on employment and payments to labor are expected to be insignificant under PA.2.

Product Quality and Product Utilization Rate

- **Direct/Indirect Effects**. A significant improvement or a conditionally significant reduction in product quality and utilization rates could occur under PA.2 relative to the baseline.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Technological advances have improved product quality and utilization for various fisheries throughout the world. The end of the race for fish has made significant differences in product quality and utilization; however, the possible increase in area closures may counteract any improvements in product quality achieved by better handling. Overall, increases in product quality and utilization are likely in the long-term given the trend towards improved fishing and preservation techniques. Thus, significant beneficial or adverse cumulative effects are possible under PA.2.

Impacts on Excess Capacity

- **Direct/Indirect Effects.** Significantly beneficial changes in excess capacity are possible under PA.2 relative to the baseline. The net effect of these measures on capacity is unknown (see the direct/indirect effects discussion in this section).

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. Although excess capacity still remains in other fisheries as well as the groundfish fishery, comprehensive rationalization and an end to the race for fish help mitigate this effect (see Appendix F-8). Assuming that these programs continue in other fisheries, as they do in the groundfish fisheries under PA.2, the cumulative effects on excess capacity are likely to be significantly beneficial compared the baseline.

Average Costs

- **Direct/Indirect Effects**. Both significantly beneficial and conditionally significant adverse effects are possible under this FMP. If implemented, spatial closures to protect habitat are likely to increase costs; however, comprehensive rationalization would decrease costs.

- **Persistent Past Effects**. For details on persistent past effects, see the beginning of Section 4.5.9.

- **Reasonably Foreseeable Future External Effects** include other fisheries, other economic development activities, and other sources of municipal and state revenue (see Section 4.5.9).

- **Cumulative Effects**. As described for catcher vessels and catcher processors, average costs in the groundfish fisheries are often associated or shared with other fisheries and include fixed and variable costs. Increases in closure areas increase costs whereas decreases in closures usually decrease costs. The cumulative effect on average costs under PA.2 is uncertain because it is unknown to what extent the FMP would create MPAs and no-take reserves to protect habitat. Furthermore, any cost increases that occur as a result of implementation of area closures could be offset to some extent by the cost reductions that are expected to occur as a result of comprehensive rationalization of the groundfish fisheries (see the direct/indirect effects discussion in this section). Significant beneficial or adverse cumulative effects are possible under PA.2.

4.9.9.2 Regional Socioeconomic Effects

The predicted direct and indirect effects of the groundfish fishery under PA.1 and PA.2 are described below (Table 4.9-6). The past/present effects on regions that participate in the groundfish fishery are described in Section 3.9 (and summarized in Table 3.9-126) and below. These regions (illustrated in Figures 3.9-9 through 3.9-14) include the Aleutian Islands/Alaska Peninsula (comprised of the Aleutians East Borough and the Aleutians West Census Area, which includes the communities of Unalaska, Nikolski, Atka, Adak and the Pribilof Islands), Kodiak Island (Kodiak Island Borough, which includes the City of Kodiak) southcentral Alaska (the Kenai Peninsula Borough, Matanuska-Susitna Borough, Municipality of Anchorage (which includes the cities of Eagle River, Chugiak, and Girdwood), the Valdez-Cordova Census Area (which includes the PWS region), southeast Alaska (all of the southeastern part of the state, from Yakutat Borough to Dixon Entrance), Washington inland waters (all counties bordering Puget Sound and the Strait of Juan de Fuca), and the Oregon coast (Lincoln, Tillamook, and Clatsop counties, the three northernmost Oregon coastal counties). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case.

Due to the linkages of potential effects on regions that participate in the groundfish fishery to changes in harvest and processing levels under each of the policy alternatives and illustrative bookends, the direct and indirect effects of each alternative are based on an economic model that distributes potential effects to each of the participating regions. The indicators used to assess potential regional effects include the following:

- In-region Processing and Related Effects.

- Regionally Owned At-Sea Processors.

- Extra-regional Deliveries of Regionally Owned Catcher Vessels.

- In-region Deliveries of Regionally Owned Catcher Vessels.
- Total Direct, Indirect, and Induced Labor Income and full-time equivalents (FTEs).

As discussed earlier, these indicators reflect changes in other important regional characteristics such as secondary economic activity associated with the support of fishing, state and municipal revenue generated by fishing, and indirectly population, to the extent that it is related to employment opportunities (see Section 4.1.7).

Direct/Indirect Effects of PA.1

Under PA.1, in general there is a net overall increase in fishery socioeconomic indicator values over baseline conditions for all regions. For example, total value of processing sales increases over baseline conditions, while total processing and harvesting related income and employment increase for all regions combined. These changes typically do not rise to the level of significance. Overall, the pattern of change is driven by the same factors seen under FMP 1 (but the caveat of inaccurate distribution indicator values associated the A-R-S-O species group between the southcentral and southeast Alaska regions applies). The following subsections provide a region-by-region summary of change under PA.1 as compared to the baseline.

Alaska Peninsula and Aleutian Islands. Under PA.1, total in-region groundfish processing value would increase (with increases occurring in the BSAI values), as would in region processing associated labor income and FTE jobs, but none of these increases would be considered significant. Regionally owned at-sea processing value (and associated payments to labor and FTEs) would increase in percentage terms, but this is a very small sector in this region, with negligible impact on a regional basis. The value of extra-regional and in-region deliveries by regionally owned catcher vessels would decrease, but by a less than significant amount. Catcher vessel payments to labor and FTE jobs associated with extra-regional deliveries would decrease for in-region deliveries, catcher vessel payments to labor. FTEs would decrease, but all of these changes are less than significant, and for both extra-regional and in-region catcher vessel deliveries, the absolute values for this region are relatively small. With respect to the relative importance of the different sectors to net regional impacts, the in-region processing related activity accounts for the vast majority of fishery associated labor income and FTEs, so the increases seen in processing values would be disproportionately important in relation to changes seen in the other sectors. Further, in-region processing value may be taken as a proxy for regionally important municipal and borough revenues generated by local fish taxes. The total regional direct, indirect, and induced labor income, and FTE employment would increase under this alternative, but this increase would not be significant. Under Alternative PA.1, the more closely sector defined impacts may be considered less than significant on a local sector as well as a regional and most likely a multiple community basis. However, this alternative may result in a number of other types of impacts that could be significant under certain conditions.

Under PA.1 some structural changes in the fishery and support sector enterprises will accrue to this and other regions as a result of the rights-based and community based management, but in the absence of program specifications, it is not possible to identify those changes in a straightforward manner. In general, with a decline in the race for fish, consolidation is likely to occur within processing and harvesting sectors and across communities. However, rights-based programs may build in caps and/or community or regional protection measures to act as a governor on consolidation, and the impacts to particular communities or regions will depend on the nature and efficacy of those caps or restrictions. Also, in general terms, the number of processing and harvesting entities will decline, as will overall employment. Support sector businesses and some coastal communities that have large support sectors deriving benefits from seasonal peaks and the economic inefficiencies of current race-for-fish fisheries will experience adverse impacts, at least in the short-term during a transition to a lower, if more stable level of employment, and in general, higher labor income per remaining position. For example, the relatively well developed support service sector in Unalaska/Dutch Harbor derives marked benefits from the current economic inefficiency within the fishery. It is relatively expensive to provide services in the community, but under conditions where it is important to minimize down-time during a fishing season, services that cost more are often utilized. Under a rationalized fishery, cost considerations become relatively more important, giving service purchasers more options to the possible detriment of providers in relatively remote locations. These types of impacts will perhaps be most apparent or severe in this region due to a relative lack of diversification in local economies, although they will likely be seen in other regions as well, especially Kodiak. The economic modeling that generated the regional impact numbers accounted for the structural changes in the fishery, but did not account for potential community protection measures. As a result, impacts may be considered conditionally significant adverse, and dependent upon the specific yet-to-be-designed protection measures.

Kodiak Island. Total in-region groundfish processing value would increase, with higher values for GOA and BSAI values are not a significant portion of the regional total. Associated labor income and FTE jobs would increase, but none of these increases would be large enough to be significant. Regionally owned at-sea processing value would increase with the majority of the increase attributable to changes in the BSAI values. Associated labor income and FTEs would increase, and the increase in total value would be significant. In this region under baseline conditions, in-region processing accounts for about three-quarters of the combined processing total value of sales, and regionally owned at-sea processing accounts for about one-quarter of the total. Labor income and FTEs distribution between these processing sectors follow a similar pattern. The value of extra-regional and in-region deliveries by regionally owned catcher vessels would increase, as would catcher vessel payments to labor and FTE jobs associated with extra-regional deliveries, but these increases would not be significant. For in-region deliveries, catcher vessel payments to labor would increase and FTEs would decrease, but these changes would be less than significant and over a smaller base than seen for extra-regional deliveries. On a regional basis, catcher vessel activity is a relatively more important component of fishery associated labor income and FTEs than was observed in the Alaska Peninsula/Aleutian Islands region, but processing activity still dominates these categories in the regional totals. The total regional direct, indirect, and induced labor income would increase, as would FTE employment under this alternative, but none of these changes would be considered significant. For the Kodiak Island region, Alternative PA.1 would not result in significant impacts on a local sector basis, or on a regional or community basis. As noted under the Alaska Peninsula and Aleutian Islands region discussion, there could be some adverse impacts to Kodiak Island region support services due to changes associated with the rationalization of the fishery, but Kodiak could also be the beneficiary of service business displaced from more remote locations, so the net impact is unknown.

Southcentral Alaska. Total in-region groundfish processing value would increase by 36 percent (all are attributable to GOA increases), as would associated labor income and FTE jobs. Regionally owned at-sea processing value would increase by 28 percent with relatively large increases in the BSAI values and smaller increases in the GOA values. Associated labor income and FTEs would each also increase by 28 percent. In this region under baseline conditions, in-region processing accounts for about four-fifths of the combined processing total value of sales, and regionally owned at-sea processing accounts for about one-fifth of the total. Labor income follows a similar pattern, but FTE employment is somewhat more heavily weighted toward the at-sea sector. The value of extra-regional deliveries by regionally owned catcher vessels would increase, but by an insignificant amount, while in-region deliveries would increase by 44 percent. For in-region deliveries, catcher vessel payments to labor and FTEs would each also increase by about 44 percent. In this region, catcher vessel-associated FTE jobs far surpass processing FTEs in the regional totals, but payments to labor for processing still surpass those for catcher vessels. Processing labor income figures for this region should be treated with caution, as the model tends to overstate actual payments due to the relative proportion of high value species processed. The total regional direct, indirect, and induced labor income would increase by about 28 percent, and FTE employment would increase by 21 percent. For the southcentral Alaska region, Alternative PA.1 would have significantly beneficial impacts on a local sector basis, but it is important to recognize that some of these changes may be overstated and some understated for the southeast Alaska region. Impacts to the region as a whole and participating communities may be less significant than would otherwise appear to be the case, given the diversified nature of the local economies and the relative lack of dependence on groundfish related activities.

Southeast Alaska. Total in-region groundfish processing value would decrease by a negligible amount; all are attributable to GOA decreases. Associated labor income and FTE jobs would decrease but both have relatively low base values. Regionally owned at-sea processing value would increase by 25 percent with increases in both BSAI and GOA values, and associated labor income and FTEs would each also increase by 25 percent. In this region under baseline conditions, in-region processing accounts for about seven-tenths of the combined processing total value of sales, and regionally owned at-sea processing accounts for about three-tenths of the total. Labor income follows a similar pattern, but FTE employment is somewhat more heavily weighted toward the at-sea sector. The value of extra-regional deliveries by regionally owned catcher vessels would increase by a slightly less than significant amount, and in-region deliveries would decrease by a negligible amount. Catcher vessel payments to labor and FTE jobs associated with extra regional deliveries would increase and in-region deliveries, catcher vessel payments to labor and FTEs would remain about the same. For this region, catcher vessel FTE employment far outpaces processing related employment, but payments to labor for processing still outpace those for catcher vessels. Processing labor income figures for this region should be treated with caution, as the model tends to overstate actual payments due to the relative proportion of high value species processed. The total regional direct, indirect, and induced labor income would increase as would FTE employment, but these changes would be less than significant. The impacts from Alternative PA.1 is significant beneficial for some local sectors, but impacts on a regional basis for southeast Alaska are less than significant, and are likely to be so for the involved communities, given the local economic diversity and relatively light dependence on the groundfish fishery.

Washington Inland Waters. Total in-region groundfish processing value changes are negligible on a regional basis due to low baseline values and small fluctuations in the baseline. Associated labor income and FTE jobs would increase by large percentages, but their overall low value render these changes not significant. Regionally owned at-sea processing value would increase with increases in both BSAI and GOA values, although GOA values are comparatively small. Associated labor income and FTEs would both increase, but these changes would be less than significant. The value of extra-regional and in-region deliveries by regionally owned catcher vessels would increase, as would catcher vessel payments to labor and FTE jobs associated with extra regional deliveries, and those associated with in-region deliveries. However, none of these changes would rise to the level of significance. In this region, processing dominates the regional labor income and FTE employment totals when compared to analogous catcher vessel figures, but it is important to note that catcher vessel totals are still far higher for this region than for any other. The total regional direct, indirect, and induced labor income would increase as would FTE jobs, but these changes would not be significant. Alternative PA.1 would have consistently beneficial effects in the Washington inland waters region, but these gains would not rise to the level of significance on a local sector, regional, or community basis.

Oregon Coast. Total in-region groundfish processing value changes are zero, along with associated labor income and FTE jobs, as there is no activity under baseline conditions or under this alternative. Similarly, there are currently no regionally owned at-sea processors under baseline conditions and none foreseen under this alternative, so all processing values, labor income, and FTE job values are zero. The value of extra-regional deliveries by regionally owned catcher vessels would increase, as would associated labor income and FTE jobs, but these increases would not be significant. There is no in-region activity by catcher vessels owned in this region, so all values for product, labor income, and FTE jobs are zero under both baseline conditions and this alternative. The total regional direct, indirect, and induced labor income would increase, as would FTE employment, but these changes would not be significant. Alternative PA.1 would have consistently beneficial impacts for the Oregon coast region, but these would not rise to a level of significance for local sectors, the region, or individual communities.

Cumulative Effects of PA.1

See Table 4.9-6 for a summary of the cumulative effects on regions and communities under PA.1.

In-Region Processing and Related Effects

- **Direct/Indirect Effects**. For PA.1, direct/indirect effects are considered insignificant for most regions except the southcentral Alaska region where a significantly beneficial increase is expected to occur.

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. For more detail, see the analysis for in-region processing, Alternative 1, Section 4.5.9.

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate changes and regime shifts (see Section 4.5.9).

- **Cumulative Effects.** Under PA.1, cumulative effects on in-region processing and related characteristics, such as municipal revenue and secondary economic development, are generally insignificant, although for different reasons in different regions. The influence of external factors is adverse for many of the in-region processors based in Alaska and their associated regions. Trends in multi-species fisheries and other sources of municipal and state revenue, primarily due to the continued crab closures, downturn in salmon and reductions in state and municipal revenue result in adverse effects on in-region processing and municipal revenue. These adverse external effects are somewhat offset by increases in Alaska in-region processing, resulting in a finding of insignificant cumulative effect except in portions of the Alaska Peninsula/Aleutian Islands Region. For the Washington inland waters and Oregon coast regions, direct/indirect effects are insignificant, and there are no reasonably foreseeable events that would have a significant contribution, resulting in a finding of insignificant cumulative effect.

Regionally Owned At-Sea Processors

- **Direct/Indirect Effects**. Under PA.1, direct/indirect effects are considered significantly beneficial for Kodiak Island, southcentral Alaska, and southeast Alaska regions. Direct/indirect effects are generally insignificant for the Alaska Peninsula/Aleutian, Washington inland waters, and Oregon coast regions.

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, and to a lesser extent, trends in state and municipal revenue (see Section 4.5.9).

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate changes and regime shifts (see Section 4.5.9).

- **Cumulative Effects**. Under PA.1, cumulative effects on regionally owned at-sea processing and on related characteristics, such as municipal revenue and secondary economic development, are generally insignificant. While direct/indirect effects are beneficial for Kodiak Island, southcentral Alaska, and southeast Alaska, the size and diversity of the southcentral Alaska regional economy, and offsetting adverse external factors related to other fisheries result in insignificant cumulative effects. Direct/indirect effects are insignificant in the Alaska Peninsula/Aleutian Islands, Washington inland waters, and Oregon coast regions. As indicated previously, with a more diversified economy and population base, cumulative effects on the at-sea processors in Kodiak will be insignificant for the Washington inland waters, and Oregon coast regions, as are effects for the Alaska Peninsula/Aleutian Islands.

Extra-regional Deliveries of Regionally Owned Catcher Vessels

- **Direct/Indirect Effects**. Under PA.1, direct and indirect effects are insignificant for all regions.

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. Catcher vessels are affected by changes that have occurred in the groundfish industry related to allocation and AFA sideboards, and by their participation in multi-species fisheries, particularly salmon, crab, and halibut (see Section 4.5.9).

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities. other sources of municipal and state revenue, and effects of long-term climate changes and regime shifts. These effects are the same for all indicators of effect for all alternatives. For more detail see the discussion of persistent past effects under in-region processing in Alternative 1, Section 4.5.9.2.

- **Cumulative Effects**. Under PA.1, extra-regional deliveries increase and direct/indirect effects are insignificant for all six regions. Given the size and diversity of regional economies in southcentral Alaska, Washington inland waters, the Oregon coast, and to a lesser extent Kodiak Island, potential adverse external effects are offset and cumulative effects are insignificant. Extra-regional deliveries decrease to the Alaska Peninsula/Aleutian Islands; adverse external effects related to other fisheries and revenue sharing results in a conditionally significant adverse cumulative effect for some communities within this region.

In-Region Deliveries of Regionally Owned Catcher Vessels

- **Direct/Indirect Effects**. Under PA.1, direct/indirect effects are insignificant with slight increases or decreases for all regions except southcentral Alaska, where the increase is significantly beneficial.

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. For more detail, see the discussion of persistent past effects under in-region processing in Alternative 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate changes and regime shifts. These effects are the same for all indicators of effect for all alternatives. For more detail see the discussion of persistent past effects under in-region processing in Alternative 1, Section 4.5.9.2.

- **Cumulative Effects**. Under PA.1, the direct/indirect effects range from beneficial to mostly insignificant. Given the size and diversity of regional economies in southcentral Alaska, Washington inland waters, the Oregon coast, and to a lesser extent Kodiak Island, potential adverse external effects are offset and cumulative effects are insignificant. Extra-regional deliveries decrease to the Alaska Peninsula/Aleutian Islands; adverse external effects related to other fisheries and revenue sharing results in a conditionally significant adverse cumulative effect for some communities within this region.

Total Direct, Indirect, and Induced Labor Income and FTE's

- **Direct/Indirect Effects**. Under PA.1, direct/indirect effects on labor income and employment are significantly beneficial for the southcentral Alaska region, and insignificant for the rest of the regions.

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, trends in state and municipal revenue, and public infrastructure and facility projects. Fishing is a major component of income and employment in many small Alaskan coastal communities. Federal, state, and local revenue has funded public infrastructure and facility projects that generate income and employment in many regions and communities. For more detail, see the discussion of persistent past effects under in-region processing in Alternative 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate changes and regime shifts. These effects are the same for all indicators of effect for all alternatives. For more detail, see the discussion of persistent past effects under in-region processing in Alternative 1, Section 4.5.9.2.

- **Cumulative Effects**. Under PA.1 direct/indirect effects on labor income and employment are insignificant for all regions, except southcentral Alaska, which is significantly beneficial. Within southcentral Alaska, Washington inland waters, and Oregon coast regions, fisheries are a small part of the regional economies and effects are dwarfed by other trends. Adverse trends in other fisheries (particularly salmon) and reductions on municipal revenue, decrease regional labor income and employment benefits, particularly in the Alaska Peninsula/Aleutian Islands, Kodiak Island, and southeast Alaska regions. Cumulative effects are generally insignificant in all regions, except for portions of the Alaska Peninsula/Aleutian Islands, where effects are conditionally significant adverse.

Direct/Indirect Effects of PA.2

Under PA.2, in general, there is more variation of gains and losses in socioeconomic indicator values across regions than seen in the previous alternatives. While total value of processing sales increases over baseline conditions by a less than significant amount, and while total processing and harvesting related income and employment increase for all regions combined by a less than significant amount, there are a variety of increases and decreases behind these totals. A more conservative TAC for sablefish and rockfish has a disproportionate, adverse impact on the southcentral and southeast Alaska regions, and on the Kodiak region. The western GOA area experiences a relative decline of Pacific cod related values. On the highest level of aggregation, the Alaska Peninsula and Aleutian Islands, Washington inland waters, and Oregon coast regions experience a net beneficial impact under Alternative PA.2, whereas the Kodiak, southcentral, and southeast Alaska regions experience a net adverse impact in socioeconomic terms. Under this alternative there are many local area closures and it is to be expected (but not apparent in the data) that the smaller catcher vessels with less effective range and less inherent geographic flexibility would feel disproportionate impacts in all regions. The rationalization that occurs under this alternative would likely serve to ameliorate the adverse impacts of area closures for most of the fleet, but inherent limitations associated with size would render these offsetting benefits less viable for the small vessels of the fleet. For all vessels, the beneficial impacts of rationalization are conditional on being able to find fish outside of the closed areas. These pragmatic challenges may push adverse impacts from borderline to significant for some communities, depending the composition of the local fleet, particularly in the southcentral and southeast Alaska regions. The following subsections provide a region-by-region summary of change under Alternative PA.2 as compared to the baseline.

Alaska Peninsula and Aleutian Islands. Under Alternative PA.2, total in-region groundfish processing value would increase, with increases in the BSAI portion somewhat offset by decreases in the much smaller GOA portion of the total. Regional processing associated labor income and FTE jobs would increase as well, but these increases would be insignificant. Regionally owned at-sea processing value and associated payments to labor and FTEs would increase in percentage terms, but this is a very small sector in this region, with negligible impact on a regional basis. The value of extra-regional deliveries by regionally owned catcher vessels would decrease by 17 percent, while in-region deliveries by regionally owned catcher vessels would decrease by 22 percent. Catcher vessel payments to labor would decrease 17 percent and FTE jobs associated with extra-regional deliveries would decrease by about 23 percent. For in-region deliveries, catcher vessel payments to labor and FTEs would decrease by about 22 and 23 percent, respectively, but for both extra-regional and in-region catcher vessel deliveries, the absolute values for this region are relatively small. With respect to the relative importance of the different sectors to net regional impacts, the in-region processing related activity accounts for the vast majority of fishery associated labor income and FTEs, so the increases seen in processing values would be disproportionately important in relation to changes seen in the other sectors. Further, in-region processing value may be taken as a proxy for regionally important municipal and borough revenues generated by local fish taxes. The total regional direct, indirect, and induced labor income would increase as would FTE employment, but these changes would be less than significant. In terms of quantitative output, the impacts of Alternative PA.2 on the Alaska Peninsula and Aleutian Islands region are a mixture of adverse and beneficial when examined on a local sector basis, but are in and of themselves not likely to illustrate significant impacts on the regional level. Community level quantitative data are largely unavailable due to confidentiality restrictions. There are two other types of regional or community impacts likely under this alternative that are not apparent in the quantitative data.

In general, as noted under PA.1, with a decline in the race for fish, consolidation is likely to occur within processing and harvesting sectors and across communities. However, rights based programs can include caps and/or community or regional protection measures to act as a governor on consolidation, and the impacts to particular communities or regions will depend on the efficacy of those caps or restrictions. Also in general terms, the number of processing and harvesting entities will decline, as will overall employment. Support sector businesses and some coastal communities that have large support sectors, that derive benefits from seasonal peaks and the economic inefficiencies of current race-for-fish fisheries will experience adverse impacts, at least in the short-term during a transition to a lower if more stable level of employment and, in general, higher labor income per remaining position. These types of impacts will be seen in other regions as well, especially Kodiak, but will perhaps be most apparent in this region due to a relative lack of diversification in local economies. The economic modeling that generated the regional impact numbers accounted for the structural changes in the fishery, but does not account for potential community protection measures. As a result, impacts may be considered conditionally significant, and dependent upon the future protection measures.

Another type of impact that is not captured by the economic output model is likely to be important for some communities in the Alaska Peninsula and Aleutian Islands region. Under PA.2, more areas are set aside for MPAs, and the impact of these on communities, especially communities with relatively small vessel fleets with limited range and flexibility to move between major fisheries, may be relatively large. However, the ultimate determinant of the level of impact of this type of management approach will be the efficacy of the counterbalancing alternative features designed to respect traditional fishing grounds and maintain open area access for coastal communities. It is not possible to assess this balance in advance of having either the MPA areas or the community protection measures specified. As a result, impacts of this nature are likely to be conditionally significant. The small vessel fleets within this region are particularly vulnerable. Further, communities within this region that have both support service sectors that may experience decline as a result of rationalization and small vessel fleets may experience interactive impacts that are not apparent from quantitative modeling outputs.

Kodiak Island. Total in-region groundfish processing value would decrease and associated labor income and FTE jobs would decrease, but none of these changes would be significant. Regionally owned at-sea processing value would increase with the vast majority of the increase attributable to changes in the BSAI values. Associated labor income and FTEs would increase, but none of these changes would rise to the level of significance. In this region under baseline conditions, in-region processing accounts for about three-quarters of the combined processing total value of sales and regionally owned at-sea processing accounts for about one-quarter of the total. Labor income and FTE distribution between these processing sectors follow a similar pattern. The value of extra-regional deliveries by regionally owned catcher vessels would increase as would catcher vessel payments to labor associated with extra-regional deliveries, but all of these changes would be less than significant, and FTE jobs would remain about the same. For in-region deliveries, the total value would remain generally the same while catcher vessel payments to labor and FTEs would decrease by insignificant amount, and over a smaller base than seen for extra-regional deliveries. On a regional basis, catcher vessel activity is a relatively more important component of fishery associated labor income and FTEs than was seen in the Alaska Peninsula/Aleutian Islands region, but processing activity still dominates these categories in the regional totals. The total regional direct, indirect, and induced labor income would decrease as would FTE employment, but all of these changes would be minimal. For the Kodiak Island region, Alternative PA.2 will have less than significant impacts on a local sector basis, as well as on a regional and community of Kodiak basis. As was the case for the Alaska Peninsula and Aleutian Islands region, there may be conditionally significant impacts that accrue to the support service sector as a result of the rationalization features of this alternative and the smaller vessels in the fleet due to the inherent lack of flexibility in dealing with extensive MPA set asides and, perhaps, the inability to take advantage of the potentially ameliorating nature or features of rationalization.

Southcentral Alaska. Total in-region groundfish processing value would decrease with all being attributable to GOA decreases. Associated labor income and FTE jobs would decrease, but these decreases would not be considered significant. Regionally owned at-sea processing value would decrease with decreases in the BSAI values and GOA values. Associated labor income and FTEs would decrease, but these changes would be less than significant. In this region under baseline conditions, in-region processing accounts for about four-fifths of the combined processing total value of sales and regionally owned at-sea processing accounts for about one-fifth of the total; labor income follows a similar pattern, but FTE employment is somewhat more heavily weighted toward the at-sea sector. The value of extra-regional deliveries by regionally owned catcher vessels would decrease and in-region deliveries increase, but not significantly. Catcher vessel payments to labor would decrease a less than significant amount and FTE jobs associated with extra regional deliveries would decrease by about 19 percent. For in-region deliveries, catcher vessel payments to labor and FTEs would increase, but not significantly. In this region, catcher vessel associated FTE jobs far surpass processing FTEs in the regional totals, but payments to labor for processing still surpass those for catcher vessels. Processing labor income figures for this region should be treated with caution as the model tends to overstate actual payments due to the relative proportion of high value species processed. The total regional direct, indirect, and induced labor income would decrease as would FTE employment, but none of these changes would appear significant. For southcentral Alaska, PA.2 would not result in significant impacts at either the local sector or the regional level. However, there may be conditionally significant impacts to some community small vessel fleets, but that cannot be ascertained prior to the development of specific features of the rationalization and MPA management approaches.

Southeast Alaska. Total in-region groundfish processing value would decrease by 33 percent and is attributable to GOA decreases. Associated labor income and FTE jobs would also decrease by 33 percent, but both are relatively low values. Regionally owned at-sea processing value would increase, with increases in both BSAI values and GOA values. Associated labor income and FTEs would decrease, but none of these changes are significant. In this region under baseline conditions, in-region processing accounts for about seven-tenths of the combined processing total value of sales and regionally owned at-sea processing accounts for about three-tenths of the total. Labor income follows a similar pattern, but FTE employment is somewhat more heavily weighted toward the at-sea sector. The value of extra-regional and in-region deliveries by regionally owned catcher vessels would decrease by 24 and 35 percent, respectively. Catcher vessel payments to labor and FTE jobs associated with extra regional deliveries would both decrease by about 24 percent. For in-region deliveries, catcher vessel payments to labor and FTEs would decrease by about 35 and 34 percent, respectively. For this region, catcher vessel FTE employment far outpaces processing related employment, but payments to labor for processing still outpace those for catcher vessels. Processing labor income figures for this region should be treated with caution as the model tends to overstate actual payments due to the relative proportion of high value species processed. The total regional direct, indirect, and induced labor income would decrease by about 22 percent and FTE employment would decrease by about 22 percent. For the southeast Alaska region, Alternative PA.2 would have significant impacts on some local sectors, but a caveat on this data is that impacts to the southcentral Alaska region may be somewhat overstated in a beneficial direction, and the impacts to southeast Alaska may be somewhat overstated in a adverse direction. Overall, impacts on the regional level or even on the involved community level are unlikely to be significant given the overall diversity of community economies in this region, and the relative lack of dependency specifically on groundfish. On the other hand, there could be conditionally significant impacts that accrue to the local small vessel fleet as a result of specific rationalization and MPA features that are unknown at this time, as noted in earlier regional sections.

Washington Inland Waters. Total in-region groundfish processing value changes are negligible on a regional basis due to low baseline values and small changes from the baseline. Associated labor income and FTE jobs would increase by large percentages, but their overall low value render these changes insignificant. Regionally owned at-sea processing value would increase with increases in both BSAI and GOA values, although GOA values are comparatively very small. Associated labor income and FTEs would decrease, but these increases would be less than significant. The value of extra-regional and in-region deliveries by regionally owned catcher vessels would increase by less than significant amounts. Catcher vessel payments to labor associated with extra regional deliveries would increase and FTE jobs would decrease, but these changes would not be significant. For in-region deliveries, catcher vessel payments to labor and FTEs would increase, but not significantly. In this region, processing dominates the regional labor income and FTE employment totals when compared to analogous catcher vessel figures, but it is important to note that catcher vessel totals are still far higher for this region than for any other. The total regional direct, indirect, and induced labor income would increase, but these changes would be less than significant. The total regional direct, indirect, and induced FTE employment would decrease slightly, but not significantly. In general, the impacts of Alternative PA.2 would not be significant for the Washington inland waters region. Impacts to local sectors are likely to be less than significant, and as are impacts to communities, given the size and nature of local economies, and the relative lack of groundfish dependency on the community or regional level. The concerns regarding small vessel fleets and MPAs under this alternative do not apply to the Washington inland waters region in the same way that they do to the Alaska regions, nor do concerns regarding unintentional consequences of rationalization on support sector businesses. Washington inland waters region support sector enterprises are likely to be the beneficiaries of increased efficiency within the fishery, and a reallocation or redistribution of support functions away from remote locations closer to the grounds.

Oregon Coast. Total in-region groundfish processing value changes are zero, along with associated labor income and FTE jobs, as there is no activity under baseline conditions or under this alternative. Similarly, there are no regionally owned at-sea processors under baseline conditions or foreseen under this alternative, so all processing values, labor income, and FTE job values are zero. The value of extra-regional deliveries by regionally owned catcher vessels would increase, as would associated labor income and FTE jobs, but these increases would not be significant. There is no in-region activity by catcher vessels owned in this region, so all values for product, labor income, and FTE jobs are zero under both baseline conditions and this alternative. The total regional direct, indirect, and induced labor income would increase as would FTE employment, but these changes would be considered less than significant. Under PA.2, Oregon coast local sectors would experience beneficial but less than significant impacts. Regional and community impacts would be considered beneficial, but less than significant. This region would not experience adverse impacts to the small vessel fleet from MPAs and rationalization as may be seen in the Alaska regions, nor is it likely to lose or gain significantly in the changes in support sector businesses that may accompany further rationalization of the fishery.

Cumulative Effects of PA.2

In-Region Processing and Related Effects

- **Direct/Indirect Effects.** For PA.2, direct/indirect effects are considered insignificant for all regions except the southeast Alaska region, which would see a significantly adverse decrease.

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. For more detail, see the analysis for in-region processing, Alternative 1, Section 4.5.9.

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate changes and regime shifts (see Section 4.5.9).

- **Cumulative Effects.** Under PA.2, in terms of direct/indirect impacts, the Alaska Peninsula and Aleutian Islands, Washington inland waters, and Oregon coast regions experience a net beneficial impact, whereas the Kodiak Island, southcentral, and southeast Alaska regions experience a net adverse impact. Within these latter three Alaska regions, decreases in processing values are exacerbated by the adverse external effects in other fisheries, economic development and state and municipal revenue. Southcentral Alaska has a relatively diversified economy and cumulative effects would be insignificant. Cumulative effects for Kodiak Island, southeast Alaska and portions of the Alaska Peninsula and Aleutian Islands are likely to be conditionally significant adverse. For the Washington inland waters and Oregon coast regions, direct/indirect effects are insignificant and there are no reasonably foreseeable events that would have a significant contribution; the cumulative effects on these regions are therefore insignificant.

Regionally Owned At-Sea Processors

- **Direct/Indirect Effects.** For PA.2, direct/indirect effects are insignificant for all regions (see the direct/indirect effects discussion in this section).

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, and to a lesser extent, trends in state and municipal revenue (see Section 4.5.9).

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate changes and regime shifts (see Section 4.5.9).

- **Cumulative Effects.** Under PA.2, direct/indirect effects are insignificant for all six regions. Cumulative effects are also insignificant for PA.2, for the same reasons discussed under PA.1.

<u>Extra-regional Deliveries of Regionally Owned Catcher Vessels</u>

- **Direct/Indirect Effects.** Under PA.2, direct and indirect effects are insignificant for all regions, except Alaska Peninsula/Aleutian Islands and southeast Alaska regions where they are significantly adverse (see the direct/indirect effects discussion in this section).

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. Catcher vessels are affected by changes that have occurred in the groundfish industry related to allocation and AFA sideboards, and by their participation in multi-species fisheries, particularly salmon, crab, and halibut (see Section 4.5.9).

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities. other sources of municipal and state revenue, and effects of long-term climate changes and regime shifts. These effects are the same for all indicators of effect for all alternatives. For more detail see the discussion of persistent past effects under in-region processing in Alternative 1, Section 4.5.9.2.

- **Cumulative Effects.** Under PA.2, cumulative effects are insignificant for four of the six regions, but adverse for Alaska Peninsula/Aleutian Islands and southeast Alaska regions. Given the size and diversity of regional economies in southcentral Alaska, Washington inland waters, the Oregon coast, and to a lesser extent Kodiak Island, potential adverse external effects are offset and cumulative effects are insignificant. In southeast Alaska and the Alaska Peninsula/Aleutian Islands, adverse external effects are likely to result in conditionally significant adverse cumulative effects.

<u>In-Region Deliveries of Regionally Owned Catcher Vessels</u>

- **Direct/Indirect Effects.** Under PA.2, direct/indirect effects are insignificant for the Kodiak Island, southcentral Alaska, Washington inland waters, and Oregon coast regions. Effects are significantly adverse for the Alaska Peninsula/Aleutian Islands and southeast Alaska regions. Refer to the previous section for a more detailed discussion of direct/indirect effects.

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. For more detail, see the discussion of persistent past effects under in-region processing in Alternative 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate changes and regime shifts. These effects are the same for all indicators of effect for all alternatives; for more detail see the discussion of persistent past effects under in-region processing in Alternative 1, Section 4.5.9.2.

- **Cumulative Effects.** Under PA.2, direct/indirect effects of in-region deliveries range from mostly insignificant to significantly adverse. Given the size and diversity of regional economies in southcentral Alaska, Washington inland waters, the Oregon coast, and to a lesser extent Kodiak Island, potential adverse external effects are offset and cumulative effects are insignificant. In the Alaska Peninsula/Aleutian Islands and southeast Alaska regions, significant adverse direct/indirect effects combine with adverse external effects in other fisheries and revenue sharing to result in a conditionally significant adverse cumulative effect.

<u>Total Direct, Indirect, and Induced Labor Income and FTE's</u>

- **Direct/Indirect Effects.** Under PA.2, direct/indirect effects on labor income and employment are insignificant for all regions except southeast Alaska, which is significantly adverse. Refer to the previous section for a more detailed discussion of direct/indirect effects.

- **Persistent Past Effects**. The persistent past effects include trends and developments in fisheries, trends in state and municipal revenue, and public infrastructure and facility projects. Fishing is a major component of income and employment in many small Alaskan coastal communities. Federal, state, and local revenue has funded public infrastructure and facility projects that generate income and employment in many regions and communities. For more detail, see the discussion of persistent past effects under in-region processing in Alternative 1, Section 4.5.9.2.

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable future effects that are external to the proposed action include other state and federal fisheries, other economic development activities, other sources of municipal and state revenue, and effects of long-term climate changes and regime shifts. These effects are the same for all indicators of effect for all alternatives. For more detail, see the discussion of persistent past effects under in-region processing in Alternative 1, Section 4.5.9.2.

- **Cumulative Effects.** Under PA.2, employment decreases in all Alaska regions, but is insignificant except in southeast Alaska where effects are significantly adverse. Within southcentral Alaska, Washington inland waters, and Oregon coast regions, fisheries are a small part of the regional economies and effects are dwarfed by other trends. Adverse trends in other fisheries, particularly salmon, and reductions on municipal revenue, decrease regional labor income and employment benefits, particularly in the Alaska Peninsula/Aleutian Islands, Kodiak Islands, and southeast Alaska regions. Cumulative effects are generally insignificant in all regions, except for portions of the Alaska Peninsula/Aleutian Islands and southeast Alaska regions, where effects are conditionally significant adverse.

4.9.9.3 Community Development Quota Program

The predicted direct and indirect effects of the groundfish fishery under the PA.1 and PA.2 are described below (Table 4.9-6). The past/present effects on CDQ are described below (Table 3.9-126). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case. The representative indicator used in this analysis is allocation of catch to CDQ groups. It should be noted that allocation reflects potential revenue to CDQ groups, and indirectly the potential funds that are available for approved economic development activities in CDQ communities.

Direct/Indirect Effects of PA.1 and PA.2

Under PA.1, the CDQ program would continue to operate as it does under baseline conditions. Under PA.1, no adverse changes to the CDQ program or region in comparison to baseline conditions are foreseen.

Under PA.2, the CDQ program would continue to operate as it does under baseline conditions. Under PA.2, no adverse changes to the CDQ program or region in comparison to baseline conditions are foreseen. Refer to Table 4.9-6 for a summary of the direct/indirect effects on CDQ programs under PA.1 and PA.2.

Cumulative Effects of PA.1 and PA.2

<u>CDQ Allocations</u>

- **Direct/Indirect Effects**. The direct/indirect effects of both PA.1 and PA.2 would be insignificant.

- **Persistent Past Effects.** The past/present effects on the CDQ program for groundfish fisheries include establishment of the CDQ program; FMP amendments that further added or defined CDQ in 1992, 1995, 1996, and 1998; establishment of multi-species CDQ programs, and persistent limitations on economic development and associated employment activities. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Reasonably Foreseeable Future Effects.** Other fisheries, other economic development activities, other sources of municipal and state revenue all have the potential to affect the CDQ program adversely or beneficially. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Cumulative Effects**. Under PA.1 and PA.2, a cumulative effect is identified for the CDQ program, and the effect is judged to be insignificant. With guaranteed CDQ shares through the CDQ program continuing to operate, no significantly adverse cumulative impacts to the CDQ program are expected.

4.9.9.4 Subsistence

The predicted direct and indirect effects of the groundfish fishery under PA.1 and PA.2 are described below (Table 4.9-6). The past/present effects on subsistence are described in Section 3.9 and below (Table 3.9-126). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case. The representative indicators used in this analysis are other fisheries such as foreign, JV, domestic, and state-managed fisheries, other economic development activities, sport and personal use, and long-term climate changes and regime shift.

Direct/Indirect Effects of PA.1 and PA.2

Potential impacts to subsistence fall into four main categories: subsistence use of groundfish, subsistence use of Steller sea lions, salmon bycatch issues, and indirect impacts on other subsistence activities, including loss of income that would otherwise be directed toward subsistence pursuits and the loss of access to commercial fishing vessels and gear that would otherwise be available for joint production opportunities. Under this alternative, no changes in the commercial fishery are anticipated that would result in impacts to baseline subsistence groundfish fishing conditions. There is no indication that this alternative would have a adverse impact on Steller sea lion subsistence activities or take over baseline conditions. Salmon bycatch would likely be decreased under PA.1 and PA.2 due to a moderate reduction in PSC limits and rationalization incentives under PA.2, but available information does not suggest that such reductions, while presumably beneficial for salmon subsistence resource use, would result in significant increases in salmon returns to salmon subsistence fishery areas. Catcher vessel activity and labor income are anticipated to increase under this alternative; therefore, no adverse indirect impacts to subsistence through a decline in income or joint production opportunities are expected to occur.

Cumulative Effects of PA.1 and PA.2

The predicted direct and indirect effects of the groundfish fishery under PA.1 and PA.2 are described above (Table 4.9-6). The past/present effects on subsistence are described in Section 3.9 (Table 3.9-126). This section will assess the potential for these effects to interact with other reasonably foreseeable future events and activities in the cumulative case. Representative indicators used in this analysis are the same as those used in the direct/indirect analysis and include subsistence use of groundfish, subsistence use of Steller sea lions, subsistence use of salmon, and indirect impacts on other subsistence activities such as income and joint production opportunities.

Subsistence Use of Groundfish

- **Direct/Indirect Effects**. Under this alternative, no changes in the commercial fishery are anticipated that would result in significantly adverse impacts to baseline subsistence groundfish fishing conditions.

- **Persistent Past Effects.** Foreign, JV, domestic, and state-managed fisheries have decreased populations of some species of groundfish used for subsistence. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Reasonably Foreseeable Future Effects**. Other fisheries and long-term climate change have a potential to adversely contribute to subsistence use of the groundfish fisheries. Economic development and sport and personal use are not likely to adversely contribute to subsistence use of the groundfish fisheries. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Cumulative Effects.** Under PA.1 and PA.2, a cumulative effect is identified for subsistence use of groundfish, but is judged to be insignificant. The external impacts of other fisheries, other economic development activities, and sport and personal use of groundfish are not likely to contribute to significantly adverse cumulative effects on the groundfish fisheries. However, other state-managed fisheries could have adverse impacts to the subsistence use of groundfish due to direct competition for the same species, but are not considered to be significant. The long-term climate change could adversely effect groundfish stocks.

Subsistence Use of Steller Sea Lions

- **Direct/Indirect Effects**. There is no indication that this alternative would have an adverse impact on Steller sea lion subsistence activities or take over baseline conditions.

- **Persistent Past Effects**. The past/present effects on subsistence use of Steller sea lions include the following: a long-term decline in population of Steller sea lions due to a number of factors; a long-term decline in relative importance of marine mammals in local diets; commercial groundfish fishing taking prey species utilized by Steller sea lions; and Steller sea lion protection measures designed to assist in population recovery instituted in 2000. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Reasonably Foreseeable Future Effects.** Other fisheries, economic development, and long-term climate change have a potential to adversely contribute to Steller sea lion subsistence activities. Sport and personal use of groundfish is not likely to adversely contribute to subsistence use of Steller sea lions. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Cumulative Effects.** Under PA.1 and PA.2, while an adverse cumulative effect is identified for subsistence use of Steller sea lions, the effect is judged to be insignificant. However, the cumulative effects of take, the continuing endangered status, and long-term decline in abundance are likely having population-level effects, but not enough to have significant indirect impacts to subsistence. The external impacts of other fisheries, other economic development activities of subsistence use of Steller sea lions are not likely to contribute adversely to the groundfish fisheries, and cumulative effects are insignificant.

Subsistence Use of Western Alaskan Salmon and Bycatch in the Groundfish Fishery

- **Direct/Indirect Effects**. Salmon bycatch would likely be decreased due to a moderate reduction in PSC limits under PA.1 and significantly reduced under PA.2, but available information does not suggest that such reductions, while presumably beneficial for salmon subsistence resource use, would result in significant increases in salmon returns to salmon subsistence fishery areas.

- **Persistent Past Effects**. The past/present effects on subsistence use of salmon include the following: utilization for subsistence since pre-contact times; and Area M closures implemented to decrease intercept of salmon; these factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Reasonably Foreseeable Future Effects**. Other fisheries, other economic development activities and long-term climate changes and regime shift could all adversely contribute to salmon subsistence activities. Sport and personal use is not likely to adversely contribute to salmon subsistence activities. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Cumulative Effects.** Under PA.1 and PA.2, a cumulative effect is identified for subsistence use of salmon, and is judged to be insignificant. There may be benefits to subsistence use from reduced bycatch in the groundfish fisheries. However, given the depressed stock status of salmon runs in western Alaska, adverse contributions from external factors, and the salmon bycatch in the BSAI and GOA, sustainability of depressed salmon stocks could be adversely impacted, but are considered insignificant.

Indirect Impacts on Other Subsistence Activities

- **Direct/Indirect Effects**. Under both PA.1 and PA.2, catcher vessel activity and labor income are anticipated to increase insignificantly; therefore, no adverse indirect impacts to subsistence through a decline in income or joint production opportunities are expected to occur.

- **Persistent Past Effects**. The past/present effects on the indirect impacts on other subsistence activities include joint production as a part of local groundfish and other commercial fishery development from the outset; income from fishing used for investment in subsistence is similar to use of income from other activities. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Reasonably Foreseeable Future Effects.** Other fisheries, other economic development activities, and long-term climate changes and regime shift could all adversely or beneficially contribute to indirect subsistence activities. Sport and personal use is not likely to adversely contribute to indirect impacts on other subsistence activities. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Cumulative Effects.** Under PA.1 and PA.2, a cumulative effect is identified for indirect subsistence use, and the effect is judged to be insignificant. Income catcher vessel activity, and joint production opportunities are not expected to be affected adversely. However, the external impacts of other fisheries, other economic development activities, and long-term climate changes and regime shift could potentially contribute adversely to the indirect subsistence use.

4.9.9.5 Environmental Justice

The predicted direct and indirect effects of the groundfish fishery under PA.1 and PA.2 are described below. The past/present effects on environmental justice are described below (Table 3.9-126). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case. The external effects used in this analysis are other fisheries such as foreign, JV, domestic, and state-managed fisheries, other economic development activities, other sources of municipal/state revenue, and long-term climate changes and regime shift.

Direct/Indirect Effects of PA.1

Potential impacts that drive environmental justice issues include employment/municipal revenue and taxes in communities with significant percentages of special populations (Alaska Native and minority processing workforce); revenue to Native owned catcher vessels; revenue to Native owned catcher processors; subsistence activities associated with groundfish, Steller sea lions, and salmon; and the loss of income from fishing that would be otherwise directed toward subsistence pursuits; and the loss of access to commercial fishing vessels and gear that would otherwise be available for joint production opportunities. The regions that could experience potential impacts include the Alaska Peninsula and Aleutian Islands, Kodiak Island, southcentral Alaska, southeast Alaska, Washington inland waters, Oregon coast, the CDQ regions, and western Alaska communities that harvest salmon for subsistence purposes.

Alaska Peninsula and Aleutian Islands. As described in existing conditions, this region encompasses a number of groundfish fishing communities, of which a number have predominantly Alaska Native populations. Also, as described under existing conditions, the in-region processing workforce is predominantly a minority population. In-region processing employment would increase over baseline conditions by about 250 jobs; therefore, no environmental justice impacts would result. Total in-region groundfish processing value would increase from $464 million to $498 million. Increased in-region processing value would correspond to additional municipal revenue and taxes to the local communities, and no associated environmental justice impacts would occur. In this region, the ownership and crews of the catcher vessels are assumed to mirror the demographic composition of populations of the home port communities, so local fleets from at least a few communities in this region are likely to be owned and crewed by Alaska Native residents. Under this alternative, the total value of catcher vessel operations would decrease as would corresponding labor income and employment; therefore, an apparent environmental justice impact would result. However, as described above, these apparent declines are likely to be attributable in large part to a shortcoming in the model regarding distribution of western GOA catch to Alaska Peninsula and Aleutian Islands region vessels. So the actual environmental justice impact is likely to be insignificant, given current data.

Kodiak Island. As described in existing conditions, groundfish processing and catcher vessel activity in this region is highly concentrated in the City of Kodiak. Although the city is ethnically diverse, it does not have a predominantly Alaska Native population as do some of the groundfish fishing communities in the Alaska Peninsula/Aleutian Islands region. However, as described under existing conditions, the in-region processing workforce is predominantly a minority population. In-region processing employment would increase over baseline conditions by about 12 jobs; therefore, no environmental justice impacts would result. Total in-region groundfish processing value would increase from $81 million to $83 million. Increased in-region processing value would correspond to additional municipal revenue and taxes to the City and the Kodiak Island Borough. Given local and regional demographics, this is not likely to be an environmental justice issue. Ownership and crews of the catcher vessels are assumed to mirror the demographic composition of populations of the City of Kodiak itself; therefore, the local fleet associated population is not likely to be predominantly Alaska Native or comprised of other identified minority populations. Under this alternative, the total value of catcher vessel operations would increase as would corresponding labor income and employment, but given demographic assumptions, this is unlikely to be relevant as an environmental justice issue.

Southcentral Alaska. As described in existing conditions, environmental justice concerns are much less salient in this region than in the Alaska Peninsula/Aleutian Islands or Kodiak Island regions. The communities most directly engaged in the groundfish fishery, particularly with respect to the processing sector, are largely non-Native communities, and have relatively large populations and diversified economic opportunities. Further, there is a relatively low level of groundfish related processing employment overall. Catcher vessel related employment is assumed to mirror community demographics, and it is unlikely that environmental justice issues will be associated with any employment change. In general, under this alternative overall combined direct, indirect, and induced labor income and FTEs increase, but this change is not linked to environmental justice concerns. Similarly, processing value increases, but these changes are not relevant to environmental justice concerns.

Southeast Alaska. The situation in this region is similar to that seen in southcentral Alaska, with the possible exception of the community of Yakutat, which is more predominantly Alaska Native than the other regionally important groundfish communities. Data confidentiality constraints preclude a discussion of Yakutat alone, but otherwise overall environmental justice concerns appear not to apply in this region. In general, under this alternative overall combined direct, indirect, and induced labor income and FTEs increase, but this change is not linked to environmental justice concerns.

Washington Inland Waters. The greater Seattle area is the regional community most engaged in the groundfish fishery, and it is a demographically and economically diverse major metropolitan area. In-region processing does not occur, and while a number of other communities in the region outside of Seattle are home to groundfish catcher vessels, there is no indication that these communities or the associated vessel owners and crew are comprised of minority populations. As described in existing conditions, environmental justice concerns for this region are concentrated in the at-sea processing sector, due to the predominance of minority representation within this workforce. Under this alternative, at-sea processing labor income and FTEs both increase, so there are no environmental justice impacts associated with this change.

Oregon Coast. This region is engaged in the commercial groundfish fishery through its regionally owned catcher vessel fleet. This fleet is concentrated in a limited number of communities in the region, and there is no indication that these are minority communities, nor is there any indication that the population directly associated with fleet ownership and/or crew is either a minority population or a low-income population. In general, under this alternative overall combined direct, indirect, and induced labor income and FTEs increase, as do catcher vessel related values, but these changes are not linked to environmental justice concerns.

CDQ Region. The CDQ region is predominantly comprised of Alaska Native communities that have relatively limited commercial economic opportunities, so any adverse impacts to this program and region are likely to involve environmental justice concerns. Under this alternative, the structure of the CDQ program would not change from baseline conditions and, as noted above, no adverse impacts to the program are anticipated. Therefore, no environmental justice impacts are likely to occur.

Subsistence. Subsistence activities typically disproportionately involve Alaska Native communities and populations. In a few cases such as Steller sea lion subsistence, exclusively involve Alaska Native individuals and groups. As a result, adverse impacts to subsistence pursuits are likely to involve environmental justice concerns. Effects from reduced by-catch of salmon and Steller sea lion subsistence activities are likely to beneficial, but insignificant. As described above, adverse impacts to subsistence activities are not foreseen under this alternative; therefore no associated environmental justice impacts are anticipated.

Cumulative Effects of PA.1

The predicted direct and indirect effects of the groundfish fishery under PA.1 are described above. The past/present effects on environmental justice are described below (Table 3.9-126). This section will assess the potential for these effects to interact with other reasonably foreseeable future events and activities in the cumulative case (Table 4.9-6). The representative indicator used in this analysis is the same as that used in the direct/indirect analysis.

- **Direct/Indirect Effects**. Under PA.1 bookend, direct/indirect impacts are generally insignificant. Reductions in catcher vessel activity in the Alaska Peninsula/Aleutian Islands and reduction in the processing workforce in several regions are adverse, but are not significant. There would be some beneficial, but insignificant effects on subsistence harvest of salmon and Steller sea lions. No changes in the commercial fishery are anticipated that would result in significantly adverse impacts to baseline environmental justice issues.

- **Persistent Past Effects**. Persistent past effects include trends and developments in fisheries and trends in state and municipal revenue. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Reasonably Foreseeable Future Effects.** Other fisheries, other economic development activities, and long-term climate changes and regime shift have the potential to adversely or beneficially affect environmental justice issues. Other sources of municipal state revenue has the potential to adversely affect environmental justice issues. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Cumulative Effects**. Under PA.1, insignificant cumulative effects are identified for environmental justice. The direct/indirect effects on income for subsistence pursuits, and participation and employment opportunities for Alaska Natives in the fishery are generally beneficial. Reductions in revenues to local communities in the Alaska Peninsula/Aleutian Islands, in conjunction with the external effects from the crab closures and downturn in the salmon industry, could potentially affect environmental justice issues, but not of a magnitude to be significant. Effects from reductions in bycatch of salmon and Steller sea lion subsistence activities are beneficial but insignificant. The effects on income and joint production activities related to subsistence in the Alaska Peninsula/Aleutian Islands region are adverse, but cumulatively insignificant.

Direct/Indirect Effects of PA.2

Alaska Peninsula and Aleutian Islands. As described in existing conditions, this region encompasses a number of groundfish fishing communities, of which a number have predominantly Alaska Native populations. Also as described under existing conditions, the in-region processing workforce is predominantly a minority population. In-region processing employment would increase over baseline conditions by about 265 jobs; therefore, no environmental justice impacts would result. Total in-region groundfish processing value would increase from $464 million to $500 million. Increased in-region processing value would correspond to additional municipal revenue and taxes to the local communities, therefore, no associated environmental justice impacts would occur. In this region, the ownership and crews of the catcher vessels are assumed to mirror the demographic composition of populations of the home port communities, so local fleets from at least a few communities in this region are likely to be owned and crewed by Alaska Native residents. Under this alternative, the total overall net value of catcher vessel operations would decrease. Similarly, the corresponding labor income and employment would also decrease. Therefore, an apparent environmental justice impact would result, but as discussed under other alternatives, this may, in part, be an artifact of the model. The impacts to the local fleets that are conditionally significant adverse, resulting from MPA and rationalization design features, could be an environmental justice issue in this region. There could be adverse impacts to Alaska Native communities with support service businesses, but those would be in the form of conditional impacts, depending on the ultimate design of the programs.

Kodiak Island. As described in existing conditions, groundfish processing and catcher vessel activity in this region is highly concentrated in the City of Kodiak. Although the city is ethnically diverse, it does not have a predominantly Alaska Native population as do some of the groundfish fishing communities in the Alaska Peninsula/Aleutian Islands region. However, as described under existing conditions, the in-region processing workforce is predominantly a minority population. In-region processing employment would decrease over baseline conditions by about 45 jobs, which may result in an environmental justice impact. Total in-region groundfish processing value would decrease from $81 million to $75 million. Decreased in-region processing value would correspond to reduced municipal revenue and taxes to the City and the Kodiak Island Borough, and but given local and regional demographics, this is not likely to be an environmental justice issue. Ownership and crews of the catcher vessels are assumed to mirror the demographic composition of populations of the City of Kodiak itself, and therefore the associated population to the local fleet is not likely to be predominantly Alaska Native (or comprised of other identified minority populations). Under this alternative, the total value of regionally-owned catcher vessel operations would decrease as would corresponding labor income and employment, but given demographic assumptions, this is unlikely to be an environmental justice issue.

Southcentral Alaska. As described in existing conditions, environmental justice concerns are much less salient in this region than in the Alaska Peninsula/Aleutian Islands or Kodiak Island regions. The communities most directly engaged in the groundfish fishery, particularly with respect to the processing sector, are largely non-Native communities, and have relatively large populations and diversified economic opportunities. Further, there is a relatively low level of groundfish-related processing employment overall. Catcher vessel related employment is assumed to mirror community demographics, and it is unlikely that environmental justice issues will be associated with any employment change. In general, under this alternative overall combined direct, indirect, induced labor income, and FTEs decrease, but this change is not linked to environmental justice concerns. Similarly, processing value decreases, as do catcher vessel associated values, but these changes are not tied to environmental justice concerns.

Southeast Alaska. The situation in this region is similar to that seen in southcentral Alaska, with the possible exception of the community of Yakutat, which is predominantly Alaska Native compared to other regionally important groundfish communities. Data confidentiality constraints preclude a discussion of Yakutat alone, but overall environmental justice concerns appear not to apply in this region. In general, under this alternative overall combined direct, indirect, induced labor income, and FTEs decrease, but this change is not linked to environmental justice concerns. Similarly, processing value decreases as do analogous catcher vessel associated values, but this change is not associated with environmental justice concerns.

Washington Inland Waters. The greater Seattle area is the regional community most engaged in the groundfish fishery, and it is a demographically and economically diverse major metropolitan area. In-region processing does not occur, and while a number of other communities in the region outside of Seattle are home to groundfish catcher vessels, there is no indication that these communities or the associated vessel owners and crew are comprised of minority populations. As described in existing conditions, environmental justice concerns for this region are concentrated in the at-sea processing sector, due to the predominance of minority representation within this workforce. Under this alternative, at-sea processing labor income and FTEs both increase, if not significantly, so there are no environmental justice impacts associated with this change.

Oregon Coast. This region is engaged in the commercial groundfish fishery through its regionally owned catcher vessel fleet. This fleet is concentrated in a limited number of communities in the region and there is no indication that these are minority communities, nor is there any indication that the population directly associated with fleet ownership and/or crew is either a minority population or a low-income population. In general, under this alternative overall combined direct, indirect, induced labor income, and FTEs increase, as do catcher vessel related values, but these changes are not linked to environmental justice concerns.

CDQ Region. The CDQ region is predominantly comprised of Alaska Native communities that have relatively limited commercial economic opportunities, so any adverse impacts to this program and region are likely to involve environmental justice concerns. Under this alternative, the structure of the CDQ program would not change from baseline conditions, and as noted above, no adverse impacts to the program are anticipated. Therefore, no environmental justice impacts are likely to occur.

Subsistence. Subsistence activities typically disproportionately involve Alaska Native communities and populations. A few cases, such as Steller sea lion subsistence activities, exclusively involve Alaska Native individuals and groups. As a result, adverse impacts to subsistence pursuits are likely to involve environmental justice concerns. Effects from reduced bycatch of salmon and Steller sea lion subsistence activities are likely to be beneficial, but insignificant. As described above, adverse impacts to subsistence activities are not foreseen under this alternative, therefore no associated environmental justice impacts are anticipated.

Cumulative Effects of PA.2

The predicted direct and indirect effects of the groundfish fishery under PA.2 are described above. The past/present effects on environmental justice are described below (Table 3.9-126). This section will assess the potential for these effects to interact with other reasonably foreseeable future events and activities in the cumulative case (Table 4.9-6). The representative indicator used in this analysis is the same as the direct/indirect analysis.

- **Direct/Indirect Effects.** Under PA.2 direct/indirect impacts on environmental justice issues in the Alaska Peninsula/Aleutian Islands region are conditionally significant adverse. This is due to reductions in catcher vessel activity and associated effects on opportunities for Alaska Natives to participate in groundfish fisheries, and on income and joint production opportunities related to subsistence. There would be some beneficial, but insignificant effects on subsistence harvest of salmon and Steller sea lions.

- **Persistent Past Effects**. Persistent past effects include trends and developments in fisheries, and trends in state and municipal revenue. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Reasonably Foreseeable Future Effects.** Other fisheries, other economic development activities, and long-term climate changes and regime shift have the potential to adversely or beneficially affect environmental justice issues. Other sources of municipal and state revenue have the potential to adversely affect environmental justice issues. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Cumulative Effects.** Under PA.2, direct/indirect effects related to environmental justice are generally insignificant for most regions. Beneficial effects are expected for subsistence harvests; however, conditionally significant adverse effects due to reductions in catcher vessel activity are expected in the Alaska Peninsula/Aleutian Islands. The external effects from the crab closures and downturn in the salmon industry and reductions in employment funded by public revenue, and reductions in revenue to Native communities are adverse, primarily in the Alaska Peninsula/Aleutian Islands, where cumulative effects are conditionally significant adverse for environmental justice issues. Effects from reduction bycatch of salmon and Steller sea lion subsistence activities are beneficial, but insignificant. Direct/indirect effects on income and joint production activities related to subsistence in the Alaska Peninsula/Aleutian Islands region are adverse but insignificant. Cumulative effects are conditionally significant adverse due to downturns in other fisheries and decreased income and opportunities for joint production.

4.9.9.6 Market Channels and Benefits to United States Consumers

The predicted direct and indirect effects of the groundfish fishery under PA.1 and PA.2 are described below (Table 4.9-6). The past/present effects on market channels and benefits to U.S. consumers are described in Section 3.9 and below (Table 3.9-127). This section will assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case (Table 4.9-6). The representative indicator used in this analysis is benefits to U.S. consumers.

Direct/Indirect Effects of PA.1 and PA.2

Neither PA.1 nor PA.2 are expected to have significant effects on benefits to U.S. consumers of groundfish products relative to the comparative baseline. Under both PA.1 and PA.2, the BSAI and GOA groundfish fisheries are expected to continue to provide high and relatively stable levels of seafood products to domestic and foreign markets. An estimate of the final market value of BSAI and GOA seafood products is not available; however, it would be substantially greater than $1.5 billion, the projected five-year mean of the wholesale product value of BSAI and GOA groundfish after primary processing under both PA.1 and PA.2. This wholesale product value mean is higher than the comparative baseline, but the increase is not significant.

The rationalization of groundfish fisheries occurring under PA.2 could increase consumer benefits by resulting in an increase in the quality of groundfish products available to consumers relative to the comparative baseline. Moreover, rationalization has the potential to increase the proportion of Alaska groundfish products that are purchased by U.S. consumers because there will be more incentive to create the fresh and value-added products that are popular in the domestic market. With current technology and tastes, the greatest gains for U.S. consumers are likely to result from a greater supply of fresh and value-added products from Pacific cod and rockfish. However, these species currently account for less than one-third of all Alaska groundfish production. Furthermore, it is unlikely that all Pacific cod and rockfish will be sold to U.S. consumers. Consequently, the increased benefits to U.S. seafood consumers are not expected to be significant.

Cumulative Effects of PA.1 and PA.2

See Table 4.9-6 for a summary of the cumulative effects on market channels under PA.1 and PA.2.

- **Direct/Indirect Effects**. Under this alternative, increases in benefits to U.S. consumers of groundfish products are expected to occur, but are insignificant.

- **Persistent Past Effects**. These effects on benefits to U.S. consumers of groundfish products include: Alaska Seafood Marketing Institute product promotion activities, research and public awareness regarding the health benefits of seafood consumption, aquaculture development increasing overall availability and demand for seafood products, competition from aquaculture products, and changes in processing technology increasing seafood quality.

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable effects include other fisheries (supply of product) and long-term climate changes and regime shift. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Cumulative Effects**. Under PA.1 and PA.2, a cumulative effect is identified for benefits to U.S. consumers of groundfish products, and the effect is judged to be insignificant. The external impacts of other fisheries have the potential to contribute adversely or beneficially to U.S. consumers of groundfish products and groundfish market channels. However, the wholesale groundfish product value in conjunction with products from other fisheries is not expected to change benefits to U.S. consumers. Long-term climate changes and regime shift could adversely effect availability for market channels due to natural fluctuations in groundfish stocks.

4.9.9.7 The Value of the Bering Sea and Gulf of Alaska Marine Ecosystems (including Non-Consumptive and Non-Use Benefits)

The predicted direct and indirect effects of the groundfish fisheries under PA.1 and PA.2 on the level of benefits that marine ecosystems and associated species provide to the U.S. general public are described below (Table 4.9-6). This section will also assess the potential for these effects to interact with other reasonably foreseeable future events in the cumulative case. The representative indicators used in this analysis are the benefits, including non-consumptive and non-use benefits, the public derives from the Bering Sea and GOA marine ecosystems and associated species.

Direct/Indirect Effects of PA.1 and PA.2

PA.1 is predicted to have no significant effects on the level of benefits the Bering Sea and GOA marine ecosystems and associated species provided relative to the comparative baseline. These findings are based on the assessment of the direct and indirect effects of PA.1 on the environment with respect to the ecosystem issues of predator-prey relationships, energy flow and balance, and diversity. This assessment of ecosystem effects is presented in Section 4.9.10 of the draft Programmatic SEIS.

The Bering Sea and GOA marine ecosystems and species associated with them provide a broad range of benefits to the American public. Some of the goods and services these ecosystems produce are not exchanged in normal market transactions but have value nonetheless. While there are difficulties in estimating the value that the public places on protecting ecological conditions, Section 3.9.7 provides a qualitative discussion of possible benefits provided by the Bering Sea and GOA marine ecosystems. In addition to supporting commercial fisheries, these ecosystems support an array of recreational fishing and subsistence activities as well as non-consumptive activities such as wildlife viewing. Furthermore, some people can not directly interact with the Bering Sea and GOA marine ecosystems and the various species associated with them, but derive satisfaction from knowing that the structure and function of these ecosystems are protected.

The focus of this analysis includes direct and indirect effects of the alternatives on ecosystem benefits other than those that accrue to members of society who make a living harvesting, processing, and distributing BSAI and GOA groundfish products or who purchase and consume these products. The direct and indirect effects of the alternatives on firms and communities that derive value from the commercial harvest and processing of groundfish are described elsewhere in the draft Programmatic SEIS. Similarly, the effects of the alternatives on consumers of groundfish products are discussed in a separate section of the draft Programmatic SEIS.

The non-monetary or social value that people assign to those marine ecosystem benefits that are unrelated to commercial groundfish fisheries are thought to be considerable. For example, the value of protecting the Steller sea lion alone could be substantial. As discussed in Section 3.9.7, a contingent valuation study suggests that there is a significant willingness to pay on the part of the American public for an expanded federal Steller sea lion recovery program. At this time, there is insufficient information to provide a comprehensive measure of the benefits derived from these ecosystems and the various species associated with them.

PA.1 would maintain current management measures that mitigate the adverse effects of the groundfish fisheries on the Bering Sea and GOA marine ecosystems and associated species. These measures include a network of spatial and temporal closure areas that disperse fisheries geographically and seasonally, a prohibition on the use of non-pelagic trawl gear to fish for pollock in the BSAI, bycatch reduction measures such as the full retention requirement for Pacific cod and pollock, and measures to reduce the incidental catch of seabirds. Furthermore, as discussed in Section 4.7.11, PA.1 is not expected to result in a significant change in the quantitative measures of any indicators of fishing impacts on marine ecosystems relative to the baseline. Consequently, the change in the level of benefits these ecosystems provide is not expected to be significant.

PA.2 is predicted to lead to a conditionally significant increase in the level of benefits the Bering Sea and GOA marine ecosystems and associated species provide relative to the comparative baseline. The significance of the increase in benefits is conditional because it is uncertain to what extent PA.2 would close additional areas as MPAs or no-take reserves. These findings are based on the assessment of the direct and indirect effects of PA.2 on the environment with respect to the ecosystem issues of predator-prey relationships, energy flow and balance, and diversity. This assessment of ecosystem effects is presented in Section 4.7.11 of the draft Programmatic SEIS.

PA.2 would maintain current management measures that mitigate the adverse effects of the groundfish fisheries on the Bering Sea and GOA marine ecosystems and associated species. In addition, under PA.2 the establishment of additional area closures is considered. If implemented, these closures would close off up to 20 percent of the EEZ as MPAs and no-take marine reserves across a full range of marine habitats within the 1000 m bathymetric line (see Figure 4.2-5). The closures would aim to provide protection for a wide range of species, from Steller sea lions to slope rockfish to prohibited species.

Furthermore, PA.2 would undertake a comprehensive rationalization of all fisheries. By extending rights-based management to additional groundfish fisheries and thereby ending the race for fish in those fisheries, this FMP bookend has the potential to provide increased protection to the Bering Sea and GOA ecosystems.

If rights-based management systems include individual quotas on bycatch, they provide strong incentives to reduce bycatch because they internalize the cost of that bycatch. In turn, a reduction in bycatch can help protect bycatch species from overexploitation and maintain the overall ecosystem of which they could be an important part. Moreover, the experience with cooperatives in the BSAI pollock fishery shows that fishing could be spread out temporally as a result of rights-based management systems. This dispersal of fishing effort would reduce the potential for local depletions of fish stocks and the associated adverse impacts on marine mammals and other species.

As discussed in Section 4.7.11, the measures implemented under PA.2 are expected to have significantly or conditionally significant beneficial consequences for predator-prey relationships and diversity. In turn, these beneficial effects on the Bering Sea and GOA marine ecosystems and associated species are expected to lead to a conditionally significant increase in the levels of some of the benefits these ecosystems and species provide.

Cumulative Effects of PA.1 and PA.2

See Table 4.9-6 for a summary of the cumulative effects on the value of ecosystems under PA.1 and PA.2.

- **Direct/Indirect Effects**. Under this PA.1 and PA.2, the adverse effects that the Alaska groundfish fishery could have on marine ecosystems are reduced. PA.1 is predicted to have a beneficial but insignificant impact on the levels of benefits these ecosystems and associated species generate. PA.2 is predicted to have a conditionally significant beneficial impact.

- **Persistent Past Effects**. Persistent past effects on the level of benefits, including non-consumptive and non-use benefits, that marine ecosystems and associated species provide to the public include: an increase in public awareness of marine ecosystems; increased participation in recreational fishing and eco-tourism activities; and persistent past effects on ecosystems, as described in Section 4.9.10. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Reasonably Foreseeable Future Effects**. Reasonably foreseeable future effects include other fisheries, long-term climate changes and regime shifts, and other factors, as described in Section 4.9.10.2. These factors do not vary among alternatives; for more detail see the analysis in Alternative 1.

- **Cumulative Effects**. Under PA.1 and PA.2, a cumulative effect is identified for benefits the public derives from marine ecosystems and associated species, including non-consumptive and non-use benefits, and the effect is judged to be insignificant and conditionally significantly beneficial, respectively. The external impacts of other fisheries, long-term climate changes and regime shifts, and other factors have the potential to contribute adversely to benefits the public derives from marine ecosystems and associated species.

4.9.10 Ecosystem Preferred Alternative Analysis

Ecosystems are populations (consisting of single species) and communities (consisting of two or more species) of interacting organisms and their physical environment that form a functional unit with a characteristic trophic structure (food web) and material cycles (movement of mass and energy among the groups). The following analyses of potential direct/indirect and cumulative effects of PA.1 and PA.2 apply to the BSAI and GOA ecosystems. Where available information allows, each ecosystem is addressed separately. In most cases, however, information is insufficient to allow individual consideration, and the two ecosystems are treated as a single entity.

As explained in Section 4.5.10, the analyses include numerous indicators representing potential direct, indirect, and cumulative effects of the alternative and of specific bookends, where applicable. Significance criteria and thresholds for the effect categories are presented in Table 4.1-7.

Direct/Indirect Effects PA.1 and PA.2 – Ecosystem

This section assesses the potential direct/indirect effects of PA.1 and PA.2 on the BSAI and GOA ecosystems.

Change in Pelagic Forage Availability

Pelagic forage availability is assessed primarily by evaluating population trends in pelagic forage biomass for species with age-structured population models. These include walleye pollock in the GOA (Figure H.4-17 of Appendix H), Bering Sea walleye pollock, and Aleutian Islands Atka mackerel (Figure H.4-18 of Appendix H). For other forage species (herring, squid, and the forage species group), bycatch trends are used as measures of the potential impact of the BSAI and GOA groundfish fisheries on forage availability (Figures H.4-19 and H.4-20 of Appendix H). Table 4.5-81 summarizes the average values from 2003 through 2008 for these measures and the percent change in the average values from the baseline amounts. Under PA.1, the estimated pelagic forage biomass for the age-modeled populations declines from the baseline in the BSAI and increases over the baseline in the GOA. Twenty-year biomass projections show similar trends. Average biomass, however, remains within the bounds of estimated biomass that occurred historically before a target fishery emerged. Bycatch of other forage species increases in the BSAI and declines in the GOA. Estimates of forage biomass from food web models of the EBS indicate that this level of bycatch is probably a small proportion of the total forage biomass (Aydin *et al.* 2002), although because population-level assessments are lacking for some members of the forage species group, corresponding biomass estimates for these species are not available. Because average biomass projections for the age-modeled forage species remain within the estimated historical boundaries, and bycatch-based estimates for other forage species are small in relation to total forage biomass, PA.1 is determined to have insignificant effects on the BSAI and GOA ecosystems with respect to pelagic forage availability.

Under PA.2, pelagic forage biomass for the age-modeled species again declines from the baseline in the BSAI and increases over the baseline in the GOA. Twenty-year biomass projections show similar trends. As with PA.1, the estimated average biomass resides within the range of the estimated biomass that occurred historically before a target fishery emerged. Bycatch of other forage species increases in the BSAI and declines in the GOA, although again, the lack of population-level assessments for some members of the forage species group prevents biomass projections for these species. Also, the extensive fishing closure areas proposed under both PA.1 and PA.2 may alter bycatch estimates in ways that cannot be accurately predicted. Because average biomass projections for the age-modeled forage species remain within the estimated historical boundaries, and bycatch-based estimates for other forage species are considered to be small in relation to total forage biomass (Aydin *et al.* 2002), PA.2 is determined to have insignificant effects on the BSAI and GOA ecosystems with respect to pelagic forage availability.

Spatial and Temporal Concentration of Fishery Impact on Forage

The spatial and temporal concentration of fishery impacts on forage species is assessed qualitatively by considering the potential for the alternative to concentrate fishing on forage species in regions utilized by predators that are tied to land, such as pinnipeds and breeding seabirds. Additionally, the possibility for concentrated fishing effort to result in an ESA listing or in the lack of recovery of a species that is already listed is also considered. PA.1 would continue the existing closures around Steller sea lion rookeries, trawl and fixed gear closures in nearshore and critical habitat areas, the ban on directed fishing for forage fish, and the spatial/temporal allocation of TAC for some BSAI and GOA species, resulting in an insignificant effect on forage species. In the GOA, identification of salmon savings areas along with establishing PSC limits are proposed measures under PA.1. In addition, BSAI pollock fisheries have shown increasing catch in northern fur seal foraging habitat, but more research is required to evaluate whether the amounts of pollock removed are having a population-level effect on fur seals. This type of catch trend data may be useful in the development of ecosystem indicators for future use in TAC-setting processes, as put forth under PA.1.

PA.2 would continue the existing closures around Steller sea lion rookeries with the possibility of designating critical habitat areas based on scientific information. In addition, modified Steller sea lion closures in the Aleutian Islands are also proposed. The existing ban on forage fish and spatial/temporal allocation of TAC for some BSAI and GOA species would continue. Maintaining current closed/restricted areas, with the potential for some of these areas to qualify as MPAs, could provide increased protection of northern fur seal foraging habitat from potential fishing effects. PA.2 proposes the prohibition of pollock bottom trawling in the GOA as well as continuing the existing ban in the BSAI. For these reasons, PA.2 is determined to have a conditionally significant beneficial effect on the spatial/temporal availability of forage, particularly for some marine mammals. Additional seabird avoidance measures in longline and trawl fisheries are proposed under PA.2, with emphasis on cooperation between NOAA Fisheries and USFWS to develop revised fishing methods that reduce incidental take for all seabird species. Although these measures may not result in significant changes in the spatial/temporal availability of forage to seabirds, it will be difficult to determine the potential effectiveness of the improved methods until they have been fully implemented.

Removal of Top Predators

Removal of top predators, either through directed fishing or bycatch, is assessed by evaluating the trophic level of the catch relative to the trophic level of the groundfish biomass (Figures H.4-21 through H.4-24 of Appendix H), bycatch levels of sensitive top predator species such as birds and sharks (Figures H.4-25 and H.4-26 of Appendix H), and a qualitative evaluation of the potential for catch levels to cause one or more top-level predator species to fall below biologically acceptable limits (MSST for groundfish; for other species, ESA listing or preventing recovery of an already-listed species). Trophic level of the catch in both the BSAI and GOA is a very stable property, changing less than 3 percent on average from the baseline, and trophic level of the groundfish species for which we have age-structured models changes less than one percent on average.

The above indicators result in no change in the evaluation of the importance of this effect relative to the baseline. The baseline determination shows that historical whaling has resulted in low present-day abundance of whale species in the North Pacific Ocean. PA.1 and PA.2 would not further impair the recovery of these species through direct takes. Similarly, it is not expected that levels of seabird and pinniped bycatch in groundfish fisheries would lead to an ESA listing for any of those populations or prevent any of the listed species from recovery under the ESA. Additional seabird avoidance measures in longline and trawl fisheries are proposed under PA.2, with emphasis on cooperation between NOAA Fisheries and USFWS to develop revised fishing methods that reduce incidental take for all seabird species. Although these measures may not result in significant changes to seabird populations, it will be difficult to determine the potential effectiveness of improved methods until implementation has taken place. Sections 4.9.7 and 4.9.8 discuss the potential effects of groundfish fishery direct takes on specific seabird and marine mammal populations under PA.1 and PA.2.

The effect of shark bycatch on shark populations is currently unknown, and further research focusing on population assessments and establishing reliable biomass estimates for these sensitive (late maturing, low fecundity, low natural mortality) species is needed to identify potential effects from the groundfish fisheries. As proposed in PA.2, breaking sharks (and additional species groups) out of the other species complex for TAC-setting purposes may result in an increased level of protection through a more species-specific TAC. As a result of implementing specific TAC-setting measures for species that have traditionally been included in the other species TAC category, improved management of these individual species may minimize potential population-level impacts resulting from bycatch mortality. In addition, improved observer coverage and species identification for non-target species, as proposed in PA.2, may provide improved bycatch data, further supporting the need for more comprehensive management of particular species within the other species group. Section 4.9.3 contains detailed information regarding potential cumulative effects of PA.1 and PA.2 on sharks, skates, and other cartilaginous fishes.

Stability in trophic level of the catch indicates that minimal effects have resulted from fishing impacts on target and PSC species top predators (Greenland turbot, arrowtooth flounder, sablefish, Pacific cod, and Pacific halibut). PA.1 maintains current PSC limits for halibut in the BSAI and GOA while considering reducing these limits by 1 to 10 percent in the BSAI, if practicable. Further reduction in PSC limits for halibut are suggested under PA.2 for both the BSAI and GOA. Section 4.9.1 and 4.9.2 discuss direct, indirect, and cumulative effects associated with PA.1 and PA.2 for target species and Pacific halibut. Overall, potential effects of PA.1 and PA.2 on top predators are predicted to be insignificant and unknown.

<u>Introduction of Non-Native Species</u>

The introduction of non-native species through ballast water exchange and hull-fouling organism release from fishing vessels could potentially disrupt the Alaskan marine food web structure (Fay 2002). There have been 24 non-indigenous plant and animal species documented in Alaskan marine waters, primarily in shallow-water nearshore and estuarine ecosystems, with 15 of those species recorded in PWS. It is possible that most of these introductions were from tankers or other large commercial vessels that have large volumes of ballast exchange. However, exchange via fishery vessels that take on ballast from areas where invasive species have already been established and then transit through Alaskan inshore waters has been identified as a threat in a recently developed State of Alaska Aquatic Nuisance Species Management Plan (Fay 2002). Consequently, this effect is evaluated as conditionally significant adverse in the baseline condition.

Total groundfish catch levels are used as an indicator of potential changes in the amount of these releases by groundfish fishery vessels (Figures H.4-27 and H.4-28 of Appendix H and Table 4.1-7). Under PA.1 and PA.2, catch levels increase in the BSAI. PA.2 results in decreasing catch levels in the GOA relative to the baseline, while GOA catch under PA.1 increases. These projected catch levels are similar to recent catches in these areas, indicating a similar level of effort and resulting in a similar potential for fishing vessel introduction of non-native species through ballast water exchange or hull-fouling organism release.

Consequently, potential effects of PA.1 and PA.2 on the introduction of non-native species from fishing vessels and gear are insignificant compared to the baseline condition.

Energy Flow and Balance

As discussed in Section 3.10, fishing may alter the amount and flow of energy in an ecosystem by removing energy and altering energetic pathways through the return of discards and fish processing offal to the sea. The recipients, locations, and forms of this returned biomass may differ from those in an unfished system. Baseline energy removals, in the form of total catch, were less than one percent of the total system energy as determined by mass-balance modeling of the system and were determined to have an insignificant impact on the ecosystem baseline. Predicted catch removals under PA.1 (Figures H.4-27 and H.4-28 of Appendix H, Table 4.5.-142) are similar to those modeled in FMP 3.1 and are determined to be insignificant with respect to the potential for producing changes in system biomass, respiration, production, or energy cycling that are outside the range of natural variability (Table 4.9-7). Predicted catch removals under PA.2 are presumed to show similar trends to FMP 3.2 (Figures H.4-27 and H.4-28 of Appendix H, Table 4.5-81), thus increasing by an estimated one percent in the BSAI and decreasing by an estimated 7 percent in the GOA relative to the baseline. These changes are also determined to be insignificant.

Energy re-direction, in the form of discards, fishery offal production, or unobserved gear-related mortality, can potentially change the natural pathways of energy flow in the ecosystem. Animals damaged when passing through the meshes of trawls may later die and be consumed by scavengers. Bottom trawls can expose benthic organisms and make them more vulnerable to predation. Discards and offal production can cause local enrichment and changes in species composition or water quality if discards or offal returns are concentrated in confined areas such as estuaries, bays, and lagoons. These effects were determined to be insignificant at the ecosystem baseline level. It is expected that trends in total discards for PA.1 will be similar to those shown under FMP 3.1 (Table 4.5-81, Figures H.4-29 and H.4-30 of Appendix H). These result in increases of less than one percent in the BSAI and decreases by approximately 8 percent in the GOA relative to the baseline. Trends in total discards (Table 4.5-81, Figures H.4-29 and H.4-30 of Appendix H) under PA.2 are presumed to decrease approximately 20 to 25 percent in the BSAI and 40 and 50 percent in the GOA relative to the baseline, as observed under FMP 3.2. These changes are considered minimal in comparison to historical amounts of discards and are insignificant to ecosystem-level energy cycling characteristics.

Change in Species Diversity

As explained in Section 3.10, commercial fishing can alter different facets of diversity. Species diversity, defined as the number of different species in an ecosystem, can be altered if fishing results in removal of one or more species from the system. Fishing can also alter functional diversity in terms of both trophic and structural habitat characteristics. Functional diversity can be altered with respect to trophic characteristics if removal or depletion of a trophic guild member occurs. Changes to distribution of biomass within a trophic guild may also result. From a structural habitat standpoint, functional diversity can be altered or damaged if benthic fishing methods such as bottom trawling remove or deplete organisms that provide structural habitat for other species (e.g., corals, sea anemones, sponges). Impacts to genetic diversity from fishing can occur by selectively removing faster-growing fish or removing spawning aggregations that may exhibit genetic characteristics that are different from other spawning aggregations. Larger, older fishes may be more heterozygous (i.e., demonstrating wider genetic differences or diversity), and some stock structures may have a genetic component (see review in Jennings and Kaiser 1998). Consequently, one would expect a decline in genetic diversity within biological populations receiving heavy exploitation by fisheries.

Significance thresholds for effects of fishing on species diversity are defined as catch removals resulting in the biomass of one or more species (target or non-target) falling below, or not recovering from levels already below, minimum biologically acceptable limits (MSST for target species, ESA listing for non-target) (Table 4.1-7). For sensitive species groups (those having low population turnover rates) that lack population estimates (e.g., skates, sharks, grenadiers, and sessile invertebrates inhabiting HAPC), bycatch data indicate the potential for fishing impacts to affect species diversity (Table 4.5-81, Figures H.4-31 and H.4-32 of Appendix H). Closed areas provide protection to these groups, particularly to less-mobile species like HAPC biota. Baseline determinations were insignificant for target and non-target species, and unknown for species groups lacking population estimates and bycatch data, including HAPC species.

Under PA.1, currently closed areas (including Steller sea lions closures) would be maintained, identification and designation of EFH and HAPC are proposed, and current no-trawl zones and fixed-gear restrictions would stay in place. Although it is unknown whether bycatch amounts of HAPC biota would be at levels high enough to reduce these species to minimum population thresholds, area closures would likely be effective in preventing population-level impacts on these sessile animals. Under PA.2, the estimated bycatch of HAPC biota is expected to decrease in the BSAI and GOA (Table 4.5-81). This FMP would also provide substantial increases in closed areas such as no-trawling MPAs and no-take reserves across a range of habitat types, review of all existing closures for qualification as MPAs, establishment of an Aleutian Islands management area to protect coral and other living habitat species, and modification of 2002 Steller sea lion with designation of critical habitat according to scientific data and assessment information. These measures may further reduce the bycatch of HAPC biota. In addition, the adoption and use of key ecosystem indicators to modify TAC-setting processes may provide further protection to sensitive groups such as HAPC biota until more life history information becomes available. Although forage species population levels are not known, their relatively high population turnover rates, along with the ban on directed fisheries for forage species in PA.1 and PA.2, are considered effective protection measures for minimizing potential population-level effects.

On the basis of the preceding considerations, potential effects of PA.1 and PA.2 on species diversity are considered insignificant and unknown. More comprehensive survey data and life history parameter determinations for skates, sharks, grenadiers, and other species groups may help to determine population status and establish additional protection measures that could minimize adverse impacts from fishing.

Change in Functional Diversity

Functional (either trophic or structural habitat) diversity can be altered through fishing if selective removal of one member of a functional guild results in increases in other guild members. A functional guild is a group of species that utilize resources within the ecosystem in similar ways. Significance thresholds are characterized by catch removals resulting in a change in functional diversity outside the range of natural variability observed for the system (Table 4.1-7). Indicators for the magnitude of this effect include qualitative evaluation of guild or size diversity changes relative to fishery removals, changes in bottom gear effort that would provide a measure of benthic guild disturbance, and bycatch amounts of HAPC biota, a structural habitat guild. Members of the HAPC biota guild serve important functional roles in providing fish and invertebrates with structural habitat and refuge from predation. The abundance level of these structural species necessary to provide protection is not known, and it may be important to retain populations of these organisms and maintain wide spatial distribution to enable them to fulfill their various functional roles. Some of these organisms have life-history traits that make them very sensitive to population-level impacts resulting from fishing. The long-lived nature of corals, in particular, makes them susceptible to permanent eradication in fished areas. Present and proposed Steller sea lion trawl closures are spread throughout the Aleutian Islands, but these closures may be further inshore than most of the coral. For this reason, the area closures proposed under PA.1 and PA.2 may not be sufficient to provide additional protection for these sensitive organisms in all areas throughout the BSAI and GOA.

Under PA.1, species composition and amounts of removals, bottom gear effort, and bycatch of HAPC biota (Table 4.5-81, Figures H.4-31 and H.4-32 of Appendix H) would remain similar to the comparative baseline, in which fishing impacts on functional guild diversity are determined to be insignificant for trophic diversity and conditionally significant and adverse for structural habitat diversity. Some of the area closures for PA.2 have been developed with corals and other living habitat species in mind. If implemented, these measures may improve protection throughout their broad spatial distribution, particularly in the Aleutian Islands. Thus, PA.2 is determined to have significantly beneficial effects on structural habitat diversity relative to the baseline, whereas PA.1 would result in an insignificant change from the baseline condition. In addition, possible effects of PA.2 on trophic diversity, species composition, and removal of target species relative to the baseline are regarded as insignificant.

Change in Genetic Diversity

Genetic diversity can be affected by fishing through heavy exploitation of certain spawning aggregations or systematic targeting of older age classes that tend to have greater genetic diversity. Under PA.1 and PA.2, target species are not expected to fall below their respective MSST, spatial/temporal management of TAC would not change, and similar catch and selectivity patterns in the fisheries would apply. The PA would result in insignificant impacts to genetic diversity. However, a baseline condition for genetic diversity remains unknown for many species, and the potential effects of fishing on genetic diversity under PA.1 and PA.2 are also largely unknown.

Cumulative Effects Analysis PA.1 – Ecosystems

The following section describes the potential cumulative effects of PA.1 on the ten ecosystem indicators explained in Section 4.5.10. These potential cumulative effects are summarized in Table 4.5-89. Data and calculations supporting the energy removal analyses for all alternatives are presented in Table 4.5-81.

Change in Pelagic Forage Availability

- **Direct/Indirect Effects.** The direct/indirect effects of PA.1 on pelagic forage availability are expected to be insignificant. Fishery-induced changes, including bycatch-related effects on forage species, are predicted to remain within the natural level of abundance or variability for prey species relative to predator demands (Table 4.9-7).

- **Persistent Past Effects.** Past effects of forage fish bycatch by the BSAI pollock and GOA rockfish domestic fisheries and targeted domestic catches of pollock and Atka mackerel are likely to have affected forage fish populations in ways that may persist into the present and future (Section 3.10.1.4). From about 1925 to 1941, Alaska herring harvests for oil and meal ranged from about 50,000 to 150,000 mt per year, and a large foreign herring fishery removed from 30,000 to 150,000 mt per year during the 1960s and 1970s (ADF&G 2003a). Past climatic changes, including inter-decadal oscillations and ENSO events, have been shown to affect forage fish populations (Section 3.10.1.5), and these effects may persist.

- **Reasonably Foreseeable Future External Effects.** The State of Alaska manages herring fisheries on a sustainable basis and has established a maximum exploitation rate (fraction of the spawning population removed by the fishery) of 20 percent. Fisheries are closed if stock size falls below MSST. Lower exploitation rates are applied when herring stocks decline to near-threshold levels (ADF&G 2003a). This management approach is expected to continue for the indefinite future. Subsistence harvests will continue to remove an increment of pelagic forage biomass each year. Relative to the BSAI and GOA groundfish fisheries, however, the additional contribution of subsistence fisheries to the annual removal of pelagic forage biomass is likely to be very small. The EVOS of 1989 suggests that a large oil or fuel spill coinciding in space and time with herring or capelin spawning would most likely produce population declines, and other pelagic forage species (such as eulachon, which spawn on beaches) might also be adversely affected. Finally, future climate change, especially a regime shift, would likely affect the productivity, and thereby the population sizes, of pelagic forage species (Section 3.10.1.5).

- **Cumulative Effects.** A conditionally significant adverse cumulative effect on pelagic forage availability is expected in the event of a large petroleum spill. The conditions under which this effect may be significant relate to the areas affected by, and seasonal timing of, the spill. If these conditions coincide with spawning locations and times, a significantly adverse cumulative effect on pelagic forage availability would most likely result. Additive or interactive contributions from State of Alaska commercial fisheries and subsistence fish harvests are not expected to be significant. A future climatic regime shift would not appreciably offset, but could intensify, this potential cumulative effect if the productivity of pelagic forage species is reduced.

Spatial and Temporal Concentration of Fishery Impact on Forage

- **Direct/Indirect Effects.** The direct/indirect effects of the spatial and temporal concentration of fishing effort under PA.1 on pelagic forage availability are expected to be insignificant. PA.1 would continue the existing closures around Steller sea lion rookeries, the ban on forage fish, and the spatial/temporal allocation of TAC for pollock and Atka mackerel, which together would result in insignificant impacts to forage species.

- **Persistent Past Effects.** Geographic and seasonal concentrations of past forage fish bycatch from the BSAI pollock and GOA rockfish fisheries, the State of Alaska directed herring fishery, and targeted catches of pollock and Atka mackerel have affected forage fish populations in ways that may persist presently and into the future (Section 3.10.1.4). Past herring fisheries have followed a stable pattern of timing and location dictated by the spawning behavior of the fish (ADF&G 2003a). Past climatic changes, including inter-decadal oscillations and ENSO events, have been correlated with changes in recruitment rates and distribution patterns of forage fish populations (Section 3.10.1.5). Such effects may persist on forage fish populations, although evidence is not sufficient to allow quantification.

- **Reasonably Foreseeable Future External Effects.** The State of Alaska directed herring fishery will exert fishing pressures on herring and other forage fish populations at particular times and locations that could overlap with fishing pressures from the groundfish fisheries. Because the herring fishery is mainly inshore, overlap with the groundfish fishery is more likely to be temporal than spatial. Subsistence harvest patterns are not coordinated with commercial fishing effort and will sometimes overlap with spatial and temporal patterns of the groundfish fishery, but the incremental contribution of subsistence to this potential cumulative effect will continue to be negligible. The EVOS of 1989 suggests that a large oil or fuel spill coinciding in space and time with herring or capelin spawning would most likely produce population declines and adversely affect other pelagic forage species (such as eulachon, which spawn on beaches). Finally, future climate change, especially a regime shift, could alter the spatial and temporal distributions of pelagic forage species in ways that are synergistic with spatial and temporal concentrations of fishing effort in the BSAI and GOA groundfish fisheries.

- **Cumulative Effects.** A conditionally significant adverse cumulative effect on pelagic forage availability could result in the future from synergistic interactions between spatial and temporal concentrations of the BSAI and/or GOA groundfish fishing effort. The conditions under which this potential effect may become significant relate to location and timing. If the fishing efforts of the State of Alaska directed fisheries (primarily herring fisheries) and subsistence fish harvests converge in space and time with a fuel or oil spill, forage fish populations could become significantly depressed, leading to impairment of the long-term viability of ecologically important top predators such as seabirds and marine mammals (Table 4.5-89). Future climate change, consistent with effects observed in the recent past (Section 3.10.1.5), could alter the spatial and temporal distributions of pelagic forage species in ways that might reduce or intensify this potential Cumulative Effects.

<u>Removal of Top Predators</u>

- **Direct/Indirect Effects.** The implementation of PA.1 is predicted to have insignificant direct/indirect effects on top predators such as whales, other marine mammals, seabirds, and top predatory fish species such as Greenland turbot, arrowtooth flounder, sablefish, Pacific cod, and Pacific halibut. This FMP would not impair the continued recovery of whale populations still reduced through direct take in the past. Predicted levels of seabird and marine mammal bycatch in the groundfish fisheries are not expected to lead to the listing of these species or prevent their recovery under the ESA. Because there is little available information on shark bycatch, the direct/indirect effect of this FMP on shark populations is unknown.

- **Persistent Past Effects.** Before passage of the MSA in 1976, groundfish fisheries in the BSAI and GOA produced much higher than present bycatch levels of sharks, seabirds, and marine mammals. Historical whaling, resulting in high mortality levels in the 1960s (Section 3.10.1.3), produced a sustained effect on these slowly reproducing populations that is reflected in the currently depressed abundance of whale species in the North Pacific Ocean. State of Alaska directed groundfish fisheries have annually removed top predators such as sablefish and Pacific cod at levels safely above MSST (ADF&G 2003b). These fisheries also produced shark, seabird, and marine mammal bycatch in the past, although quantitative data are lacking on past and current bycatch levels in these fisheries. Past and present groundfish fisheries operating outside of U.S. jurisdiction in the western Bering Sea have also contributed to the bycatch of top predators, in some cases at high levels (Sections 3.7.1 and 3.10.1). Marine mammals continue to be removed for subsistence, although at much lower levels than those observed in the past. Adverse effects from these past harvests may persist on some populations today. Finally, there is evidence that past climatic variability may have affected the recruitment and distribution of some top predator fish species (Section 3.10.1.5; Hollowed *et al.* 1998).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fishery will continue to remove sustainable numbers of Pacific halibut, a top predator. The current management plan is likely to continue in the future, although a modified approach has been proposed to produce a yield similar to the present policy while reducing variations in annual yield due to changes in stock abundance, assessment methods, and estimated removals by other fisheries (Clark and Hare 2003). Seabird bycatch and resulting direct mortality are expected to continue annually in North Pacific Ocean longline fisheries operating outside of the EEZ. Available data and estimates for the annual incidental take of individual bird species by these external fisheries are provided and discussed in Sections 3.7.1-3.7.19. The State of Alaska directed groundfish fisheries, operating in state waters of the eastern GOA and southeast Alaska, Cook Inlet, PWS, Kodiak, and the Alaska Peninsula, and in all state waters for lingcod, sablefish, and Pacific cod, will continue to remove targeted top predatory fish species in small numbers relative to the domestic groundfish harvests in federal waters (ADF&G 2003b). Subsistence harvests of marine mammals will continue in the future, with an increasing trend toward co-management by NOAA Fisheries and Alaska Native organizations. The Protected Resources Division of NOAA Fisheries will continue to develop management and conservation programs to ensure that annual subsistence harvests are sustainable (NOAA Fisheries 2003). A large fuel or oil spill at sea may result in direct mortality of marine mammals, with mortality levels depending on the location, size, and timing of the spill. Finally, a future climatic regime shift could alter total numbers of top predators in the BSAI and GOA ecosystems by increasing or limiting recruitment.

- **Cumulative Effects.** A conditionally significant adverse cumulative effect on populations of top predators could result primarily from continued seabird bycatch by North Pacific Ocean longline fisheries operating outside the EEZ. The conditions under which this cumulative effect may become significant include the continuation of seabird bycatch in conjunction with a large fuel or oil spill, along with incremental removals of top predators by the IPHC longline fishery, State of Alaska directed groundfish fisheries, and subsistence harvests of marine mammals. As determined from recent climatic studies (Section 3.3), a climatic regime shift is probable in the future, and this could intensify or reduce this potential cumulative effect by influencing recruitment.

Introduction of Non-Native Species

- **Direct/Indirect Effects.** Under PA.1, projected catch levels would maintain a potential for fishing-vessel introduction of non-native species through ballast water exchange or release of hull-fouling organisms similar to that which currently exists under baseline conditions. Therefore, the potential direct/indirect effect of PA.1 on predator-prey relationships through the introduction of exotic species is evaluated as insignificant.

- **Persistent Past Effects.** For decades, the annual arrival of groundfish fishing vessels from ports outside of Alaska has made it possible for non-native species to enter Alaskan waters through the release of ballast water and hull-fouling organisms. Commercial shipping has provided a similar means for the introduction of non-native species (Fay 2002). There have been 24 non-indigenous species of plants and animals documented in Alaskan marine waters, with 15 of these recorded in PWS, where most of the research has been conducted. Although oil tankers, through the release of ballast water, have been speculated to be the primary source for these introductions, cruise ships and fishing vessels coming from areas where invasive species have already been established have also been identified as a threat in the State of Alaska Aquatic Nuisance Species Management Plan (Fay 2002). From 1991 to 2001, 396,522 accidental escapes of Atlantic salmon were reported from British Columbia fish farms (ADF&G 2002a). Concerns have been expressed regarding the potential effects of introduced Atlantic salmon on native Pacific salmon populations, including disease and parasites, colonization, interbreeding and hybridization, predation, habitat destruction, and competition, particularly in locations where depressed stocks of Pacific salmon species provide a potential niche for the Atlantic species (Brodeur and Busby 1998, ADF&G 2002a). In the past, Alaska's northern climate, geographic isolation, and small human population, among other factors, may have prevented the establishment of viable populations by non-native species introduced from more temperate regions (Fay 2002).

- **Reasonably Foreseeable Future External Effects.** IPHC longline fishery vessels, international longline and groundfish fleets operating outside the EEZ, and vessels participating in the State of Alaska directed fisheries will continue to be potential sources for exotic species introductions. In addition, commercial shipping, including cruise ships, barges, and tankers with high-volume ballast water releases, will continue to bring non-native species into Alaskan waters on a recurring basis, maintaining a continuing pressure on indigenous populations (Fay 2002). Escapees and releases of farmed Atlantic salmon from Washington and British Columbia net-pens could eventually establish runs in the GOA coastal streams and rivers. Introduced pathogens and parasites associated with farmed Atlantic or Pacific salmon could affect wild stocks. A future regime shift or long-term warming trend may deplete the current protection that colder conditions provide against exotic species, allowing viable non-native populations to become established.

- **Cumulative Effects.** When sources of exotic species external to the domestic groundfish industry are considered in combination with PA.1, it is conceivable that viable populations could become established in the BSAI and/or GOA, producing a conditionally significant adverse cumulative effect on indigenous species (Table 4.5-89). One possible, but unproven, condition for this outcome would be a future climatic regime shift or long-term warming trend that would allow exotic species currently limited by low seawater temperatures to establish viable populations in the BSAI and/or GOA. External sources that could contribute to this potential cumulative effect in the future include fishing vessels participating in the IPHC and State of Alaska commercial fisheries and commercial ships such as tankers and cruise ships, all of which can introduce non-native species through the release of ballast water and hull-fouling organisms (Fay 2002). In addition, Atlantic salmon released or escaped from coastal net-pen farms could establish viable runs throughout coastal areas of Alaska in the future (ADF&G 2002a).

Energy Removal

- **Direct/Indirect Effects.** The direct/indirect effects of PA.1 on energy removal are expected to be insignificant when compared to current baseline conditions. Therefore, estimated energy removals under PA.1 would not have the potential to produce changes in system biomass, respiration, production, or energy cycling outside the range of natural variability (Table 4.9-7).

- **Persistent Past Effects.** The domestic groundfish fisheries, State of Alaska commercial fisheries, IPHC longline fisheries, commercial harvests of marine mammals, and subsistence harvests have all removed biomass from the BSAI and GOA ecosystems, either as targeted species or as bycatch. These removals are regulated and mitigated and continue today (Section 3.10). Aggregate levels of biomass removed by unregulated past human activities may have been influenced by climatic effects on overall system productivity, with biomass removals increasing as productivity increased, and decreasing with climate-related productivity declines.

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fisheries, State of Alaska commercial fisheries, subsistence fish harvests, and subsistence marine mammal harvests will continue to remove biomass from the BSAI and GOA ecosystems in the future. It should be noted that Russian and other fisheries operating in the western Bering Sea and in international waters of the central Bering Sea (donut hole) will also remove biomass in the future, but these regions show sufficient differences from the EBS with respect to production regimes and topographic and hydrographic features that they are viewed as only partly comparable systems. Their interactive components with the EBS, where present, have not yet been characterized (Aydin *et al.* 2002).

- **Cumulative Effects.** The implementation of PA.1 is predicted to have an insignificant cumulative effect on energy removal in the future. The overall biomass removal from internal and external fisheries is not considered sufficient to produce a long-term change in system biomass, respiration, production, or energy cycling outside the range of natural variability (Table 4.5-89).

Energy Redirection

- **Direct/Indirect Effects.** The direct/indirect effects of PA.1 on energy redirection are expected to be insignificant. Predicted effects are minimal relative to the baseline, and fishery discarding and offal production practices under PA.1 would not produce long-term changes in system biomass, respiration, production, or energy cycling outside the range of natural variability (Table 4.9-7).

- **Persistent Past Effects.** Ecosystem energetics is a dynamic process, and it is difficult to know whether past changes in energy cycling and in pathways of energy flow in the BSAI and GOA produced effects that still persist. The most far-reaching changes in quantities and geographic patterns of bycatch discards and offal production from both fish and marine mammal harvests came with international agreements, legislation, and regulatory actions in the 1950s through the 1970s, culminating in passage of the MSA in 1976 (Section 3.10.1.3). These corrective actions greatly curtailed the destabilizing levels of energy redirection that reached their peak in the mid-twentieth century from commercial whaling, fur seal harvests, high-seas driftnet fisheries, and the international commercial groundfish and salmon fisheries. It seems likely, therefore, that under current management practices, quantities and patterns of energy redirection in the BSAI and GOA are much more limited than they were 50 years ago.

- **Reasonably Foreseeable Future External Effects.** Quantities and geographic patterns of bycatch discards and fish processing wastes released into the sea from the IPHC and State of Alaska commercial fisheries and subsistence harvests are not expected to change substantially in the future. External energy will enter the system as graywater and refuse released into the sea from commercial freighters, tankers, and cruise ships. Finally, future climatic trends have the potential to affect energy cycling in the ecosystem; in particular, a warming trend would be expected to accelerate rates of energy conversion, whereas cooler conditions would tend to have a retarding effect.

- **Cumulative Effects.** The implementation of PA.1 is predicted to have an insignificant cumulative effect on energy redirection. The predicted direct/indirect effects under PA.1 in combination with external sources is not expected to depart from the comparative baseline condition sufficiently to produce long-term changes outside the range of natural variability. The discharge of offal from fish processing facilities and of graywater and other refuse from marine vessels into Alaskan waters is regulated through USEPA and ADEC permitting programs, respectively.

<u>Change in Species Diversity</u>

- **Direct/Indirect Effects.** The expected direct/indirect effects of PA.1 on species diversity are rated as unknown for skates, sharks, grenadiers, and other non-managed species and insignificant for other species groups. It is unknown whether bycatch of HAPC biota would result in levels high enough to bring these species to minimum population thresholds, but area closures would likely be sufficient to prevent species removal for these sessile animals. Predicted catch amounts of target species, prohibited species, seabirds, and marine mammals would be insufficient to bring species within these groups below minimum population thresholds.

- **Persistent Past Effects.** Although the pre-MSA international groundfish fisheries, the domestic groundfish fisheries after passage of the MSA in 1976, and the IPHC, State of Alaska, and subsistence fisheries have cumulatively removed large quantities of fish from the BSAI and GOA ecosystems in the past, the timing of various increases and decreases in species abundance of fish, seabirds, and marine mammals has not shown a consistent correlation with groundfish fishing intensity (Sections 3.10.1). With the notable exception of the Steller's sea cow extinction in the 1760s (Section 3.10.1.1), changes in species diversity have not characterized the BSAI and GOA ecosystems. Although no fishing-related species removals have been documented under fisheries management policies in effect during the past 30 years, elasmobranchs (sharks, skates, and rays) are particularly susceptible to removal, and benthic invertebrate species (including HAPC species) are susceptible to impacts from bottom trawling (Section 3.10.3). Seabirds have been particularly vulnerable to bycatch mortality, reducing populations of some seabird species below minimum biologically acceptable limits. Lack of data on seabird population trends prevents analysis of past effects of fisheries management or environmental change on most seabird species (Section 3.7), but commercial fisheries have been implicated for some declines through bycatch. Livingston *et al.* (1999) found that long-term increases and decreases in the abundance of selected BSAI invertebrate, fish, bird, and marine mammal species did not show beneficial correlations with prey abundance, and cyclic fluctuations in species abundance occurred in both fished and unfished species. As emphasized in Section 3.10.1.5, evidence is accumulating that physical oceanographic factors, particularly climate, have a controlling influence on biological community composition in the BSAI and GOA.

- **Reasonably Foreseeable Future External Effects.** Although past levels of seabird bycatch by the IPHC, western Bering Sea, and State of Alaska fisheries have not been thoroughly or consistently quantified, the rates are considered substantial and can be expected to continue in the future (Section 3.7). In addition, subsistence harvests of some marine mammal species (Section 3.8), particularly those with relatively small and geographically distinct subpopulations (e.g, belugas, harbor seals), may deplete numbers to levels near or below biologically acceptable limits in the future. The potential for introduced exotic species to establish viable populations in the BSAI and GOA will also continue. Such exotics may include Atlantic salmon escapes from net-pen farms, invertebrates and plants introduced through ballast water discharge and from ship hulls, and pathogens introduced by Pacific salmon species that have escaped from fish farms (Fay 2002, ADF&G 2002a, Brodeur and Busby 1998). Future climate changes could alter the productivity and distribution of individual species and enable introduced exotic species to establish viable populations.

- **Cumulative Effects.** Under PA.1, a conditionally significant adverse effect on species diversity could result from high levels of seabird bycatch in the IPHC longline fishery, western Bering Sea fisheries, and State of Alaska commercial fisheries, in combination with the BSAI and GOA groundfish fisheries. In addition, one or more introduced exotic species may, at some time in the future, establish viable populations that could alter species diversity by competing with native species for food and habitat (Fay 2002). The consistent, sustained concentration of harvest effort on particularly accessible subpopulations of marine mammals from year to year (e.g., belugas) could intensify this potential effect. Finally, climate change has the potential to alter species productivity and distribution, and a long-term warming trend might facilitate the establishment of viable populations by one or more exotic species. Under some combination of these conditions, the biomass of one or more species could fall below, or be kept from recovering from levels already below, minimum biologically acceptable limits (Table 4.5-89).

Change in Functional (Trophic) Diversity

- **Direct/Indirect Effects.** Under PA.1, the predicted direct/indirect effects of the groundfish fisheries on trophic diversity are rated as insignificant because they are expected to be similar to the comparative baseline conditions, for which fishing effects on trophic diversity are also rated as insignificant.

- **Persistent Past Effects.** It is considered unlikely that past removals of fish by the pre-MSA international groundfish fisheries, the domestic groundfish fisheries after passage of the MSA in 1976, and the IPHC, State of Alaska, and subsistence fisheries significantly affected the variety of species within trophic guilds. Livingston *et al.* (1999) found no evidence that groundfish fisheries had caused declines in trophic guild diversity for the groups studied. They also found that past changes in species diversity within guilds related to increases in a dominant guild member (e.g., pollock, rock sole) rather than to decreases in abundance caused by fishing pressure (Section 3.10.3). Past variations in climate, such as ENSO events, interdecadal oscillations, and regime shifts, may have affected trophic diversity by influencing the productivity and distribution of different species in different ways, thereby altering the relative proportions of species within guilds. However, research on this type of effect in the BSAI and GOA has been minimal.

- **Reasonably Foreseeable Future External Effects.** NOAA Fisheries and ADF&G biologists have recently brought attention to the potential for escaped farmed Atlantic salmon to establish viable Alaskan populations in competition with one or more of the five Pacific salmon species and steelhead trout (Brodeur and Busby 1998, ADF&G 2002a, Fay 2002). In addition, the concentrated take of marine mammals from the same local subpopulations over a period of years could affect species diversity within piscivore guilds, that is, guilds consisting of fish-eating species. Exotic species introduced to BSAI and GOA waters from fishing vessels and commercial shipping could also lead to the establishment of viable populations in competition with native species at similar trophic levels (Fay 2002). A climatic regime shift in the future could affect trophic diversity by expanding some trophic levels and contracting others. In addition, a long-term warming trend could facilitate the establishment of relatively cold-intolerant exotic species populations.

- **Cumulative Effects.** The implementation of PA.1 could produce a conditionally significant adverse effect on trophic diversity. The primary condition for this effect is largely speculative: a climatic regime shift could result in a trophic guild containing one or more groundfish fishery target species becoming more vulnerable to fishing pressure. A regime shift in the future, similar to well-documented examples that have occurred in the past (Sections 3.3 and 3.10.1.5), may affect species diversity within a trophic guild by reducing the productivity or shifting the distributional range of one or more member species. If this climatic effect went undetected and without compensatory adjustments to fishing effort, the continued removal of particular target species, especially slow-growing species such as rockfish, could decrease their representation within trophic guilds (Heifitz *et al.* 2001).

Change in Functional (Structural Habitat) Diversity

- **Direct/Indirect Effects.** The issue of concern with respect to functional diversity is the removal, by bottom gear, of HAPC biota such as corals, sea anemones, and other sessile invertebrates that provide physical structures for habitat by other species, including economically important groundfish species and their prey. Present (comparative baseline) trawl closures to protect Steller sea lion habitat are spread throughout the Aleutian Islands, but these closures are in nearshore waters that may not include all areas of living structural habitat species. Under PA.1, the species composition and biomass levels of removals, bottom gear effort and resulting bycatch amounts of HAPC biota, and areas closed to trawling relative to coral distribution are similar to the baseline. Therefore, the change from baseline conditions that would result from implementation of this FMP is evaluated as insignificant with respect to structural habitat diversity.

- **Persistent Past Effects.** Bottom-trawling by the pre-MSA international groundfish fisheries, groundfish fisheries after passage of the MSA in 1976, and State of Alaska scallop fisheries have all contributed to the damage or depletion of the structural habitat functional guild in past years.

  Because little is known about the taxonomic structure of benthic communities of the BSAI and GOA, any past effects of trawling and other fishing-related activities on the species diversity of these communities cannot be quantified. Long-term climatic trends may also have influenced HAPC species through effects on their productivity and distribution, but in the absence of data no conclusions can be made.

- **Reasonably Foreseeable Future External Effects.** The State of Alaska scallop fishery will employ bottom dredges that will continue to damage or remove structural habitat provided by sessile invertebrates such as corals, sea anemones, and sponges. This effect is not likely to be reduced in the future. In addition, a large oil or fuel spill could affect areas where these sensitive bottom-dwelling organisms live and damage or kill them. A climatic regime shift could change the mean annual seawater temperature sufficiently to increase or retard the growth of benthic organisms, thereby altering structural habitat diversity.

- **Cumulative Effects.** Direct/indirect effects of PA.1, rated insignificant, could contribute to a conditionally significant adverse cumulative effect on structural habitat diversity under any of the following three conditions. First, the additive effect of the scallop fishery, which employs bottom dredges, could add to the direct/indirect effects of bottom trawling by the groundfish fisheries on HAPC biota. Second, a large petroleum spill could also damage these sensitive organisms. Third, a change in seawater temperature resulting from a climatic regime shift in the future could reduce the productivity, and thus the population size, as well as the distribution, of bottom-dwelling invertebrates that provide structural habitat.

Change in Genetic Diversity

- **Direct/Indirect Effects.** Under PA.1, target species are not expected to fall below MSST, and spatial/temporal management of TAC, other catch, and selectivity patterns in the fisheries would be similar to the comparative baseline conditions. Consequently, the direct/indirect effects of the groundfish fisheries on genetic diversity are expected to be insignificant under this FMP. However, baseline genetic diversity remains unknown for many species, and the actual direct/indirect effects that fishing may have on genetic diversity are also largely unknown.

- **Persistent Past Effects.** The pre-MSA international groundfish fisheries, the domestic groundfish fisheries after passage of the MSA in 1976, and the IPHC, State of Alaska, and subsistence fisheries have cumulatively removed large quantities of fish from the BSAI and GOA ecosystems in the past, but data are not available to indicate whether genetic diversity was significantly altered. As discussed in Section 3.10.3, if a fishery concentrates on certain spawning aggregations or on older (larger) age classes of a target species that tend to have greater genetic diversity (i.e., dating from an earlier period when fishing was less intensive), then genetic diversity tends to decline in fished versus unfished systems. It is possible that genetic diversity has already declined in the BSAI and GOA ecosystems, but this cannot be determined in the absence of reliable data. Genetic assessments of North Pacific pollock populations and subpopulations conducted by Bailey *et al.* (1999) have found genetic variations among different stocks, but these studies have not found genetic variability across time within the same stocks that might indicate effects from commercial fishing. Heavy exploitation of certain spawning aggregations existed historically (e.g., Bogoslof pollock), but recent and current spatial/temporal management of groundfish has been designed to reduce fishing pressure on spawning aggregations.

- **Reasonably Foreseeable Future External Effects.** Several external factors have the potential to affect the genetic diversity of the BSAI and GOA ecosystems. Atlantic salmon escapees from coastal net-pen farms in Washington and British Columbia could establish Alaskan runs and viable populations (ADF&G 2002a, Fay 2002). Subsistence harvests of fish could concentrate effort on the same specific subpopulations from year to year, inadvertently but selectively depleting genetically distinct stocks. Similarly, subsistence harvests of some marine mammal species (Section 3.8), particularly those with relatively small and geographically distinct subpopulations (e.g, belugas, harbor seals), may also deplete genetic diversity. The potential for introduced exotic invertebrates to establish viable populations in the BSAI and GOA will unavoidably continue with fishing vessel and commercial shipping traffic in the future. Future climate changes could alter the productivity and distribution of individual species and enable exotic species to establish viable populations.

- **Cumulative Effects.** The implementation of PA.1 is predicted to have an insignificant cumulative effect on genetic diversity. Several external factors, such as Atlantic salmon escapes, subsistence harvests of marine mammals that concentrate on the same subpopulations year after year, exotic species introduced through commercial shipping traffic, and climatic facilitation of viable exotic populations, have the potential to produce changes in the genetic diversity of the BSAI and GOA ecosystems. None of these, however, would affect the genetic diversity of species targeted or taken incidentally by the groundfish fisheries. For this reason, external sources of potential change in genetic diversity would not be additive or interactive with the groundfish fisheries in the reasonably foreseeable future.

Cumulative Effects Analysis PA.2 – Ecosystems

The following section briefly discusses the potential cumulative effects of PA.2 on the ten ecosystem indicators explained in Section 4.5.10. The cumulative effects conclusions are summarized in Table 4.5-89. Data and calculations supporting the energy removal analyses for the alternatives are presented in Table 4.5-81.

<u>Change in Pelagic Forage Availability</u>

- **Direct/Indirect Effects.** The direct/indirect effects of PA.2 on pelagic forage availability are expected to be insignificant. Fishery-induced changes, including bycatch-related effects on forage species, would remain within the natural level of abundance or variability for prey species relative to predator demands (Table 4.9-7).

- **Persistent Past Effects.** Past effects of forage fish bycatch by the BSAI pollock and GOA rockfish domestic fisheries, and targeted domestic catches of pollock and Atka mackerel, are likely to have affected forage fish populations in ways that may persist into the present and future (Section 3.10.1.4). From about 1925 to 1941, Alaska herring harvests for oil and meal ranged from about 50,000 to 150,000 mt per year, and a large foreign herring fishery removed between 30,000 to 150,000 mt per year during the 1960s and 1970s (ADF&G 2003a). Past climatic changes, including inter-decadal oscillations and ENSO events, have been shown to affect forage fish populations (Section 3.10.1.5), and effects may persist.

- **Reasonably Foreseeable Future External Effects.** The State of Alaska manages herring fisheries on a sustainable basis and has established a maximum exploitation rate (fraction of the spawning population removed by the fishery) of 20 percent. Fisheries are closed if stock size falls below MSST. Lower exploitation rates are applied when herring stocks decline to near-threshold levels (ADF&G 2003a). This management approach is expected to continue for the indefinite future. Subsistence harvests will continue to remove an increment of pelagic forage biomass each year. Relative to the BSAI and GOA groundfish fisheries, however, the additional contribution of subsistence fisheries to the annual removal of pelagic forage biomass is likely to be very small. The EVOS suggests that a large oil or fuel spill coinciding in space and time with herring or capelin spawning would most likely produce population declines, and other pelagic forage species (such as eulachon, which spawn on beaches) might also be adversely affected. Finally, future climate change, especially a regime shift, would likely affect the productivity, and thereby the population size, of pelagic forage species (Section 3.10.1.5).

- **Cumulative Effects.** A conditionally significant adverse cumulative effect on pelagic forage availability could occur in the event of a large petroleum spill. The conditions under which this effect could be significant relate to the areas affected by, and seasonal timing of, the spill. If these conditions coincide with spawning locations and times, a significantly adverse effect on pelagic forage availability would most likely result. A future climatic regime shift would not appreciably offset, but could intensify, this potential cumulative effect if the productivity of pelagic forage species is reduced.

Spatial and Temporal Concentration of Fishery Impact on Forage

- **Direct/Indirect Effects.** PA.2 would continue the existing closures around Steller sea lion rookeries, with the possibility of designating critical habitat areas based on scientific information. In addition, modified Steller sea lion closures in the Aleutian Islands are also proposed. The existing ban on forage fish and spatial/temporal allocation of TAC for some BSAI and GOA species would continue. These measures would not produce a significant change in the spatial/temporal availability of forage to seabirds, but they would be notable improvements over the baseline for top-predator fish and marine mammals. Maintaining current closed/restricted areas, with the potential for some of these areas to qualify as MPAs, could provide increased protection to northern fur seal foraging habitat from potential fishing effects. PA.2 proposes the prohibition on Pollock bottom trawl in the GOA as well as the existing ban in the BSAI. For these reasons, PA.2 is predicted to have a conditionally significant beneficial effect on the spatial/temporal availability of forage, particularly for some marine mammals, but insignificant effects on forage availability to seabirds.

- **Persistent Past Effects.** Geographic and seasonal concentrations of past forage fish bycatch from the BSAI pollock and GOA rockfish fisheries, herring bycatch, and targeted catches of pollock and Atka mackerel have affected forage fish populations in ways that may persist presently and into the future (Section 3.10.1.4). Past herring fisheries have followed a stable pattern of timing and location dictated by the spawning behavior of the fish (ADF&G 2003a). Past climatic changes, including inter-decadal oscillations and ENSO events, have been correlated with changes in recruitment rates and distribution patterns of forage fish populations (Section 3.10.1.5). Such effects may persist on forage fish populations, although evidence is not sufficient to allow quantification.

- **Reasonably Foreseeable Future External Effects.** The State of Alaska directed herring fishery will exert fishing pressures on herring and other forage fish populations at particular times and locations that could overlap with fishing pressures from the groundfish fisheries. Because the herring fishery is mainly inshore, overlap with the groundfish fishery is more likely to be temporal than spatial. Subsistence harvest patterns are not coordinated with commercial fishing effort and will sometimes overlap with spatial and temporal patterns of the groundfish fishery, but the incremental contribution of subsistence to this cumulative effect will continue to be negligible. The EVOS of 1989 suggests that a large oil or fuel spill coinciding in space and time with herring or capelin spawning would most likely produce population declines and adversely affect other pelagic forage species (such as eulachon, which spawn on beaches). Finally, future climate change, especially a regime shift, could alter the spatial and temporal distributions of pelagic forage species in ways that are synergistic with spatial and temporal concentrations of fishing effort in the BSAI and GOA groundfish fisheries.

- **Cumulative Effects.** A conditionally significant adverse cumulative effect on pelagic forage availability could result in the future through synergistic interactions between spatial and temporal concentrations of the BSAI and/or GOA groundfish fishing effort. The conditions under which this effect could be significant relate to location and timing. If the fishing efforts of State of Alaska directed fisheries (primarily herring fisheries) and subsistence fish harvests converge in space and time with a fuel or oil spill, forage fish populations could be significantly depressed, thereby impairing the long-term viability of ecologically important top predators such as seabirds and marine mammals (Table 4.5-89). Future climate change, consistent with effects observed in the recent past (Section 3.10.1.5), could alter the spatial and temporal distributions of pelagic forage species in ways that might reduce or intensify this potential cumulative effects.

<u>Removal of Top Predators</u>

- **Direct/Indirect Effects.** The implementation of PA.2 is predicted to have insignificant direct/indirect effects on top predators such as whales, other marine mammals, seabirds, and top predatory fish species such as Greenland turbot, arrowtooth flounder, sablefish, Pacific cod, and Pacific halibut. This FMP would not impair the continued recovery of whale populations still reduced through direct take in the past. Predicted levels of seabird and marine mammal bycatch in the groundfish fisheries would not lead to listing of these species or prevent recovery of currently listed species under the ESA. Because there is little available information on shark bycatch, the effect of this FMP on shark populations is unknown.

- **Persistent Past Effects.** Before passage of the MSA in 1976, groundfish fisheries in the BSAI and GOA produced much higher than present bycatch levels of shark, seabirds, and marine mammals. Historical whaling, resulting in high mortality levels in the 1960s (Section 3.10.1.3), produced a sustained effect on these slowly reproducing populations that is reflected in the currently depressed abundance of whale species in the North Pacific Ocean. State of Alaska directed groundfish fisheries have annually removed top predators such as sablefish and Pacific cod at levels safely above MSST (ADF&G 2003b). These fisheries also produced shark, seabird, and marine mammal bycatch in the past, although quantitative data are lacking on past and current bycatch levels in these fisheries. Past and present groundfish fisheries operating outside of U.S. jurisdiction in the western Bering Sea have also contributed to the bycatch of top predators, in some cases at high levels (Sections 3.7.1 and 3.10.1). Marine mammals continue to be removed for subsistence, although at much lower levels than those observed in the past. These past harvests may have persistent effects on some populations today. Finally, there is evidence that past climatic variability may have affected the recruitment and distribution of some top predator fish species (Section 3.10.1.5; Hollowed *et al.* 1998).

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fishery will continue to remove sustainable numbers of Pacific halibut, a top predator. The current management plan is likely to continue in the future, although a modified approach has been proposed to produce a yield similar to the present policy while reducing variations in annual yield due to changes in stock abundance, assessment methods, and estimated removals by other fisheries (Clark and Hare 2003). Seabird bycatch and resulting direct mortality are expected to continue annually in North Pacific Ocean longline fisheries operating outside of the EEZ. Available data and estimates for the annual incidental take of individual bird species by these external fisheries are provided and discussed in Sections 3.7.1-3.7.19. The State of Alaska directed groundfish fisheries, operating in state waters of the eastern GOA and southeast Alaska, Cook Inlet, PWS, Kodiak, and the Alaska Peninsula, and in all state waters for lingcod, sablefish, and Pacific cod, will continue to remove targeted top predatory fish species in small numbers relative to the domestic groundfish fisheries in federal waters (ADF&G 2003b). Subsistence harvests of marine mammals will continue in the future, with an increasing trend toward co-management by NOAA Fisheries and Alaska Native organizations. The Protected Resources Division of NOAA Fisheries will continue to develop management and conservation programs to ensure that annual subsistence harvests are sustainable (NOAA Fisheries 2003). A large fuel or oil spill at sea may result in direct mortality of marine mammals, with mortality levels depending on the location, size, and timing of the spill. Finally, a future climatic regime shift could alter total numbers of top predators in the BSAI and GOA ecosystems by increasing or limiting recruitment.

- **Cumulative Effects.** A conditionally significant adverse cumulative effect on populations of top predators could result primarily from the contribution of continued seabird bycatch by North Pacific Ocean longline fisheries operating outside the EEZ. The conditions under which this potential cumulative effect could become significant include continued bycatch of seabirds in conjunction with a large fuel or oil spill and incremental removals of top predators by the IPHC longline fishery, State of Alaska directed groundfish fisheries, and subsistence harvests of marine mammals. As determined from recent climatic studies (Section 3.3), a climatic regime shift is probable in the future, and this could intensify or reduce this potential cumulative effect by influencing recruitment.

<u>Introduction of Non-Native Species</u>

- **Direct/Indirect Effects.** Under PA.2, the predicted catch levels indicate that this FMP would have the same potential for fishing-vessel introduction of non-native species through ballast water exchange or release of hull-fouling organisms that currently exists under baseline conditions. Therefore, the effect of PA.2 on predator-prey relationships through the introduction of exotic species is evaluated as insignificant.

- **Persistent Past Effects.** For decades, the annual arrival of groundfish fishing vessels from ports outside of Alaska has made it possible for non-native species to enter Alaskan waters through the release of ballast water and hull-fouling organisms. Commercial shipping has provided a similar means for the introduction of non-native species (Fay 2002). There have been 24 non-indigenous species of plants and animals documented in Alaskan marine waters, with 15 of these recorded in PWS, where most of the research has been conducted. Although oil tankers, through the release of ballast water, have been speculated to be the primary source for these introductions, cruise ships and fishing vessels coming from areas where invasive species have already been established have also been identified as a threat in the State of Alaska Aquatic Nuisance Species Management Plan (Fay 2002). From 1991 to 2001, 396,522 accidental escapes of Atlantic salmon were reported from British Columbia fish farms (ADF&G 2002a). Concerns have been expressed regarding the potential effects of introduced Atlantic salmon on native Pacific salmon populations, including disease and parasites, colonization, interbreeding and hybridization, predation, habitat destruction, and competition, particularly in locations where depressed stocks of Pacific salmon species provide a potential niche for the Atlantic species (Brodeur and Busby 1998, ADF&G 2002a). In the past, Alaska's northern climate, geographic isolation, and small human population, among other factors, may have prevented the establishment of viable populations by non-native species introduced from more temperate regions (Fay 2002).

- **Reasonably Foreseeable Future External Effects.** IPHC longline fishery vessels, international longline and groundfish fleets operating outside the EEZ, and vessels participating in State of Alaska directed fisheries will continue to act as potential sources for exotic species introductions. In addition, commercial shipping, including cruise ships, barges, and tankers with high-volume ballast water releases, will continue to bring non-native species into Alaskan waters on a recurring basis, maintaining a continuing pressure on indigenous populations (Fay 2002). Escapees and releases of farmed Atlantic salmon from Washington and British Columbia net-pens could eventually establish runs in the GOA coastal streams and rivers. Introduced pathogens and parasites associated with farmed Atlantic or Pacific salmon could affect wild stocks. A future regime shift or long-term warming trend may deplete the current protection that colder conditions may provide against exotic species, allowing viable non-native populations to become established.

- **Cumulative Effects.** When sources of exotic species external to the domestic groundfish industry are considered in combination with PA.2, it is conceivable that viable exotic populations could eventually become established in the BSAI and/or GOA, producing a conditionally significant adverse effect on indigenous species (Table 4.5-89). One possible, but unproven, condition for this outcome would be a future climatic regime shift or long-term warming trend that enables exotic species, currently limited by low seawater temperatures, to establish viable populations in the BSAI and/or GOA. External sources that could contribute to this potential cumulative effect in the future include fishing vessels participating in the IPHC and State of Alaska commercial fisheries, and commercial ships such as tankers and cruise ships, all of which can introduce non-native species through the discharge of ballast water and release of hull-fouling organisms (Fay 2002). In addition, Atlantic salmon released or escaped from coastal net-pen farms could establish viable runs in coastal areas of southeast Alaska in the future (ADF&G 2002a).

Energy Removal

- **Direct/Indirect Effects.** The direct/indirect effects of PA.2 on energy removal are expected to be insignificant. Baseline energy removals, in the form of total catch, are less than one percent of the total ecosystem energy, as estimated by mass-balance modeling, and were determined to have an insignificant impact on the ecosystem baseline. Estimated energy removals under PA.2 would not exhibit potential for producing significant changes to system biomass, respiration, production, or energy cycling outside the range of natural variability (Table 4.9-7).

- **Persistent Past Effects.** The domestic groundfish fisheries, State of Alaska commercial fisheries, IPHC longline fisheries, commercial harvests of marine mammals, and subsistence harvests have all removed biomass from the BSAI and GOA ecosystems, either as targeted species or as bycatch. These removals are regulated and mitigated and continue today (Section 3.10). Aggregate levels of biomass removed by unregulated past human activities may have been influenced by climatic effects on overall system productivity, with biomass removals increasing as productivity increased and decreasing with climate-related productivity declines.

- **Reasonably Foreseeable Future External Effects.** The IPHC longline fisheries, State of Alaska commercial fisheries, subsistence fish harvests, and subsistence marine mammal harvests will continue to remove biomass from the BSAI and GOA ecosystems in the future. It should be noted that Russian and other fisheries operating in the western Bering Sea and in international waters of the central Bering Sea (donut hole) will also remove biomass in the future, but these regions show sufficient differences from the EBS with respect to production regimes and topographic and hydrographic features that they are viewed as only partly comparable systems. Their interactive components with the EBS, where present, have not yet been characterized (Aydin *et al.* 2002).

- **Cumulative Effects.** The implementation of PA.2 is predicted to have an insignificant cumulative effect on energy removal in the future. The cumulative biomass removal from internal and external fisheries under this FMP is not considered sufficient to produce a long-term change in system biomass, respiration, production, or energy cycling outside the range of natural variability (Table 4.5-89).

Energy Redirection

- **Direct/Indirect Effects.** The direct/indirect effects of PA.2 on energy redirection are expected to be insignificant. Predicted effects are minimal relative to the baseline and would not produce long-term changes in system biomass, respiration, production, or energy cycling outside the range of natural variability due to fishery discarding and offal production practices (Table 4.9-7).

- **Persistent Past Effects.** Ecosystem energetics is a dynamic process, and it is difficult to know whether past changes in energy cycling and pathways of energy flow in the BSAI and GOA produced effects that still persist. The most far-reaching changes in quantities and geographic patterns of bycatch discards and offal production from both fish and marine mammal harvests came with international agreements, legislation, and regulatory actions in the 1950s through the 1970s, culminating in passage of the MSA in 1976 (Section 3.10.1.3). These corrective actions greatly curtailed the destabilizing levels of energy redirection that reached their peak in the mid-twentieth century from commercial whaling, fur seal harvests, high-seas driftnet fisheries, and the international commercial groundfish and salmon fisheries. It seems likely, therefore, that under current management practices, quantities and patterns of energy redirection in the BSAI and GOA are much more limited than they were 50 years ago.

- **Reasonably Foreseeable Future External Effects.** Quantities and geographic patterns of bycatch discards and fish processing wastes released into the sea from the IPHC and State of Alaska commercial fisheries and subsistence harvests are not expected to change substantially in the future. External energy will enter the system as graywater and refuse released into the sea from commercial freighters, tankers, and cruise ships. Finally, future climatic trends have the potential to affect energy cycling in the ecosystem; in particular, a warming trend would be expected to accelerate rates of energy conversion, whereas cooler conditions would tend to have a retarding effect.

- **Cumulative Effects.** The implementation of PA.2 is predicted to have an insignificant cumulative effect on energy redirection. Even with the decreases in discards predicted (Table 4.5-81), the cumulative effect of PA.2 in combination with external sources is not expected to depart from the comparative baseline condition enough to produce long-term changes outside the range of natural variability. The discharge of offal from fish processing facilities and of graywater and other refuse from marine vessels into Alaskan waters is regulated through USEPA and ADEC permitting programs, respectively.

Change in Species Diversity

- **Direct/Indirect Effects.** The expected direct/indirect effects of PA.2 on species diversity are rated as unknown for skates, sharks, grenadiers, and other non-managed species, and insignificant for other species groups. This FMP would also provide substantial increases in closed areas such as no-trawling MPAs and no-take reserves across a range of habitat types, review of all existing closures for qualification as MPAs, establishment of an Aleutian Islands management area to protect coral and other living habitat species, and modification of 2002 Steller sea lion protection measures with designation of critical habitat according to scientific data and assessment information. These closures may result in further reductions in HAPC biota bycatch. The adoption and use of key ecosystem indicators for modifying TAC-setting processes may also provide further protection to sensitive groups such as these until more is learned about their life histories. Catch amounts of target species, prohibited species, seabirds, and marine mammals would be insufficient to bring species within these groups below minimum population thresholds. Although forage species population levels are not known, their relatively high turnover rates and the ban on forage fish fisheries under this FMP are considered sufficient to protect them from falling below minimum biologically acceptable limits.

- **Persistent Past Effects.** Although the pre-MSA international groundfish fisheries, the domestic groundfish fisheries after passage of the MSA in 1976, and the IPHC, State of Alaska, and subsistence fisheries have cumulatively removed large quantities of fish from the BSAI and GOA ecosystems in the past, the timing of various increases and decreases in species abundance of fish, seabirds, and marine mammals has not shown a consistent correlation with groundfish fishing intensity (Sections 3.10.1). With the notable exception of the Steller's sea cow extinction in the 1760s (Section 3.10.1.1), changes in species diversity have not characterized the BSAI and GOA ecosystems. Although no fishing-related species removals have been documented under fisheries management policies in effect during the past 30 years, elasmobranchs (sharks, skates, and rays) are particularly susceptible to removal, and benthic invertebrate species (including HAPC species) are susceptible to impacts from bottom trawling (Section 3.10.3). Seabirds have been particularly vulnerable to bycatch mortality, leading to reduced populations of some bird species below minimum biologically acceptable limits. Lack of data on seabird population trends prevents analysis of past effects of fisheries management or environmental change on most seabird species (Section 3.7), but commercial fisheries have been implicated for some declines through bycatch potential. Livingston *et al.* (1999) found that long-term increases and decreases in the abundance of selected BSAI invertebrate, fish, bird, and marine mammal species did not show beneficial correlations with prey abundance, and cyclic fluctuations in species abundance occurred in both fished and unfished species. As emphasized in Section 3.10.1.5, evidence is accumulating that physical oceanographic factors, particularly climate, have a controlling influence on biological community composition in the BSAI and GOA.

- **Reasonably Foreseeable Future External Effects.** Although past levels of seabird bycatch by the IPHC, western Bering Sea, and State of Alaska fisheries have not been thoroughly or consistently quantified, the rates are considered substantial and can be expected to continue in the future (Section 3.7). In addition, subsistence harvests of some marine mammal species (Section 3.8), particularly those with relatively small and geographically distinct subpopulations (e.g, belugas, harbor seals), may deplete numbers to levels near or below biologically acceptable limits in the future. The potential for introduced exotic species to establish viable populations in the BSAI and GOA will also continue. Such exotics may include Atlantic salmon escapees from net-pen farms, invertebrates and plants introduced through ballast water and from ship hulls, and pathogens introduced by Pacific salmon species that have escaped from fish farms (Fay 2002, ADF&G 2002a, Brodeur and Busby 1998). Future climate changes could alter the productivity and distribution of individual species and enable introduced exotic species to establish viable populations.

- **Cumulative Effects.** Under PA.2, a conditionally significant adverse effect on species diversity could result from continued seabird bycatch in the IPHC longline fishery, western Bering Sea fisheries, and State of Alaska commercial fisheries, in combination with the BSAI and GOA groundfish fisheries. In addition, introduced exotic species may establish viable populations that could alter species diversity by competing with native species for food and habitat (Fay 2002). The consistent, sustained concentration of subsistence harvest effort on particularly accessible subpopulations of marine mammals from year to year could intensify this potential effect. Finally, climate change has the potential to alter species productivity and distribution, and a long-term warming trend might facilitate successful establishment of viable populations of exotic species.

Change in Functional (Trophic) Diversity

- **Direct/Indirect Effects.** Potential effects on trophic diversity relate to changes in the variety of species within trophic guilds. Under PA.2, the predicted direct/indirect effects of the groundfish fisheries on trophic diversity are rated as insignificant. Expected results are similar to the comparative baseline condition, for which fishing effects on trophic diversity are also rated as insignificant.

- **Persistent Past Effects.** It is considered unlikely that past removals of fish by the pre-MSA international groundfish fisheries, the domestic groundfish fisheries after passage of the MSA in 1976, and the IPHC, State of Alaska, and subsistence fisheries significantly altered the variety of species within trophic guilds. Livingston *et al.* (1999) found no evidence that groundfish fisheries had caused declines in trophic guild diversity for the groups studied. They also found that past changes in species diversity within guilds related to increases in a dominant guild member (e.g., pollock, rock sole) rather than to decreases in abundance caused by fishing pressure (Section 3.10.3). Past variations in climate, such as ENSO events, interdecadal oscillations, and regime shifts, may have affected trophic diversity by influencing the productivity and distribution of different species in different ways, thereby altering the relative proportions of species within guilds. However, minimal research on this type of effect has been conducted for the BSAI and GOA.

- **Reasonably Foreseeable Future External Effects.** NOAA Fisheries and ADF&G biologists have recently brought attention to the potential for escaped farmed Atlantic salmon to establish viable Alaskan populations in competition with one or more of the five Pacific salmon species and steelhead trout (Brodeur and Busby 1998, ADF&G 2002a, Fay 2002). In addition, the concentrated take of marine mammals from the same local subpopulations over a period of years could affect species diversity within piscivore guilds, that is, guilds consisting of fish-eating species. Exotic species introduced to BSAI and GOA waters from fishing vessels and commercial shipping could lead to the establishment of viable populations in competition with native species at similar trophic levels (Fay 2002). A climatic regime shift in the future could affect trophic diversity by expanding some trophic levels and contracting others. In addition, a long-term warming trend could facilitate the establishment of relatively cold-intolerant exotic species populations.

- **Cumulative Effects.** The implementation of PA.2 could result in a conditionally significant adverse effect on trophic diversity. The primary condition for this potential effect is largely speculative—a climatic regime shift could make a trophic guild containing one or more groundfish fishery target species more vulnerable to fishing pressure. A regime shift in the future, similar to well-documented examples that have occurred in the past (Sections 3.3 and 3.10.1.5), could also decrease species diversity within a trophic guild by reducing the productivity or shifting the distributional range of one or more member species. If this climatic effect went undetected and without compensatory adjustments to fishing effort, the continued removal of particular target species, especially slow-growing species such as the rockfish, could decrease their representation within trophic guilds (Heifitz *et al.* 2001).

Change in Functional (Structural Habitat) Diversity

- **Direct/Indirect Effects.** The issue of concern with respect to structural habitat diversity is the removal of HAPC biota such as corals, sea anemones, and other sessile invertebrates that provide physical structures used as habitat by other species, including economically important groundfish species and their prey. Some of the area closures proposed under PA.2 have been developed with corals and other living habitat species in mind. If implemented, these measures could improve protection of HAPC biota throughout their broad spatial distribution, particularly in the Aleutian Islands. With respect to structural habitat diversity, PA.2 is thought to provide significantly beneficial effects relative to the baseline.

- **Persistent Past Effects.** Bottom-trawling by the pre-MSA international groundfish fisheries, groundfish fisheries after passage of the MSA in 1976, and State of Alaska scallop fisheries have all contributed to the damage or depletion of the structural habitat functional guild in past years. Because little is known about the taxonomic structure of benthic communities of the BSAI and GOA, any past effects of trawling and other fishing-related activities on the species diversity of these communities cannot be quantified. Long-term climatic trends may also have influenced HAPC species through effects on their productivity and distribution, but in the absence of data no conclusions can be made.

- **Reasonably Foreseeable Future External Effects.** The State of Alaska scallop fishery will employ bottom dredges that will continue to damage or remove structural habitat provided by sessile invertebrates such as corals, sea anemones, and sponges. This effect is not likely to be reduced in the future. In addition, a large oil or fuel spill could affect areas where these sensitive bottom-dwelling organisms live and damage or kill them. A climatic regime shift could change the mean annual seawater temperature sufficiently to increase or retard the growth of benthic organisms, thereby altering structural habitat diversity.

- **Cumulative Effects.** Direct/indirect effects of PA.2, rated significantly beneficial, could contribute to a conditionally significant beneficial cumulative effect on structural habitat diversity. This rating is conditional because the direct/indirect effect of PA.2 could be offset under any of the following three conditions. First, the additive effect of the scallop fishery, which employs bottom dredges, could counteract, to an unknown extent, the potential benefits of PA.2 on HAPC biota. Second, a large petroleum spill could also damage or destroy these sensitive organisms. Third, a change in seawater temperature resulting from a future climatic regime shift could reduce the productivity, population size, and distribution of bottom-dwelling invertebrates that provide structural habitat.

Change in Genetic Diversity

- **Direct/Indirect Effects.** Under PA.2, target species are not expected to fall below MSST, and spatial/temporal management of TAC, other catch, and selectivity patterns in the fisheries would be similar to the comparative baseline conditions. Consequently, the direct/indirect effects of the groundfish fisheries on genetic diversity are expected to be insignificant under PA.2. However, baseline genetic diversity remains unknown for many species, and the actual effects that fishing may exert on genetic diversity are also largely unknown.

- **Persistent Past Effects.** The pre-MSA international groundfish fisheries, the domestic groundfish fisheries after passage of the MSA in 1976, and the IPHC, State of Alaska, and subsistence fisheries have cumulatively removed large quantities of fish from the BSAI and GOA ecosystems in the past, but data are not available to indicate whether genetic diversity was significantly altered. As discussed in Section 3.10.3, if a fishery concentrates on certain spawning aggregations or on older (larger) age classes of a target species that tend to have greater genetic diversity (dating from an earlier period when fishing was less intensive), then genetic diversity tends to decline in fished versus unfished systems. It is possible that genetic diversity has already declined in the BSAI and GOA ecosystems, but this cannot be determined in the absence of reliable data. Genetic assessments of North Pacific pollock populations and subpopulations conducted by Bailey *et al.* (1999) have found genetic variations among different stocks, but these studies have not found genetic variability across time within the same stocks that might indicate effects from commercial fishing. Heavy exploitation of certain spawning aggregations existed historically (e.g., Bogoslof pollock), but recent and current spatial/temporal management of groundfish has been designed to reduce fishing pressure on spawning aggregations.

- **Reasonably Foreseeable Future External Effects.** Several external factors have the potential to affect the genetic diversity of the BSAI and GOA ecosystems. Atlantic salmon escapes from coastal net-pen farms in Washington State and British Columbia could establish Alaskan runs and viable populations (ADF&G 2002a, Fay 2002). Subsistence harvests of fish could concentrate effort on the same specific subpopulations from year to year, inadvertently but selectively depleting genetically distinct stocks. Similarly, subsistence harvests of some marine mammal species (Section 3.8), particularly those with relatively small and geographically distinct subpopulations (e.g, belugas, harbor seals), may also deplete genetic diversity. The potential for introduced exotic invertebrates to establish viable populations in the BSAI and GOA will unavoidably continue with fishing vessel and commercial shipping traffic in the future. Future climate changes could alter the productivity and distribution of individual species and enable exotic species to establish viable populations.

- **Cumulative Effects.** The potential cumulative effect of PA.2 on genetic diversity is predicted to be insignificant. Several external factors, such as Atlantic salmon escapes, subsistence harvests of marine mammals that concentrate on the same subpopulations year after year, introduction of exotic species through commercial shipping traffic, and climatic facilitation of viable exotic populations have the potential to produce changes in the genetic diversity of the BSAI and GOA ecosystems. None of these, however, would affect the genetic diversity of species targeted or taken incidentally by the groundfish fisheries. For this reason, external sources of potential change in genetic diversity would not be additive or interactive with the groundfish fisheries in the reasonably foreseeable future.

4.10 Analysis of Alternatives at the Policy Level

As presented in Chapter 2 of this document, there are four policy-level alternatives and a preferred alternative (PA) analyzed in this Programmatic SEIS. Alternative 1 represents the status quo and consists of the explicit policy statements included in the current BSAI and GOA FMPs and the refined management policy embodied in the NPFMC actions and FMP amendments taken since the FMP policy statements were developed. Three alternatives to the status quo are also considered, and a PA has been identified.

In this section, we analyze the impacts on the human environment of the management policy approaches, goals, and objectives of each alternative.

4.10.1 Summary of Framework Analyses

In order to assist in the analysis of the policy alternatives, a two-dimensional analytical framework has been developed that defines a range of implementing management measures for each alternative. This framework consists of a set of FMP components (i.e., TAC-setting Process, Bycatch and Incidental Catch Restrictions, etc.) and a set of example FMPs that include management measures addressing each FMP component. Each alternative, except for Alternative 1, contains a pair of example FMP "bookends" that illustrate and frame the range of that alternative's management measures (see Section 4.2 for further details). Alternative 1, representing status quo, contains just one FMP: the existing management regime in place for the BSAI and GOA, including NPFMC-approved (but not necessarily implemented in regulation yet) measures through June 2002. The intention is that the FMP framework structure will represent a range of management measures that address each FMP component and that are representative of the management measures likely to be implemented under a chosen alternative.

Each of the two dimensions of the framework (the FMP components and the example FMPs) has been analyzed, either qualitatively or quantitatively. Section 4.3 provides a summary of the qualitative analysis papers written for each FMP component. Each paper provides background on the choice of management measures used to address that FMP component and describes the range of management measures that are implemented under each alternative. Additionally, the papers provide a preliminary assessment of the potential impacts of implementing the management measures in a static environment; cumulative impacts between FMP components are not analyzed in these papers. (For the full text of the papers, see Appendix F.)

Sections 4.5 through 4.9 examine the example FMPs in their entirety. The cumulative impacts of implementing all the management measures in an example FMP are analyzed and discussed for each alternative. These analyses incorporate results from the multi-species model developed for this Programmatic SEIS (see Section 4.1.5) as well as other relevant data.

Included in the sections that follow is a summary of relevant conclusions from the framework analyses as they relate to the overall management policy approaches, goals, and objectives of each alternative.

4.10.1.1 FMP Components – Qualitative Analysis

As stated above, Section 4.3 presents a summary of the FMP component qualitative analysis assessment papers, the full text of which can be found in Appendix F. For the purposes of the detailed framework-level analysis of the alternatives, the implications of certain aspects of the framework, particularly those that initiate or define a process rather than implement an action (e.g., development of criteria to set TAC in space and time as opposed to actually setting the TAC), are exclusively dealt with in the qualitative analysis papers. Table 4.10-1 lists those elements of the analytical framework that are dealt with in the qualitative analysis papers but not included in the example FMP analyses.

4.10.1.2 Example FMPs

The example FMPs were each analyzed against a baseline condition, referred to as the comparative baseline, which is described in Chapter 3 and summarized in Section 4.4. A detailed summary of the example FMP analysis for each alternative can be found in the various summary sections, Section 4.5.11 for Alternative 1, Section 4.6.11 for Alternative 2, Section 4.7.11 for Alternative 3, Section 4.8.11 for Alternative 4, and Tables 4.9-1 through 4.9-7 for the PA. A more global summary of the example FMP analysis is found in Tables 4.10-2a and 4.10-2b. For each of the major resource categories that are analyzed in Sections 4.5 to 4.9, the table contains a series of summary statements comparing impacts across the alternatives.

4.10.2 Analysis of Alternative 1

Alternative 1 consists of two policy statements. The first contains the policy statements explicitly stated within the BSAI FMP, dating from 1981, and the GOA FMP, dating from 1979 and as amended in 1985 (identified as Alternative 1(a) in Chapter 2). Although the specific policy language differs between the GOA and BSAI FMPs, the intent in terms of a management policy is very similar. The second is an updated policy (identified as Alternative 1(b) in Chapter 2) that represents the current management policy of the NPFMC and NOAA Fisheries whether as explicitly stated within the FMPs or as evidenced by the management measures that have been adopted by the NPFMC and NOAA Fisheries since the policy statements were included in the FMPs.

Alternative 1(a)

The 1979 BSAI policy statement consists of a set of broad goals that are supported by a number of secondary objectives. The essential management policy for the BSAI is to promote conservation while providing for the optimum yield of the region's groundfish resource. The following additional guidelines are given:

- Conservation and management measures have taken into account the unpredictable characteristics of future resource availability and socioeconomic factors influencing the viability of the industry.

- These goals are intended to meet the requirements of the NPFMC constituency, the resources, and Fishery Conservation Management Act (the original Magnuson-Stevens Fishery Conservation and Management Act).

The 1985 GOA policy statement consists of a set of goals including a principal management goal and a number of objectives. The fundamental management policy for the GOA is to manage the groundfish resources of the GOA to maximize positive economic benefits to the United States, consistent with resource stewardship responsibilities. Fishery management is also required to conform to the National Standards and to the NPFMC Comprehensive Fishery Management Goals.

The existing FMP policy statements date from a period of North Pacific groundfish management history when the principal goal was to develop domestic groundfish fisheries in order to fully utilize the groundfish resources. The FMPs were trying to encourage domestic groundfish exploitation, and therefore the focus of the management policy was to facilitate economic benefit in order to provide incentives to expand the domestic fleet. The environmental issues of bycatch, seabird and marine mammal interaction, habitat degradation, and ecosystem interactions were generally captured under the objective to avoid irreversible or long-term adverse impact to the environment. These problems were not as pressing at the time the existing policy statements were written, due to the smaller size of the domestic fleet, as well as the comparative lack of information on the impact of the fisheries, which twenty years of fishery monitoring data has altered.

Alternative 1(b)

Since the FMP policy statements were adopted, the NPFMC and NOAA Fisheries have implemented management measures that indicate changes in the management policy. The policy statements themselves have not been updated to reflect these changes. In order to incorporate these modifications into this programmatic analysis, an updated policy statement for Alternative 1 (Alternative 1(b)) has been developed. This updated policy statement represents the current policies of the NPFMC and NOAA Fisheries whether as explicitly stated within the FMPs or as evidenced by the management measures that have been adopted.

The updated management approach statement underscores the policy objective that fishery impacts to the environment are mitigated as scientific evidence indicates that the fishery is adversely impacting the ecosystem. The management approach statement is summarized in Table 4.10-3. This policy is based on the assumption that fishing does produce some adverse impact on the environment and, that as these impacts become known, mitigation measures are developed and FMP amendments are implemented.

The updated management approach statement recognizes that the NPFMC management process:

- Is adaptive to new information and reactive to new environmental issues.
- Works towards goals through existing institutions and processes.
- Uses National Standards and other applicable law as its guide in practicing adaptive management, responsible decision-making to consistently amend FMPs accordingly.
- Addresses issues as they are identified through NPFMC staff tasking and research priorities.

The updated management approach statement is fully consistent with the FMP policy statements and the NPFMC and NOAA Fisheries implementation of those policies since they were adopted. The updated policy statement also facilitates a comparison of Alternative 1 to the other alternatives.

Because the current wording of the policy statements in the FMPs differs from the actual implementation of those policies by the NPFMC and NOAA Fisheries, a distinction between Alternative 1(a) and Alternative 1(b) is necessary in order to accurately describe the status quo. If the NPFMC identifies Alternative 1 as its preferred alternative, it will also have to choose whether or not to continue using the current FMP policy statements (Alternative 1(a)) or to amend the FMPs to incorporate the updated policy statements (Alternative 1(b)). However, for analytical purposes, no distinction is necessary because the updated policy statements contained in Alternative 1(b) represent the NPFMC and NOAA Fisheries' interpretation of the policy statements contained in the FMPs. Therefore, the policy-level analysis of Alternative 1 will be representative of both Alternatives 1(a) and 1(b).

A summary of the impacts of Alternative 1 follows below in Section 4.10.2.1. In the remainder of Section 4.10.2, the impacts of the alternative are analyzed in relation to eight policy subheadings: prevent overfishing; preserve food web; reduce and avoid bycatch; avoid impacts to seabirds and marine mammals; reduce and avoid impacts to habitat; allocation issues; increase Alaska Native consultation; and data quality, monitoring, and enforcement. For each subheading, the impacts of the relevant goals and objectives from the management approach are analyzed using the range of implementing management measures for Alternative 1 as a guideline. These guidelines are identified in Section 4.2 and analyzed in Section 4.5.

4.10.2.1 Summary of Alternative 1

The key policy elements that predominantly influence the impacts under Alternative 1 are: the current harvest strategy that incorporates automatic stock rebuilding (ensuring the sustainability of target stocks); incidental catch and bycatch controls; the existing system of closure areas (to protect a variety of species from groundfish fishery interactions); the objective to reduce the adverse effects of the race-for-fish (resulting in gradual implementation of rationalization); and reporting and monitoring requirements (increasing the accuracy of catch accounting).

Alternative 1 is successful at preventing overfishing of target stocks and thus meeting the goal of ensuring the sustainability of the fisheries. Alternative 1 also includes automatic stock rebuilding provisions which have proven to be effective. A weakness of this alternative is that there is no incentive to research fishery impacts on Tier 4-6 stocks in order to change their management status. It is also possible under this alternative to overharvest a vulnerable member of a stock complex.

This alternative is partially successful in achieving the goal of preserving the food web through its protection measures for dominant target species, forage species, and ESA-listed species. However, it will likely make slow, incremental progress in protecting other food web components. This policy is likely effective in protecting food web components that are more well-studied than others and those that are at critical population thresholds, but it is uncertain whether sufficient protection is provided to other food web components for which less complete information is available.

The bycatch management program under Alternative 1 is effective at limiting incidental catch of non-target species and reducing bycatch through incentive programs and monitoring. The weaknesses of the alternative are that bycatch is often reported as a complex rather than as individual species, and that observers are not present to monitor catch on vessels less than 60 ft LOA, which may result in inaccurate estimates of bycatch. This alternative may therefore not provide adequate protection for non-target species.

Alternative 1 is effective at providing protection to listed seabirds and marine mammals as a result of its explicit objectives for ESA-listed species. Although not an explicit policy goal, some protection may also be provided to non-listed seabirds through reduced incidental take as a result of implementing additional seabird protection measures.

This alternative emphasizes incremental implementation of habitat protection measures as scientific information becomes available. As a result, impacts to habitat may be alleviated, albeit slowly. This strategy is likely to be effective in protecting habitat components that are more well-studied than others, but it is uncertain whether sufficient protection will be provided to habitat components for which there is less complete information. Cumulatively, continued adverse impacts result from historical impacts that have potentially caused long-term and possibly irreversible loss of living habitat, especially to long-lived, slow-growing species that are slow to recover.

Alternative 1 is expected to continue to provide economic and community stability within the current management system while adapting management programs when the need arises. The alternative could eliminate the race-for-fish and, by doing so, would increase net-revenues to producers and provide benefits to consumers. However, fewer, although possibly higher paying, fishery related jobs would be created. Non-market, recreation, and tourism values could decrease in the short-run before the transition to rights-based systems is completed.

The goals and policies for Alaska Native consultation and participation in fishery management would continue at the current levels and comply with relevant EOs and other federal law. Traditional knowledge in fishery management would continue to be incorporated in environmental documents as available and appropriate. Subsistence uses would continue consistent with federal law.

This policy will result in a data collection program that will continue to meet minimum acceptable standards for scientific management of the fisheries. Although aspects of the catch collection program could be improved, such as non-random coverage in the 30 percent component of the fleet, current practices do provide useful data for fishery management while remaining mindful of the cost burden on industry of the monitoring program.

4.10.2.2 Prevent Overfishing

Alternative 1 for the BSAI and GOA represents the policy statement currently implemented in the BSAI and GOA. The alternative seeks to prevent overfishing by adopting conservative harvest levels for single species fisheries and specification of OY range. Alternative 1 promotes conservation by avoiding irreversible or long-term adverse effects on fishery resources, and ensures the availability of a multiplicity of options with respect to the future use of groundfish resources. Alternative 1 also sets objectives to meet these goals by promoting rebuilding when stocks have declined below a level capable of producing MSY. The alternative maintains a margin of safety between ABC and OFL to prevent overfishing when the quality of information concerning the resource and ecosystem is questionable.

The Alternative 1 policy is illustrated through FMP 1, which contains a number of management measures that pertain to the sustainability of fisheries and fishery resources. FMP 1 defines four management categories for which catch is constrained by various regulatory mechanisms: target species, prohibited species, other species, and forage fish species. Stocks can be moved from one management category into another only by FMP amendment. There is a fifth category of non-specified species that encompasses all species that may be caught in commercial fisheries but the catch of which is not constrained. Within the target species category, stocks are managed either individually or as part of a stock complex. Stocks within the target species category can be added to or removed from a stock complex within the same category as part of the TAC-setting process (i.e., without an FMP amendment).

Goals, Objectives	**Corresponding Management Measures**	
<u>Goals</u> • Maintain sustainable fisheries • Manage the groundfish fisheries through the current risk-averse conservation and management program that is based on a conservative harvest strategy • Incorporate and apply ecosystem-based management principles <u>Objectives</u> • Adopt conservative harvest levels for single species fisheries and specify OY • Continue to use existing OY cap for BSAI and GOA fisheries • Provide for adaptive management by continuing to specify OY as a range	TAC≤ABC≤OFL Automatic Rebuilding	Quota management based on a tier system. F_{ABC} set below F_{OFL} except at very low stock sizes protecting the stock from unintentional overfishing. The ABC can be set anywhere between zero and the maximum permissible ABC under the Tier system. In practice ABCs are often set below the maximum permissible ABC to address uncertainty in the stock assessment (e.g. BSAI pollock, GOA pollock, BSAI and GOA cod). For Tier 3 stocks, F_{ABC} is decreased linearly with biomass whenever biomass falls below a tier-specific reference level.
	Time/Area	For several species, fishing quotas are distributed across time and area in proportion to the expected underlying biomass of fish in the region at that time. These policies reduce the possibility of spatial temporal concentration of the catch.
	Gear restrictions	For walleye pollock, Pacific cod, and sablefish, gear allocations partition catch to specific gear groups. Differences in gear selectivity are addressed in the stock assessment models and quotas reflect the expected age distribution of the catch by gear.
	OY caps	Optimum Yield restrictions cap the aggregated groundfish catch in the GOA and BSAI. These caps limit the expansion of fisheries (particularly in the BSAI).
	Inseason Multi-species TAC and ABC monitoring	The catch of a given target species is limited by prohibited species bycatch caps and the TACs for other groundfish. The halibut bycatch caps serve as a constraint to BSAI and GOA flatfish expansion.

Impacts of Policy

An illustration of the harvest constraints imposed by Alternative 1 is provided by FMP 1, the current 2002 management regime for the BSAI and GOA. This FMP addresses the impact of fishing mortality by constraining catch. FMP 1 adopts precautionary measures that build sustainable fisheries and promote rebuilding of overfished stocks. The recommended fishing mortality under FMP 1 would not exceed the OFL for any target stock; however, should any stock decline below a level capable of producing MSY, NOAA Fisheries would develop a rebuilding plan to be put in place that would rebuild the stock within ten years or the specified time period for rebuilding plus one generation time. The objective to include a margin of safety when the quality of information is questionable is accommodated by the buffer between F_{ABC} and F_{OFL}, which would reduce the chance of unintentionally overfishing a stock. Irreversible or long-term adverse effects on fishery resources are avoided through harvest rates that prevent overfishing. This policy implements in-season multi-species catch monitoring to ensure that catch does not exceed the OFLs. In the EBS, the upper limit of the OY range (2 million mt) curtails the expansion of some groundfish fisheries. Relative to the baseline, the expected fishing mortality under FMP 1 would have no significant impact on any of the target groundfish stocks.

Under FMP 1, none of the 19 stocks managed in Tiers 1-3 would be expected to become overfished (Table 4.10-2a). The policy promotes healthy spawning stocks by reducing fishing mortality whenever the stock falls below $B_{40\%}$. Relative to the baseline, no significant impacts due to changes in spawning biomass are expected for stocks managed in Tiers 1-3. For stocks or stock complexes managed in Tiers 4-6, the impacts on spawning biomass are unknown because the status of the stock relative to its MSST is unknown for these stocks (Table 4.10-2a). The impacts of Alternative 1 on fishing mortality of GOA Atka mackerel are unknown. Consideration of cumulative impacts does not change the expectations for direct or indirect impacts of this alternative on fishing mortality.

FMP 1 includes numerous spatial/temporal restrictions on catch that should reduce impacts resulting from concentration of the catch. Under this policy, commercial fishing is not expected to have significant impacts on the genetic makeup or the reproductive success of the stocks managed in Tiers 1-3 (Table 4.10-2a). The impact of commercial fishing on the genetic make-up or reproductive success of stocks managed in Tiers 4-6 is unknown because the status of such stocks relative to their respective MSST is unknown (Table 4.10-2a). Consideration of cumulative impacts does not change the expectations for direct or indirect impacts of this alternative on fishing mortality.

Harvest restrictions and spatial temporal partitions diffuse the impacts of commercial fishing on prey availability and predation mortality. Impacts of commercial fishing on prey availability for the 19 stocks managed in Tiers 1-3 are expected to be insignificant relative to the baseline (Table 4.10-2a). Impacts of commercial fishing on prey availability of stocks or stock complexes that are managed in Tiers 4-6 are unknown because the status of such stocks relative to their respective MSST is unknown (Table 4.10-2a). Consideration of cumulative impacts does not change the expectations for direct or indirect impacts of this alternative on fishing mortality.

Harvest restrictions, spatial temporal constraints and gear allocations all serve to mitigate the impact of commercial fishing on fish habitat. The existing closure system in the BSAI and GOA sets aside approximately 11 percent of the EEZ to some form of MPA and designates 0.1 percent of the EEZ as a no-take reserve (Figure 4.2-1). For the fishable area (depth to 1,000 m) of the EEZ, FMP 1 would designate approximately 28 percent of the fishable area as some form of MPA, of which 0.3 percent is designated as a no-take reserve. Relative to the baseline, the impacts on target species resulting from habitat disturbance are considered insignificant for all stocks managed in Tiers 1-3 (Table 4.10-2a). The impacts are unknown for stocks or stock complexes managed in Tiers 4-6.

When taken in aggregate, Alternative 1 is expected to achieve the goals of promoting conservation by avoiding irreversible or long-term adverse effects on fishery resources, and to ensure the availability of multiple options with respect to the future use of groundfish resources. The Alternative 1 policy is consistent with NOAA Fisheries' goal of building and maintaining sustainable fisheries. This policy is also consistent with ecosystem principles that call for in-season multi-species catch monitoring to ensure that catch does not exceed the OFLs. This catch monitoring is facilitated by at-sea observers, port samplers, weekly production reports, and fish ticket information (Appendix F-10). A strength of Alternative 1 is that it encourages automatic rebuilding by linearly reducing F_{ABC} when the stock falls below $B_{40\%}$. This feature may mitigate the lack of a formal declaration of a method for annually assessing the status of stocks relative to the MSST in the FMP. The National Standard Guidelines require FMPs to specify MSST whenever possible (Appendix F-1). Alternative 1 is the only alternative that has an observed track record. This track record shows that none of the stocks managed in Tiers 1-3 is overfished. The track record also shows that the harvest policy is effective at rebuilding depleted stocks (e.g., Aleutian Islands and GOA rockfish stocks). A weakness of Alternative 1 is that there is no incentive to reduce the number of stocks where the status relative to an overfished condition is unknown. While harvest policies may build and maintain the species complex, it is still possible to overharvest a vulnerable member of the complex. Alternative 1 does not require formal examination of the status of groundfish stocks relative to MSST. In practice, this is a technical omission because NOAA Fisheries conducts annual status reviews for the stocks managed in Tiers 1-3. These status reviews are included in the SAFE chapters that are presented to the NPFMC for their use in setting annual TACs.

4.10.2.3 Preserve Food Web

The Alternative 1 policy sets goals and objectives to preserve the food web, as well as specifying management measures that would allow implementation of this policy.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
<u>Goals</u> • Incorporate and apply ecosystem-based management principles • Consider the impact of fishing on predator-prey and other important ecological relationships <u>Objectives</u> • Incorporate ecosystem considerations into fishery management decisions • Continue to protect the integrity of the food web through limits on the harvest of forage species • Develop a conceptual model of the food web	TAC-setting Process	prohibit directed fishery for forage fish
		precautionary adjustments to ABCs, incorporate uncertainty only in Tier 1
		develop ecosystem indicators for future use in TAC-setting

Impacts of Policy

Impacts to foods webs of the BSAI and GOA are mitigated through many of the goals and objectives and the related management measures of this FMP. Alternative 1 objectives specifically incorporate ecosystem considerations into fisheries management decisions, prohibit directed fisheries for forage fish (which often form a central position in channeling energy through the food web), and require precautionary adjustments to ABCs made to Tier 1 stocks. Alternative 1 policies and goals also seek to prevent overfishing, reduce and avoid bycatch, avoid impacts to seabirds and marine mammals, reduce and avoid impacts to habitat, and improve data quality, monitoring, and enforcement, all of which are critical to protection of food web components. These components include target and non-specified species, PSC species, HAPC biota, and marine mammals and seabirds. Various management measures provide protection to important food web components: conservative harvest levels for target species and OY cap (Section 4.10.3.2); accounting for bycatch mortality and PSC limits for prohibited species (Section 4.10.3.4); SSL prey species low biomass rules; spatial/temporal distribution of TAC; closure areas to protect walrus and Steller sea lions, gear modifications to protect seabirds, and short-tailed albatross take restrictions (Section 4.10.3.5), existing closed areas and efforts to identify and designate EFH and HAPC (Section 4.10.3.6); the Observer Program, VMS for Steller sea lion prey species, and scales (Section 4.10.3.9). See the policy analysis in those sections for details on the level of protection provided by Alternative 1 to these individual components.

This alternative specifically attempts to incorporate ecosystem considerations into fishery management decisions through development of ecosystem indicators, conceptual models of the food webs, and prohibition of directed fisheries for forage fish, which often form a central position in channeling energy through the food web. Analysis of the ecosystem effects of FMP 1 involved selection of indicators that would show changes in key members or ecosystem characteristics that are important to the structure and function of marine food webs. Changes in pelagic forage species, top predators, spatial/temporal availability of prey, exotic species introductions, energy removal and redirection through fishery catch removals, discarding, and offal production, and various measures of diversity were evaluated with respect to the potential of fishing to cause changes sufficient to bring these attributes below population, community, or ecosystem thresholds, if such thresholds could be defined. Most of these indicators show an insignificant impact on these ecosystem attributes. However, there were unknown effects on some top predator species and on species diversity due to our lack of knowledge of abundance levels and life history characteristics of species such as skates, sharks, and grenadiers. The continued possibility of adverse impacts was described due to introductions of non-native species from fishing vessel ballast water, such non-native species have the potential to drastically change food webs. Other adverse impacts are possible due to the possible loss of functional diversity through the lack of protection of sensitive, structural habitat organisms such as corals that are very slow growing and remained unchanged relative to the baseline. Qualitative analysis of the alternative with respect to ecosystem effects of the TAC-setting process (Appendix F-1) showed that this alternative has the potential to be considerate of ecosystem needs but would need a more formalized decision-making system to explicitly implement.

Through its protection measures for dominant target species, forage species, and ESA-listed species, when considered as a whole this alternative is partially successful in achieving the goal of preserving the food web. However, it will likely make slow, incremental progress in protecting other food web components. The emphasis in this alternative is on incremental improvements to the fishery management regime as more information becomes available and on protection measures devised in response to requirements for protecting ESA-listed species. This strategy is likely effective in protecting food web components that are more well-studied than others and those that are at critical population thresholds, but it is uncertain whether sufficient protection is provided to others for which we have less complete information.

4.10.2.4 Reduce and Avoid Bycatch

Alternative 1 represents the current management policy in the BSAI and GOA. The alternative seeks to reduce bycatch by implementing gear restrictions, time area restrictions, and in-season bycatch monitoring by deploying domestic observers, port samplers, and requirements for weekly production reports. Bycatch is defined as species that are caught and discarded at sea. A detailed description of the regulations impacting bycatch can be found in the Bycatch qualitative analysis paper (Appendix F-5).

Gear restrictions and time/area restrictions to reduce bycatch in groundfish fisheries are implemented under FMP 1. The FMP prohibits directed fishing for pollock with non-pelagic trawl gear in the BSAI. Directed fishing for sablefish is restricted to longline gear in the GOA. This restriction may reduce the bycatch of species captured in trawl fisheries but may increase the bycatch of sharks and selected rockfish commonly caught in longline fisheries. Non-pelagic trawling is prohibited in the Bristol Bay Red King Crab Savings Area in the BSAI, and in the Cook Inlet in the GOA. Additionally, various areas around Kodiak Island are closed to non-pelagic trawling either year-round or seasonally to protect crab stocks (see Figure 4.2-1).

Groundfish fisheries in the BSAI and GOA are required to discard any incidental catch of halibut, salmon, crab, herring, or Steelhead trout, known collectively as prohibited species. The FMPs currently set catch limits on many of the prohibited species, with penalties ranging from closure of a particular zone or whole management area to closure of a directed fishery or fisheries for a specified season or for the rest of the year. In the BSAI FMP, stair step limits for trawl bycatch within specified zones are set for red king crab and *C. bairdi* crab. The catch limit varies based on stock abundance. The BSAI FMP also specifies an absolute trawl catch limit for chinook salmon and other salmon within specified zones. Once the apportioned PSC limit for a trawl fishery is reached within a zone, the fishery is prohibited from fishing within that zone. The BSAI FMP specifies a trawl catch limit for herring in the BSAI at one percent of annual biomass. Catch limits on *C. opilio* crab and halibut bycatch in the BSAI are established in regulation. The *C. opilio* catch limit applies to a specified zone, and is based on an adjusted percentage of biomass that must fall within a certain range. The halibut catch limit is a BSAI-wide metric ton limit and is based on halibut mortality. Catch limits on halibut bycatch in the GOA are authorized in the FMP, and are set by the NPFMC as part of the annual procedure for setting groundfish harvest levels. There are no other prohibited species catch limits set in the GOA.

Other bycatch reduction measures are required under FMP 1 as well. Full retention by vessels fishing for groundfish of all pollock and Pacific cod fit for human consumption is required under IR/IU regulations. A minimum utilization standard of 15 percent for other groundfish species is also set for all processors. Additional measures that would reduce bycatch of other groundfish are also under consideration. For example, the NPFMC is considering an amendment to require full retention of DSR by hook-and-line and jig vessels in southeast Outside. A Vessel Incentive Program encourages bycatch reduction by setting bycatch reduction standards biannually. If a vessel fails to meet these standards, it can be penalized. In-season bycatch management measures establish fishing seasons for bycatch management and give the NOAA Fisheries Regional Administrator the authority to close areas with high bycatch.

Impacts of Policy

Alternative 1 is expected to encourage the development of practical measures that reduce bycatch and incidental catch of prohibited species, target groundfish, other species, forage fish, and non-specified species. Relative to the baseline, the direct and indirect impacts of Alternative 1 on prohibited species, other species, forage fish, and non-specified species are insignificant (Tables 4.10-2a and 4.10-2b). These rankings do not imply that current harvest practices are safe for all species within the categories noted above. The rankings do imply that adopting Alternative 1 would not represent a significant change relative to the baseline. Two issues are of particular concern. Some prohibited species are currently in a depressed (BSAI chinook) or overfished condition (*C. bairdi* crab, *C. opilio* crab, BSAI red king crab, and BSAI blue king crab). Although the fishing mortality of depressed or overfished non-target species is minor, the additional mortality resulting from groundfish fisheries is not beneficial to these stocks. When cumulative effects are considered, conditionally significant adverse impacts due to fishing mortality are expected for depressed and overfished species. Conditionally significant adverse impacts are also expected for crab species due to change in biomass.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Goals • Encourage the development of practical measures that minimize bycatch • Protect threatened and endangered species Objectives • Continue current incidental catch and bycatch management program • Continue to manage incidental catch and bycatch through seasonal distribution of TAC and geographical gear restrictions • Continue to account for bycatch mortality in monitoring annual TACs • Control the bycatch of prohibited species through PSC limits • Continue program to require full utilization of target species • Continue to respond to evidence of population declines by closing areas and implementing gear and seasonal restrictions in affected areas	Bycatch and Incidental Catch Restrictions	Quota management is based on a tier system. F_{ABC} set below F_{OFL} except at very low stock sizes protecting the stock from unintentional overfishing. The ABC can be set anywhere between zero and the maximum permissible ABC under the Tier system. In practice ABCs are often set below the maximum permissible ABC to address uncertainty in the stock assessment (e.g. BSAI pollock, GOA pollock, BSAI and GOA cod). For Tier 3 stocks, F_{ABC} is decreased linearly with biomass whenever biomass falls below a tier-specific reference level.
	Gear Restrictions and Allocations	Directed harvest of walleye pollock in the BSAI is restricted to pelagic gear.
	Spatial/ Temporal Management of TAC	For several species, fishing quotas are distributed across time and area in proportion to the expected underlying biomass of fish in the region at that time. These policies reduce the possibility of spatial/temporal concentration of the catch.

Alternative 1 is effective at limiting the incidental catch of target and non-target species and reducing bycatch. Bycatch monitoring programs are consistent with ecosystem principles that call for in-season multi-species catch monitoring to ensure that catch does not exceed the OFLs. Implementation of at-sea catch monitoring has proved to be beneficial to reducing bycatch of prohibited species. The track record shows that some bycatch reduction incentives coupled with catch monitoring have been effective in reducing the bycatch of prohibited species in groundfish fisheries. A weakness of Alternative 1 is that bycatch is often reported as a complex rather than by species. The absence of at-sea catch monitoring for vessels less than 60 ft LOA may result in less than adequate protection of non-target species. Implementation of IR/IU coupled with AFA has been effective at reducing the bycatch in pollock and Pacific cod fisheries. However, AFA had the negative impact of mandating head and gut vessels to discard pollock when catches exceed 20 percent of the retained catch in the flatfish fisheries.

4.10.2.5 Avoid Impacts to Seabirds and Marine Mammals

The Alternative 1 policy sets goals and objectives to avoid impacts to seabirds and marine mammals, as well as specifying management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Goals • Protect threatened and endangered species Objectives • Continue to cooperate with USFWS to protect ESA-listed and other seabird species • Maintain current protection measures to avoid jeopardy to ESA-listed Steller sea lions	TAC-setting Process, Steller sea lion Measures	Steller sea lion prey species low biomass rules
	TAC-setting Process	prohibit directed fishery for forage fish
	Spatial/ Temporal Management of TAC	spatial/temporal distribution of TAC
	MPAs and EFH/ Steller sea lion Measures/ Gear Restrictions and Allocations	seasonal, gear/fishery specific, and total closure areas identified to protect walrus and Steller sea lions
	Seabird Measures	short-tailed albatross take restrictions
		gear modifications to protect seabirds

Impacts of Policy

Impacts to seabirds and marine mammals are mitigated in Alternative 1 through the stated goal of protecting threatened and endangered species. The objectives of this alternative are to continue to cooperate with USFWS to protect ESA-listed and other seabird species and to maintain current protection measures to avoid jeopardy to ESA-listed Steller sea lions. Management measures that provide protection to seabirds and marine mammals in this alternative include: Steller sea lion prey species low biomass rules, prohibition of directed fishery for forage fish, spatial/temporal distribution of TAC, a variety of time/area/gear/fishery closures, fishery closures to protect walrus and Steller sea lions, short-tailed albatross take restrictions, and gear modifications to protect seabirds. Impacts of the alternative with respect to seabirds were evaluated with respect to the potential for fisheries to cause direct mortality through fishing gear and vessel strikes, changes in prey availability (including offal), and changes in benthic habitat that might affect certain prey species of seabirds. Impacts for marine mammals were evaluated with respect to the potential for fishery incidental take or entanglement in marine debris, harvest of prey species, spatial/temporal concentration of fishing on prey, and fishing vessel disturbance.

This alternative is successful at meeting its objective of protection of threatened and endangered species. Impact indicators showed that Alternative 1 impacts to seabirds were minimal. Incidental take of surface-feeding seabirds was substantially reduced from the baseline due to the new mitigation measures in the longline fleet. The risk of exceeding ESA-thresholds for mortality of short-tailed albatross was reduced from the baseline level. The qualitative analysis of seabird protection measures (Appendix F-6) noted the importance of the Observer Program in both monitoring the levels of incidental take and in researching the effectiveness of different seabird avoidance techniques. The groundfish fishery in this alternative is not expected to have population level effects on any seabird species through mortality, changes in food availability, or impacts on benthic habitat. Although some piscivorous bird species such as glaucous-winged gulls might be gaining food subsidies in the baseline, other piscivorous birds would be negatively impacted by competitive interactions with gulls, thus offsetting any changes for the piscivorous bird group as a whole.

Qualitative analysis of the impacts of this alternative on Steller sea lions (Appendix F-4) and the quantitative analysis of impacts on marine mammals showed that impacts were insignificant with respect to all the indicators relative to the baseline. However, the spatial shift in fisheries from closed areas increases the possibility of fishery competitive interaction with other species such as northern fur seals.

This alternative, through its explicit retention of measures for protecting ESA-listed species, is effective at providing protection to listed seabirds and marine mammals. Although some protection is afforded to non-listed seabirds through the implementation of the 2001 seabird protection measures, this is not an explicit part of its policy goal.

4.10.2.6 Reduce and Avoid Impacts to Habitat

The Alternative 1 policy sets goals and objectives to reduce and avoid impacts to habitat, as well as specifying management measures that would implement these objectives.

<table>
<tr><th rowspan="2">Goals, Objectives</th><th colspan="2">Corresponding Management Measures</th></tr>
<tr><th>FMP Component</th><th>Management Measure</th></tr>
<tr><td rowspan="3"><u>Goals</u>
• Protect, conserve and restore living marine resource habitat
• Consider the impact of fishing on habitat
• Encourage the development of practical measures that minimize adverse effects on essential fishing habitat

<u>Objectives</u>
• Respond to new scientific information regarding areas of critical habitat by closing those regions to all fishing (i.e., no-take marine reserves such as Sitka Pinnacles)
• Evaluate the impacts of trawl gear on habitat through the stepwise implementation of a comprehensive research plan, to determine appropriate habitat protection measures
• Continue to evaluate candidate areas for MPAs</td><td>MPAs and EFH, Bycatch and Incidental Catch Restrictions, Gear Restrictions and Allocations</td><td>Existing system of closed areas including Sitka Pinnacles</td></tr>
<tr><td rowspan="2">MPAs and EFH</td><td>EO 13158 description and evaluation of potential MPA areas</td></tr>
<tr><td>Identify and designate EFH and HAPC</td></tr>
</table>

Impacts of Policy

Alternative 1 addresses impacts to habitat by having specific goals and objectives that focus on living marine habitat. Implementation of this policy is expected to result in a gradual reduction and avoidance of impacts to habitat. This reduction in impacts will occur over the long-term in response to new scientific information. Such scientific information will be obtained through a stepwise implementation of a research plan that focuses on the impacts of trawl gear on habitat. Evaluation of areas as potential MPAs and identification and designation of EFH and HAPC are specific management measures. Given that this policy relies on responsiveness to new scientific information and implementation of a research program, it is expected that adverse impacts to habitat will continue in the short-term. This policy will likely be effective for habitat components that are well studied, but it is uncertain whether sufficient protection is provided to components with less complete information.

In addition to the objectives specifically designed for habitat, Alternative 1 policies to prevent overfishing, reduce and avoid bycatch, incorporate ecosystem considerations, and data quality and enforcement goals are important ancillary objectives that could provide reduced impacts to habitat. Management measures such as conservative harvest levels for target species and PSC limits can reduce impacts to habitat because fishing effort may be reduced. Closures for marine mammal protection, especially if they are year-round for all target species, can also provide protection to specific habitat types.

Analysis of FMP 1 involved assessing effects to mortality, damage, and diversity of living marine habitat. In addition, an assessment of effects on the diversity of impacts was performed with the assertion that within fished areas spatially diverse or patchy fishing impacts are preferable to uniformly distributed impacts. These effects are expected to cause insignificant change relative to the baseline. However, adverse impacts could occur because continued mortality and damage to living habitat coupled with historical impacts may cause long-term and possible irreversible loss of living habitat, especially long-lived, slow-growing species which are slow to recover. There are expanses of fished areas where adverse impacts could result from Alternative 1. In these fished areas, continued fishing at Alternative 1 levels may result in habitat levels substantially below unfished levels. In addition, the geographic and habitat type distribution of closures is not expected to provide a diversity of impacts within fished areas. Most areas that are closed to bottom trawling year-round to all species are nearshore areas, or of one habitat type, with the exception of the southeast Alaska trawl exclusion zone. This configuration of closures may change as the goals and objectives of this policy are implemented.

From a cumulative impacts perspective, the baseline condition is adversely impacted due to historical impacts that have potentially caused long-term and possibly irreversible loss of living habitat, especially to long-lived, slow-growing species that are slow to recover. The cumulative impact for this alternative is conditionally significant adverse due to the adverse state of the baseline condition coupled with continued damage and mortality to living habitat.

Overall this alternative emphasizes incremental implementation of habitat protection measures as scientific information becomes available. As a result, impacts to habitat may be alleviated, albeit slowly. This strategy is likely to be effective in protecting habitat components that are more well studied than others but it is uncertain whether sufficient protection will be provided to habitat components for which we have less complete information.

4.10.2.7 Address Allocation Issues

Management measures under Alternative 1 implement a conservative and risk-averse policy that balances sustainability of the resource and the environment with socioeconomic benefits. This policy emphasizes allocation issues and equitable access to the resources among fishery participants and fishing communities. It also includes an explicit recognition of broader ecosystem concerns.

<table>
<tr><th rowspan="2">Goals, Objectives</th><th colspan="2">Corresponding Management Measures</th></tr>
<tr><th>FMP Component</th><th>Management Measure</th></tr>
<tr><td rowspan="3">Goals
• Maintain statutorily mandated programs to reduce excess capacity and the race-for-fish

Objectives
• Continue to reduce excess fishing capacity, overcapitalization and the adverse effects of the race-for-fish
• Provide economic and community stability by maintaining current allocation percentages to harvesting and processing sectors</td><td>Gear Restrictions and Allocations</td><td>Allocate by gear for certain directed fisheries</td></tr>
<tr><td rowspan="2">Overcapacity</td><td>LLP program for groundfish fisheries</td></tr>
<tr><td>Rights-based management programs for certain directed fisheries, and community quota programs</td></tr>
</table>

Impacts of Policy

Alternative 1 explicitly recognizes the adverse effects of the race-for-fish and promotes actions that alleviate those problems while providing for economic and community stability. This policy is evolutionary and adaptive in nature as it responds to management issues. The alternative also recognizes the importance of ecosystem health and the broad range of benefits that the BSAI and GOA marine ecosystems and associated species provide to the American public.

As the race-for-fish is eliminated, in what could be an extended process, the alternative could result in beneficial effects in terms of producer net revenue, consumer benefits, and participant health and safety (see Appendix F-8). The policy provides economic stability to fishery participants and communities by maintaining current allocation percentages to sectors. However, the elimination of the race-for-fish will likely result in a decrease in overall participation levels. In the long-run, communities are likely to see fewer persons employed in jobs related to the fishing industry (fishing, processing, or support sectors), but the jobs that remain could result in longer periods of work and higher pay.

Because elimination of the race-for-fish is expected to be gradual in nature and unlikely to completed in the near-term, it is likely that the adverse effects of the race-for-fish will continue in the short-term. For this reason, the alternative could result in decreased non-market, recreational, and tourism values attributed to the ecosystem. In the long-run, however, with completion of the transition away from the race-for-fish, non-market ecosystem values may increase due to reductions in bycatch and greater harvesting efficiency that are anticipated with rights-based management.

4.10.2.8 Increase Alaska Native Consultation

The Alternative 1 policy sets goals and objectives to increase Alaska Native consultation, as well as specifying management measures that would implement these objectives.

<table>
<tr><th rowspan="2">Goals, Objectives</th><th colspan="2">Corresponding Management Measures</th></tr>
<tr><th>FMP Component</th><th>Management Measure</th></tr>
<tr><td rowspan="3">Objectives
• Continue to incorporate Traditional Knowledge in fishery management
• Continue current levels of Alaska Native participation and consultation in fishery management</td><td rowspan="3">Alaska Native Issues</td><td>Incorporate Traditional Knowledge in fisheries management through existing literature, on-staff anthropologist</td></tr>
<tr><td>Advisory Panel and NPFMC representation</td></tr>
<tr><td>Allow for subsistence uses consistent with Federal law</td></tr>
</table>

Impacts of Policy

Alaska Native consultation in the management of Alaska groundfish fisheries is currently accomplished through a number of measures. These mechanisms include 1) executing Government-to-Government Consultation with federally recognized tribes in accordance with EO 13175; 2) identifying sources of pertinent Traditional Knowledge and incorporating it into NEPA compliance and fishery management activities; 3) representation of Alaska Native groups on the NPFMC and its Advisory Panel; 4) addressing issues related to Alaska Natives during NEPA compliance (effects on Alaska Natives participating in commercial fisheries, effects on Alaska Native communities, effects on subsistence, and Environmental Justice impacts); and 5) allowing for subsistence harvest of fish and wildlife in accordance with federal law.

Under Alternative 1, current management policies and measures used by NOAA Fisheries and the NPFMC regarding Alaska Native consultation would be continued. Through the resources of NOAA Fisheries staff anthropologists, the collection of existing Traditional Knowledge, expansion of an in-house Traditional Knowledge database, and informal consultation with individuals in Alaska Native communities would continue. Formal consultation with federally recognized tribal governments during NEPA compliance under EO 13175 would also continue at current levels during NEPA scoping activities and public comment periods on draft NEPA documents. Similarly, opportunities for Alaska Native participation in NEPA compliance and NPFMC deliberations would continue to be available during NEPA scoping, comment on draft NEPA documents, review of NPFMC documents, and at NPFMC meetings.

Alaska Native representation on the NPFMC and its Advisory Panel would remain the same. Currently one NPFMC seat and two Advisory Panel seats are held by Alaska Native representatives.

Alaska Native participation in groundfish fisheries through individual catcher vessels and CDQ groups would continue at current levels, resulting in benefits to those participants. Similarly, benefits to affected Alaska Native communities would also continue. Primary benefits include: generation of local employment, generation of secondary economic activities that support of the fishing industry, and of community revenue through fish taxes and service fees. Steller sea lion protection measures would remain in effect and subsistence harvest of sea lions are expected to stay at current levels. Direct and indirect effects of groundfish fishing on subsistence resulting from salmon bycatch would be insignificant, although BSAI salmon stocks in Western Alaska are depressed and remain a concern to Alaska Natives. Alternative 1 would not result in adverse Environmental Justice effects on Alaska Natives (see Alaska Native issues qualitative analysis paper in Appendix F-9).

Under Alternative 1, subsistence uses would continue consistent with federal law. Joint-production of subsistence resources, where Alaska Natives who participate in groundfish fishing take advantage of their commercial fishing efforts to harvest subsistence resources, would continue at current levels.

4.10.2.9 Improve Data Quality, Monitoring, and Enforcement

The Alternative 1 policy sets goals and objectives to address data quality, monitoring and enforcement, as well as specifying management measures that would implement these objectives.

Impacts of Policy

Alternative 1 emphasizes the importance of accurate data to guide management decisions pertaining to the groundfish fisheries. In pursuit of this goal, the alternative identifies a number of objectives: to continue monitoring of catch through industry reporting and the Observer Program; to improve community and regional economic impact assessments; and to utilize advances in technology, such as at-sea scales and VMS, to improve monitoring data. These objectives are discussed in further detail below. A related topic is addressed in Chapter 5, which contains a description of ongoing and proposed North Pacific research efforts and identified data gaps.

The Alternative 1 objectives for catch monitoring and economic impacts assessments are implemented primarily through the FMP 1 requirements for industry participants to submit logbook data at regulated intervals, and through the North Pacific Groundfish Observer Program. These programs are described in detail in Appendix F-10 Observer Program and Appendix F-11 Data and Reporting Requirements.

The Data and Reporting Requirements paper describes the requirements under FMP 1 in detail. Fishing and production logbooks submitted on a daily or weekly basis, and State of Alaska fish tickets, supply data such as the groundfish and prohibited species catch weight (or number of animals), species composition, haul location, discard weight and disposition information, and price paid/received. While the biological information on target species catch composition is thorough under the existing system, the economic data collected is very limited (only revenue and prices are collected systematically under mandatory programs). Other efforts, as described in the Data and Reporting Requirements paper, are underway to improve the ability of fishery managers to assess the economic impacts of management decisions, but have so far had mixed success. The paper also identifies the lack of observer coverage on smaller fishing vessels as a weakness of the current system, as well as the low precision level in estimates of discarded fish. The costs to industry and the federal government of collecting and processing the data are rated as insignificant.

<table>
<tr><th rowspan="2">Goals, Objectives</th><th colspan="2">Corresponding Management Measures</th></tr>
<tr><th>FMP Component</th><th>Management Measure</th></tr>
<tr><td rowspan="5"><u>Goals</u>
• Management decisions will use the best available scientific information
• Management process will be adaptive to new information and reactive to new environmental issues
• Draw upon federal, state and academic capabilities in carrying out research, administration, management and enforcement
• Consider the effects of fishing

<u>Objectives</u>
• Continue the existing reporting requirements and Observer Program to provide catch estimates and biological information
• Continue ongoing effort to improve community and regional economic impact assessments
• Increase the quality of monitoring data through improved technological means</td><td rowspan="2">Observer Program</td><td>Fixed 0/30/100% Observer Program coverage; 100/200% for A.A. and CDQ</td></tr>
<tr><td>Third party, pay-as-you-go service delivery model</td></tr>
<tr><td rowspan="3">Data and Reporting Requirements</td><td>Require economic data from industry participants</td></tr>
<tr><td>Require appropriate scales</td></tr>
<tr><td>Require VMS for Steller sea lion prey species</td></tr>
</table>

The elements of and issues related to the Observer Program are discussed in the Observer Program qualitative analysis paper in Appendix F-10. Developed in 1990, the third party pay-as-you-go system is a service delivery model where industry contracts for observer coverage with a third party provider, whose observers are trained by NOAA Fisheries. The agency is responsible for managing the data, which includes biological data on incidental catch of marine mammals and endangered seabirds, fishing effort information, and species composition data. The level of species identification recorded by observers is minimally to the level of the management categories. At the request of NOAA Fisheries stock assessment scientists or others, the Observer Program continues to break out more species for identification; however, many non-target species and some species that are managed within a stock complex are not individually identified at the current time. This program was meant as an interim program, and has been and continues to be improved and changed. A continuing area of controversy is the appearance of conflict of interest that arises from the direct financial relationship between the observer's employer and industry. Additionally, for the component of the fleet with only 30 percent coverage (vessels between 60 ft and 125 ft LOA), observer deployment is non-random and may not be a representative sample of the catch.

Data collected under FMP 1 through industry reporting, the Observer Program, and NOAA Fisheries independent resource surveys (described in Appendix B), are combined into a system that is widely regarded as one of the most comprehensive fishery data collection systems in the world (Appendix F-11). The existing system provides sufficient information to assess the current stock condition of target species and accurately estimate the biomass levels used to set appropriate catch quotas.

The Alternative 1 objective to improve the quality of monitoring data through improved technological means is implemented under FMP 1 through the requirement of certified scales for observer sampling in certain fisheries, and the use of VMS on vessels targeting Steller sea lion prey species. A description of the requirements for certified scales, including motion-compensated scales, in the rationalized AFA and CDQ fisheries, is included in the Data and Reporting Requirements paper in Appendix F-11. The requirements for certified scales in these fisheries has improved the accuracy of observer data.

The introduction of mandatory VMS as a management measure is an example of fishery management reacting to new environmental issues. The rapid decline in the abundance of the western stock of Steller sea lions caused the NPFMC/NOAA Fisheries to implement a series of circular closure areas around rookeries and haulouts. Concentric circles around a point are more difficult to monitor and enforce than linear closures based on latitude and longitude, particularly when they overlap one another (NMFS 2001– Steller sea lion SEIS, Section 3.11). The use of VMS has allowed effective monitoring and enforcement of the Steller sea lion protection measures. For further description of the management implications of VMS, see Section 5.2. FMP 1 demonstrates that the use of new technology has successfully improved data quality in monitoring and enforcement activities.

The emphasis of Alternative 1 is to continue current efforts to improve the scientific understanding of the North Pacific environment and of the effects of fishing, and to use this understanding to manage the groundfish fisheries in a sustainable and conservative manner. The objectives to implement and improve data quality, monitoring, and enforcement will result in a data collection system that allows accurate assessment of managed species or species complexes so as to result in a low threat of overfishing in target fisheries. As the focus of data collection in these objectives is primarily centered on industry vessels (reporting requirements, observers), however, the policy will be most effective for target species and will return less data on those species or ages that are not targeted. This policy will result in a data collection program that will continue to meet minimum acceptable standards for scientific management of the fisheries. Although aspects of the catch collection program could be improved, current practices do provide useful data for fishery management while remaining mindful of the cost burden on industry of the monitoring program.

4.10.3 Analysis of Alternative 2

Alternative 2 consists of a management approach statement and a set of policy objectives. The management approach statement provides the key to the underlying rationale and assumptions for the policy, along with goals and additional guidelines.

The management approach statement for Alternative 2 identifies the goal of maximizing biological and economic yield from the resource by establishing a more aggressive harvest strategy. The management approach statement is summarized in Table 4.10-3. This policy is based on the assumption that fishing does not have an adverse impact on the environment except in specific cases as noted.

A summary of the impacts of Alternative 2 follows below in Section 4.10.3.1. In the remainder of Section 4.10.3, the impacts of the alternative are analyzed in detail, in relation to eight policy subheadings: prevent overfishing; preserve food web; reduce and avoid bycatch; avoid impacts to seabirds and marine mammals; reduce and avoid impacts to habitat; allocation issues; increase Alaska Native consultation; and data quality, monitoring and enforcement. For each subheading, the impacts of the relevant goals and objectives from the management approach are analyzed, using as a guideline the range of implementing management measures for Alternative 2, identified in Section 4.2, and analyzed in Section 4.6.

4.10.3.1 Summary of Alternative 2

The key policy elements that predominantly influence the impacts under Alternative 2 are: resetting of the OY cap to the sum of OFL or the sum of ABCs (resulting in increased yield); absence of an objective to eliminate the race-for-fish (resulting in increased effort); absence of objectives to maintain existing closure areas (resulting in potentially adverse impacts to areas that have been closed to fishing); and the consideration to repeal the Observer Program (resulting in less monitoring and research data.)

The impacts analysis of Alternative 2 is hampered to a certain extent by the fact that controls and restrictions on the fishery are removed under this alternative. It is more difficult to predict the impact of removing rather than imposing restrictions; consequently, the uncertainty about predicted reactions of the fishery and the environment could result in an increased risk to the human environment under this alternative.

Alternative 2 would maximize economic yield while preventing overfishing of target stocks, but it is not effective at preventing stocks from becoming overfished. The weaknesses of this alternative are that it increases the chance of unintentionally overfishing a stock, and catch estimates may be uncertain under this alternative if the Observer Program is repealed. Also, as in Alternative 1, there is no incentive to change the management status of stocks where the impact of fishing is unknown, and it is still possible to overharvest vulnerable members of a managed stock complex.

There is a high potential to create adverse food web impacts under Alternative 2 through its lack of precaution, which leaves no room for uncertainty. The possible lack of catch monitoring results in the potential for adverse food web impacts to go undetected until dramatic food web changes are seen. This alternative provides less precautionary management to many components of the food web.

Alternative 2, as illustrated in FMP 2.1, would not be consistent with the objective of monitoring prohibited species catch, as repeal of the Observer Program would negatively impact catch monitoring. Alternative 2 policies, as illustrated by FMP 2.2, would be less severe. As in Alternative 1, additional weaknesses of the alternative are that bycatch is often reported as a complex rather than as individual species, and the absence of observer monitoring of catch on vessels less than 60 ft LOA may result in inaccurate estimates of bycatch. Therefore Alternative 2 may not provide adequate protection for non-target species.

Alternative 2 retains seabird and marine mammal protection measures for ESA-listed species, but does not go beyond ESA-required protection measures. Additionally, other goals and objectives under this alternative remove management measures currently in place in the comparative baseline. The more aggressive harvesting policy, the relaxation of area closures, and the possible repeal of the Observer Program create a high potential to increase fishery interactions with seabirds and marine mammals that may result in adverse impacts to those species.

The alternative could result in increased impacts to habitat because of less precautionary management measures. Possible elimination of current closed areas and increases in TAC have the potential to result in adverse impacts to habitat that could be hard to reverse, especially for long-lived, slow-recovering living habitats. The policy goal of developing practical measures to minimize adverse effects to EFH could be difficult to achieve if such irreversible impacts occur.

Alternative 2 has the potential to increase allowable catches to maximum biological levels and could eliminate the cushion between ABC levels and levels that result in OFLs. This alternative is expected to significantly increase revenues but would also increase operating costs with the elimination of the LLP and IFQ programs. While fishery production is maximized, product quality and the health and safety of participants suffer. Of particular importance may be the amount of variability in harvests, which could increase significantly and therefore make it much more difficult to make long-term business and infrastructure decisions. Finally, non-market, recreation, and tourism values that accrue to the ecosystem could be reduced substantially.

As in Alternative 1, the goals and policies for Alaska Native consultation and participation in fishery management under Alternative 2 would continue at the current levels and comply with relevant EOs and other federal law. Traditional Knowledge in fishery management would continue to be incorporated in environmental documents as available and appropriate. Subsistence uses would continue consistent with federal law. Other goals and objectives in Alternative 2 would affect Alaska Natives by the increase in economic benefits accruing to participants in the fishery, particularly the CDQ pollock fishery. The increased fishing effort under this alternative may however result in increased salmon bycatch, which could have adverse effects on salmon fisheries particularly in the western Alaska Yukon-Kuskokwim river system.

Alternative 2 objectives maintain a minimum level of data collection to meet conservation requirements. The consideration to repeal the Observer Program may compromise management on the best science available as a result of reduced accuracy and breadth of fishery data. The presumed risk of adversely impacting the environment is assumed in this alternative to be low, however, the costs to industry of funding the Observer Program to gather fishery data may not be considered necessary.

4.10.3.2 Prevent Overfishing

The goals of Alternative 2 are to maximize biological and economic yield from the resource by establishing a more aggressive harvest strategy, while still preventing overfishing of the groundfish stocks. This management approach uses the best scientific information available while taking into account individual stock and ecosystem variability. Alternative 2 would encourage the NPFMC to continue to work with other agencies in protecting threatened and endangered species. A more aggressive harvest strategy would be implemented under Alternative 2. The alternative is based upon the concept that the present FMP is overly conservative and that higher harvests could be taken without threat of overfishing of the target groundfish stocks. This policy assumes that fishing at the recommended maximum harvest level would have no adverse impact on the environment, except in specific cases that are known and mitigated.

The Alternative 2 policy is illustrated through FMP 2.1 and FMP 2.2. Each FMP contains a number of management measures that pertain to the sustainability of fisheries and fishery resources. A full description of the actions imposed under FMP 2.1 and FMP 2.2 can be found in Section 4.2. The bookends represent a range of actions that relax constraints to fishery removals.

Goals, Objectives	Corresponding Management Measures	
Goals • Maximize biological and economic yield from the resource while still preventing overfishing of the groundfish stocks. • Prevent overfishing of target groundfish stocks. • Take into account individual stock and ecosystem variability Objectives • Set OY cap at sum of OFL (FMP 2.1) or the sum of ABCs (FMP 2.2) for each species. • Provide for adaptive management by continuing to specify OY range.	Example Range: F_{OFL}= F_{ABC} to no change from FMP 1	Quota management based on a tier system. Buffers between the target (F_{ABC}) and limit (F_{OFL}) fishing mortality levels may (FMP 2.1) or may not (FMP 2.2) be eliminated. The uncertainty corrections for GOA pollock, BSAI and GOA cod implemented under FMP 1 would be eliminated. For stocks managed in Tier 3, F_{ABC} may (FMP 2.2) or may not (FMP 2.1) be decreased linearly with biomass whenever biomass falls below a tier-specific reference level.
	Time/Area	With the exception of sea lion protection measures, time and area closures would be rescinded allowing open access to fishing grounds within the EEZ. These policies would increase the possibility of spatial temporal concentration of the catch and a race-for-fish. In the case of pollock fisheries the race-for-fish may be mitigated by the development of cooperatives and rationalized fisheries under AFA.
	Gear restrictions	Gear restrictions for walleye pollock, Pacific cod, and sablefish, gear allocations would be rescinded. However, the impact of these changes on the sustainability of the stock may be minor for stocks managed in Tiers 1-3 because stock assessment models account for gear selectivity.
	OY caps	Optimum Yield restrictions would be capped at the sum, by region, of the groundfish ABCs for the BSAI and GOA. In the BSAI this would allow an expansion of some fisheries.
	Inseason Multi-species TAC and ABC monitoring	Under FMP 2.1, the catch of target species would no longer be limited by prohibited species bycatch caps. This would allow the expansion of some groundfish fisheries. Monitoring bycatch would be difficult as a result of an 80% reduction in the number of observer days.

FMP 2.1 adopts a more aggressive harvest strategy by removing the buffer between ABC and the OFL, allowing the maximum OY to float as the sum of the OFLs of the BSAI or GOA groundfish stocks respectively. Prohibited species bycatch limits and bycatch reduction incentive provisions currently imposed by IR/IU would be eliminated. Additionally, the precautionary decrease of F_{ABC} linearly with biomass when the biomass falls below a specific reference level is removed. FMP 2.1 also removes physical constraints from the fisheries by repealing several time/area closures currently in place. The fishery will be returned to an open access scenario, where time/area closures, gear restrictions, and prohibited species catch restrictions are repealed. The potential impact of the groundfish fisheries on Steller sea lions, however, means that the current suite of mitigating protection measures that constrain fishing around rookeries and haulouts and protect Steller sea lion prey species (pollock, Pacific cod and Atka mackerel) when at a low biomass, will remain in place (see Figure 4.2-2). This is necessary to avoid jeopardy and adverse modification, as required by the ESA. The same applies to the impact of groundfish fishing on short-tailed albatross, with the

consequent take limits remaining in effect. Additionally, the federally-mandated effort limitation program enacted under the AFA would remain in place, with its adjunct CDQ allocation, but all other effort limitation programs (such as the sablefish IFQ program and the multi-species CDQ program) would be repealed. Reporting requirements would remain in place, in order to keep track of the impact of the fisheries, but the Observer Program, except as federally mandated by the AFA, would be repealed, and VMS would not be required in the fisheries. This action would reduce the number of observer days by an estimated 80 percent (Observer qualitative analysis paper Appendix F-10).

A more moderate illustration of the Alternative 2 aggressive harvest strategy is provided by FMP 2.2. In this case, the mechanisms for setting ABC and TAC remain the same as Alternative 1 with the following notable exceptions. The uncertainty corrections imposed on BSAI and GOA Pacific cod and GOA walleye pollock would not apply under FMP 2.2. The current OY range that caps yield at 2 million mt in the BSAI and 800,000 mt in the GOA would be removed in favor of an annually varying maximum OY equaling the sum of the ABCs for groundfish stocks in the BSAI and GOA. Additionally, bycatch reduction incentives and bycatch restrictions would be repealed, other than those related to PSC limits or IR/IU. Under the assumption that fishing does not have an impact on the environment other than what is generally known and mitigated, the NPFMC's more stringent seabird avoidance measures enacted in 2001 would be repealed, leaving only the mitigation measures recommended by USFWS to avoid jeopardy for short-tailed albatross. Closure areas in FMP 2.2 mirror those in FMP 1 (see Figure 4.2-3).

Impacts of Policy

Alternative 2 for the BSAI and GOA limits the impact of fishing mortality by constraining catch to the OFL (FMP 2.1) or maximum permissible ABC (FMP 2.2). This alternative defines four management categories for which catch is constrained by various regulatory mechanisms: target species, other species, prohibited species, and forage fish species. Alternative 2 harvest policies are consistent with ecosystem principles that call for in-season multi-species catch monitoring to ensure that catch does not exceed the OFL of groundfish. Stocks can be moved from one management category into another only by FMP amendment. Within the target species category, stocks are managed either individually or as part of a stock complex. Stocks within the target species category can be added to or removed from a stock complex within the same category as part of the TAC-setting process (i.e., without an FMP amendment).

The bookends provide a range of potential impacts associated with this alternative. FMP 2.1 is more aggressive than FMP 2.2; thus, the potential impacts of this alternative represent the upper bound of potential impacts imposed by Alternative 2. This upper bound will serve as the reference for discussion of potential impacts of adoption of Alternative 2. Consideration of cumulative impacts did not change the significance ranking for the impacts of this alternative.

Alternative 2 adopts more aggressive harvest measures that continue to prevent overfishing. Several harvest polices allow for an increase in commercial catch. First, the ABC could be set equal to OFL under this alternative. This does not allow a margin of safety to address uncertainty in the recommended harvest level. Elimination of the buffer between F_{ABC} and F_{OFL}, would increase the chance of unintentionally overfishing a stock. Unintentional overfishing occurs when the harvest recommendation is based on a point estimate from the stock assessment that in retrospect proves to be in error. Second, in-season monitoring of catch and enforcement of quotas would be impeded by the repeal of the Observer Program and reductions in the number of observer sea days. Third, the quality of input data for stock assessments would be reduced due to a reduction in the availability of demographic data typically collected by observers. Fourth, FMPs allows expansion of commercial fisheries. Fifth, in the BSAI, FMP 2.1 removes the prohibited species bycatch cap allowing some fisheries to expand. Overfishing did not occur in the stocks or stock complexes modeled under FMPs 2.1 or 2.2. With the exception of GOA DSR, the expected fishing mortality under Alternative 2 would have no significant impact on any of the target groundfish stocks (Table 4.10-2a). Significantly adverse impacts of fishing mortality are expected for GOA DSR (Table 4.10-2a).

Irreversible or long-term adverse effects on fishery resources are avoided by imposing rebuilding regulations when stocks fall below the level capable of producing MSY. However, the likelihood of a stock falling below the level where the stock is capable of producing MSY is higher under Alternative 2 because the linear reduction in fishing mortality when spawning stock falls below $B_{40\%}$ may (FMP 2.2) or may not (FMP 2.1) be imposed. Under FMP 2.1, seven stocks (BSAI and GOA Pacific cod, EBS pollock, BSAI Greenland turbot, AI Atka mackerel, sablefish, and GOA demersal shelf rockfish) would be expected to become overfished. This finding suggests that the impact of Alternative 2 on changes in biomass of target groundfish stocks would be significantly adverse for these stocks when compared to the baseline (Table 4.10-2a). With the exception of GOA Demersal shelf rockfish, the impacts of Alternative 2 on the change in biomass of stocks or stock complexes managed in Tiers 4-6 would be unknown (Table 4.10-2a). Significantly adverse (FMP 2.1) or conditionally significant adverse (FMP 2.2) impacts on the change in biomass of GOA Demersal shelf rockfish are expected under Alternative 2 (Table 4.10-2a).

Relative to the baseline, Alternative 2 relaxes several spatial/temporal restrictions on catch. With the exception of Steller sea lion protection measures, time and area closures would be removed, allowing open access to fishing grounds within the EEZ. These policies would increase the possibility of spatial temporal concentration of the catch and a race-for-fish. In the case of pollock fisheries the race-for-fish may be mitigated by the development of cooperatives and rationalized fisheries under AFA and CDQ. Under this policy, commercial fishing is expected to have unknown impacts on the genetic structure or the reproductive success of the four of 19 stocks managed in Tiers 1-3 (BSAI and GOA Pacific cod, AI Atka mackerel, and BSAI northern rockfish). With the exception of GOA Demersal shelf rockfish, the impact of commercial fishing on the genetic structure or reproductive success of stocks or stock complexes managed in Tiers 4-6 is unknown because the status of such stock relative to their respective MSST, is unknown. Conditionally significant adverse impacts on the genetic structure and reproductive success of GOA Demersal shelf rockfish are anticipated under Alternative 2 (Table 4.10-2a). Additionally, significantly adverse or insignificant impacts on the genetic structure and reproductive success of BSAI Greenland turbot are anticipated.

Relative to the baseline, Alternative 2 would relax restrictions on the spatial temporal partitioning of catch and could increase overall harvest. The impact of these changes on prey availability is expected to be insignificant for all stocks managed in Tiers 1-3. Impacts of commercial fishing on prey availability for all stocks or stock complexes managed in Tiers 4-6 are unknown.

Harvest restrictions, spatial temporal constraints, and gear allocations all serve to mitigate the impact of commercial fishing on fish habitat. With the exception of four stocks (BSAI and GOA Pacific cod, BSAI Atka mackerel, and sablefish), the impacts on target species resulting from habitat disturbance are considered insignificant for all stocks managed in Tier 1-3 (Table 4.10-2a). With the exception of GOA Demersal shelf rockfish, the impacts of Alternative 2 on habitat for stocks or stock complexes managed in Tiers 4-6 are unknown (Table 4.10-2). Conditionally significant adverse impacts on habitat of GOA Demersal shelf rockfish are expected under Alternative 2 (Table 4.10-2a).

When taken in aggregate, Alternative 2 appears to achieve the goal of maximizing economic yield from the resource while still preventing overfishing of the groundfish stocks. Alternative 2 is not effective at preventing the stocks from falling into an overfished condition. Alternative 2 has several weaknesses. First, the buffer between ABC and OFL could be eliminated which would increase the chance of unintentionally overfishing a stock. Second, in-season catch estimates would be more uncertain due to the repeal of the Observer Program. Third, there is no incentive to reduce the number of stocks where stock status is unknown. While harvest policies may build and maintain the species complex, it is still possible to over-harvest a vulnerable member of the complex. Finally, Alternative 2 under FMP 2.1 could eliminate the linear reduction in fishing mortality when spawning biomass falls below $B_{40\%}$. This would allow fishing at the OFL to continue until the stock biomass fell into an overfished condition. As in Alternative 1, Alternative 2 does not require formal definition of MSST for stocks in Tiers 1-3. In practice, this is a technical omission because NOAA Fisheries conducts annual status reviews for the stocks managed in Tiers 1-3. These reviews are included in the SAFE chapters and provided to the NPFMC for use in annual TAC-setting.

The management actions adopted under Alternative 2 would not be consistent with the goal of taking into account individual stock and ecosystem variability. The ability to enforce quotas during the fishing season would be impeded by the repeal of the Observer Program. The repeal of the Observer Program would also lead to increased uncertainty in the stock assessment because of reductions in demographic information typically collected by observers.

4.10.3.3 Preserve Food Web

Impacts to food webs of the BSAI and GOA are not explicitly considered in the goals and objectives and the related management measures of this FMP. Alternative 2 has policies and goals to prevent overfishing, reduce and avoid bycatch, avoid impacts to marine mammals and birds, reduce and avoid impacts to habitat, and address data quality, monitoring and enforcement issues, all of which are important to protection of food web components that include target and non-specified species, PSC species, HAPC biota, and marine mammals and seabirds. However, the management measures proposed to implement these policies, particularly in the FMP 2.1, do not provide as much protection as in the baseline. Specifically, the less stringent OY formula and lack of precautionary adjustments in ABCs (Section 4.10.3.2), elimination of seasonal catch and PSC limits, repeal of IR/IU (Section 4.10.3.4), allowing a directed fishery for forage species (Section 4.10.3.5), repeal of closed areas (Section 4.10.3.6), repeal Observer Program coverage, and repeal of scales and VMS for Steller sea lion prey species (Section 4.10.3.9) provide less protection to a variety of important food web components. The policy analysis in those sections contain details on the level of protection provided by Alternative 2 to these individual components.

One bookend of this alternative (FMP 2.1) does not specifically attempt to incorporate ecosystem considerations into fishery management decisions and could potentially remove some of those that exist in the baseline such as development of ecosystem indicators, building of conceptual models of the food webs and prohibition of directed fisheries for forage fish (which often form a central position in channeling energy through the food web). Analysis of the ecosystem effects of the alternatives involved selection of indicators that would show changes in key members or ecosystem characteristics that are important to the structure and function of marine food webs. Changes in pelagic forage, top predators, spatial/temporal availability of prey, exotic species introductions, energy removal and redirection through fishery catch removals, discarding and offal production, and various measures of diversity were evaluated with respect to the potential of fishing to cause changes sufficient to bring these attributes below population, community, or ecosystem thresholds when such thresholds could be defined.

This alternative showed large negative changes relative to the baseline in some ecosystem indicators such as energy removal and redirection. There were potential impacts to the pelagic forage of northern fur seals and seabirds and significantly adverse impacts to the pelagic forage availability for Steller sea lions and harbor seals, primarily due to the policy of fishing target species up to OFL and opening up the possibility of harvesting forage species. There were conditionally significant adverse impacts to spatial/temporal concentration of prey because this alternative proposes to open up many previously closed areas and may remove seasonal allocations of TAC. Top predators such as seabirds could experience conditionally significant adverse effects because the areas around the Pribilof Islands are opened to fishing. The possibility of introduction of exotic species via fishing vessel ballast water is largely increased relative to the baseline due to the increased levels of fishing vessel effort that might occur in this alternative. Species diversity would be significantly impacted because fishing levels bring some target species such as walleye pollock and Atka mackerel below minimum stock size thresholds. Other species are potentially adversely affected, such as corals and seabirds, while the effects on others, such as sharks, are unknown.

This alternative also has the potential to adversely affect trophic guild diversity by fishing more heavily on target species, such as walleye pollock and Atka mackerel, that tend to be dominant members of their trophic guilds. Structural habitat diversity is adversely affected because of the lack of closed areas to protect sensitive, slow-growing structural habitat members such as corals. Removing the sablefish IFQ program could increase the number of boats and fishing impacts in coral habitats. Qualitative analysis of Alternative 2 with respect to ecosystem effects of the TAC-setting process (Appendix F-1) showed that this alternative has a greater potential to alter community structure through higher harvest levels that would impact predators dependent on those species and through greater gear-related habitat impacts.

Through its assumption that there is no need to provide explicit protection to the food web, this alternative performs poorly at protecting most food web components, even those that are of the most importance economically. This alternative could provide less precautionary management to a whole spectrum of food web components including top predators, pelagic forage, and structural habitat species through its FMP 2.1 management measures. This more aggressive harvesting policy assumes that fishing does not affect the food web and assumes that fishery data collection efforts necessary to monitor fishery effects are mostly unnecessary. This policy has a high potential to create adverse food web impacts through its lack of precaution, which leaves no room for uncertainty, and its possible lack of fishery catch monitoring, which has the potential for adverse impacts to go undetected until dramatic food web changes are seen.

4.10.3.4 Reduce and Avoid Bycatch

Several policy changes adopted in Alternative 2 would impact the incidental catch of target and non-target species and bycatch. A more aggressive harvest strategy would be implemented as illustrated by an open access fishery with very few constraints under FMP 2.1 to a moderately constrained fishery as illustrated by FMP 2.2. Several time, area, or gear constraints to fishing are repealed under Alternative 2 (see Figures 4.2-2 and 4.2-3). With the exception of the AFA and CDQ fisheries, the Observer Program requirements would be repealed in FMP 2.1. Bycatch reduction incentives and bycatch restrictions would be repealed under FMP 2.1, as would PSC limits and IR/IU.

<table>
<tr><th rowspan="2">Goals, Objectives</th><th colspan="2">Corresponding Management Measures</th></tr>
<tr><th>FMP Component</th><th>Management Measure</th></tr>
<tr><td rowspan="7">Goals
• Encourage development of practical measures that minimize bycatch
• Work with state and federal agencies to protect threatened and endangered species

Objectives
• Monitor prohibited species bycatch and adjust or eliminate PSC limits
• Manage incidental catch and bycatch through closure areas for selected gear types</td><td>Spatial/ Temporal Management of TAC</td><td>Spatial/temporal distribution of TAC</td></tr>
<tr><td>MPAs and EFH, Bycatch and Incidental Catch Restrictions, Gear Restrictions and Allocations</td><td>Eliminate/maintain seasonal, gear/fishery specific, and total closure areas identified to reduce bycatch</td></tr>
<tr><td rowspan="4">Bycatch and Incidental Catch Restrictions</td><td>Eliminate/maintain bycatch limits for prohibited species</td></tr>
<tr><td>Procedure to develop adjustable PSC limits based on a percentage of the annual stock status</td></tr>
<tr><td>Repeal/maintain retention standards for pollock and Pacific cod (IR/IU) and DSR</td></tr>
<tr><td>Repeal/maintain incentive programs (VIP) and bycatch restrictions (including in-season)</td></tr>
</table>

Impacts of Policy

Alternative 2 as illustrated by FMP 2.1 and FMP 2.2 is expected to discourage the development of practical measures that reduce bycatch and incidental catch of prohibited species, target species, other species, forage fish and non-specified species. Relative to the comparative baseline, the direct, indirect, and cumulative impacts of mortality and change in biomass of crab stocks would be significantly adverse (FMP 2.1) or conditionally significant adverse (FMP 2.2) for prohibited species that are currently in a depressed or overfished condition (BSAI *C. bairdi* crab, *C. opilio* crab, BSAI and GOA red king crab, and BSAI blue king crab) (Table 4.10-2a). Impacts on GOA *C. bairdi* crab would be conditionally significant adverse (FMP 2.1) or unknown (FMP 2.2). For BSAI chinook and other salmon and GOA chinook salmon, conditionally significant adverse impacts of fishing mortality would be expected under this alternative, and impacts on GOA other salmon would be conditionally significant adverse under FMP 2.1. The expansion of groundfish fisheries, the repeal of the Observer Program, the elimination of prohibited species bycatch limits, and the removal of bycatch reduction incentives would all lead to increased bycatch and incidental catch of non-target species and target species. The development of target fisheries on forage species would be possible under Alternative 2. However, the impacts of new fisheries on forage species are considered insignificant as these fisheries would be restricted by harvest policies as mandated under Alternative 2.

Alternative 2 policies as illustrated by FMP 2.1 are also inconsistent with the objectives of monitoring prohibited species bycatch. Alternative 2 policies as illustrated by FMP 2.2 would be less severe. Repeal of the Observer Program would negatively impact the quality of catch monitoring. Bycatch is often reported as a complex rather than as a species in Alternative 2. The absence of at-sea catch monitoring for vessels less than 60 ft LOA and reduced at-sea catch monitoring due to the repeal of the Observer Program may result in less than adequate protection of non-target species.

4.10.3.5 Avoid Impacts to Seabirds and Marine Mammals

The Alternative 2 policy sets goals and objectives to avoid impacts to seabirds and marine mammals, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	**Management Measure**
Goals • Work with state and federal agencies to protect threatened and endangered species Objectives • Maintain current protection measures to protect ESA-listed seabird species • Maintain current protection measures to avoid jeopardy to ESA-listed Steller sea lions	TAC-setting Process, Steller sea lion Measures	Steller sea lion prey species low biomass rules
	TAC-setting Process	Allow/prohibit directed fishery for forage fish
	Spatial/ Temporal Management of TAC	Spatial/temporal distribution of TAC
	MPAs and EFH, Steller sea lion Measures, Gear Restrictions and Allocations	Seasonal, gear/fishery specific, and total closure areas identified to protect Steller sea lions; repeal/maintain walrus closures
	Seabird Measures	Short-tailed albatross take restrictions
		RPA-recommended gear modifications to protect seabirds

Impacts of Policy

Alternative 2 has a goal of working with state and federal agencies to protect threatened and endangered species by maintaining current protection measures for ESA-listed seabirds and those designed to avoid jeopardy to ESA-listed Steller sea lions. The management measures employed in this alternative include: Steller sea lion prey species low biomass rules, spatial/temporal distribution of TAC, a variety of time/area/gear/fishery closures, total closure areas for Steller sea lion protections, short-tailed albatross take restrictions, and RPA-recommended gear modifications to protect seabirds. This alternative has the potential to allow directed fisheries on forage species and repeal walrus closure areas. Impacts of the alternative with respect to seabirds were evaluated with respect to the potential for fisheries to cause direct mortality through fishing gear and vessel strikes, changes in prey availability (including offal), and changes in benthic habitat that might affect certain prey species of seabirds. Impacts for marine mammals were evaluated with respect to the potential for fishery incidental take or entanglement in marine debris, harvest of prey species, spatial/temporal concentration of fishing on prey, and fishing vessel disturbance.

These indicators showed that impacts of Alternative 2 on seabirds and marine mammals were increased relative to the baseline condition. The incidental take of short-tailed albatross on longline and trawl third-wire collisions may increase above baseline levels because of increased fishing effort. Removal of area closures around the Pribilof Islands may lead to disproportionate take of fulmars from that colony. Elimination of the sablefish IFQ program could also increase seabird incidental take by the increasing longline effort that would occur in that fishery. Potential development of directed forage fish fisheries could substantially alter prey availability and have population level effects on piscivorous seabirds. Although some piscivorous bird species such as glaucous-winged gulls might be gaining food subsidies from discards and offal in the baseline, other piscivorous birds would be negatively impacted by competitive interactions with gulls, thus offsetting any changes for the piscivorous bird group as a whole that might occur in this alternative. Qualitative analysis of the seabird protection measures (Appendix F-6) noted that the reduced emphasis or elimination of the Observer Program under this alternative would compromise the collection of data on seabird/fishery interactions.

Qualitative analysis of the impacts of this alternative with respect to Steller seal lions (Appendix F-4) showed that management measures repealed under this alternative result in large increases in impacts to some marine mammals even though the Steller sea lion-specific measures are retained. The increased catch of key groundfish prey species that would occur in this alternative results in a significantly adverse impact on Steller sea lions. Although the policy objective is to maintain minimum ESA-required protection measures for ESA-listed species, the analysis of FMP 2.1 indicated that the combination of management measures under this FMP may negate the 'no jeopardy' finding in the 2001 Biological Opinion. As a result, FMP 2.1 in its current form may not meet this objective or comply with Federal law. Also, increased catch of prey species may result in potentially adverse effects on other pinnipeds such as northern fur seal and harbor seals that use these prey. The potential repeal of some area closures may result in adverse impacts to groundfish consuming marine mammals through spatial/temporal prey availability and through increased disturbance.

This alternative does poorly at its goal of avoiding impacts to seabirds and marine mammals. It assumes that measures found in the baseline that are not explicitly for protecting marine mammals and seabirds are unnecessary. The potentially more aggressive harvesting policy, relaxation of area closures, possible repeal of the Observer Program and less stringent seabird protection measures do not provide as much certainty about protection to seabirds and marine mammals as in the baseline.

4.10.3.6 Reduce and Avoid Impacts to Habitat

The Alternative 2 policy sets a goal and objectives to reduce and avoid impacts to habitat, as well as recommending a range of management measures that would implement these objectives.

<table>
<tr><th rowspan="2">Goals, Objectives</th><th colspan="2">Corresponding Management Measures</th></tr>
<tr><th>FMP Component</th><th>Management Measure</th></tr>
<tr><td rowspan="3"><u>Goals</u>
• Encourage development of practical measures that minimize the adverse effects of EFH

<u>Objectives</u>
• Evaluate impacts of trawl gear on habitat through implementation of the existing research plan, identify EFH, and determine appropriate habitat protection measures
• Evaluate candidate areas for MPAs</td><td>MPAs and EFH, Bycatch and Incidental Catch Restrictions, Gear Restrictions and Allocations</td><td>Repeal/maintain existing system of closed areas including Sitka Pinnacles</td></tr>
<tr><td rowspan="2">MPAs and EFH</td><td>EO 13158 description and evaluation of potential MPA areas</td></tr>
<tr><td>Identify and designate EFH and HAPC</td></tr>
</table>

Impacts of Policy

Alternative 2 addresses impacts to habitat by specifying goals and objectives that focus on practical measures that minimize adverse effects to EFH. Evaluation of areas as potential MPAs and implementation of the existing research plan to evaluate trawl gear impacts and determine appropriate protection measures are objectives specifically designed for habitat. These goals and objectives could potentially reduce and avoid impacts to habitat in the long-term; however, the overriding objective of Alternative 2 is the maximization of biological and economic yield from the resource by adopting a more aggressive harvest policy for groundfish stocks. This policy is less precautionary than Alternative 1, and the maximization of fishery yield can potentially come at the expense of increased habitat impacts. In addition, the fishery could be returned to an open access regime, where closures, gear restrictions, and prohibited species catch limits are repealed.

Analysis of Alternative 2 involved assessing effects to mortality, damage and diversity of living marine habitat. An assessment of effects on diversity of impacts was performed with the assertion that within fished areas spatially diverse or patchy fishing impacts are preferable to uniformly distributed impacts. Increased TAC levels and repeal of existing closures are expected to cause increased mortality and damage to living habitat, decreased levels of diversity of living marine habitat, and decreased diversity of fishing impacts. Hence, for almost all effects these impacts are rated as significantly adverse or conditionally significant adverse relative to the comparative baseline. The only insignificant effect is diversity of impacts in the Aleutian Islands because under the baseline there are no notable reserves except for shallow areas near Steller sea lion rookeries which will remain closed in this alternative. Though not specifically analyzed, the relaxing of gear restrictions and returning to open access fishing will also increase impacts. For example, bottom trawl gear may replace pelagic trawl gear in some fisheries which will result in more impacts to benthic habitat.

Overall this policy could result in increased impacts to habitat because of less precautionary management measures. Potential elimination of current closed areas and increases in TAC have the potential to result in adverse impacts to habitat that could be hard to reverse, especially for long-lived, slow-recovering living habitats. The policy goal of developing practical measures to minimize adverse effects to EFH could be difficult to achieve if such irreversible impacts occur.

4.10.3.7 Address Allocation Issues

The Alternative 2 policy maximizes biological and economic yield from the resource while still preventing overfishing of the groundfish stocks. A more aggressive harvest strategy would be implemented based upon the concept that the present policy is overly conservative and that higher harvests could be taken without threat of overfishing. In general, Alternative 2 is based on the premise that fishing has minimal negative impacts on marine resources or the ecosystem and therefore places an increased emphasis on the extraction of commercial benefits. The alternative could remove many of the controls on the industry and considers reducing the burden placed on the industry to report its activities.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	**Management Measure**
Goals • Maintain statutorily-mandated programs to reduce excess capacity and the race-for-fish • Involve and be responsive to the needs and interests of affected states and citizens Objectives • Maintain AFA. and CDQ program as authorized by MSA	Gear Restrictions and Allocations	Allocate by gear for certain directed fisheries
	Overcapacity	Statutorily-mandated rights-based management programs (AFA.)
		Could eliminate or maintain LLP, IFQ sablefish, multi-species CDQ, and community quota share

Impacts of Policy

Alternative 2 has the potential to increase catches to the maximum levels allowable while remaining within OFLs. The alternative could eliminate the cushion between ABC levels and levels that result in OFLs. Because of the emphasis on higher harvests, the alternative is expected to significantly increase revenues that can be extracted from the marine resources. However, because harvests are expected to increase with no real change in biomass levels, it is likely that costs to harvest the additional fish will be higher.

The alternative implicitly presumes that additional restrictions on access to the groundfish fisheries are unnecessary, and in the extreme could result in the elimination of programs that are not mandated by Federal statute. Currently, the groundfish LLP, the sablefish IFQ program, AFA, and CDQ programs restrict access to the marine resources to a limited number of persons. If the alternative removes the LLP and IFQ programs (AFA and pollock CDQs are mandated by Federal statute), it is likely that a significant increase in the number of participants in the fisheries will occur (see Appendix F-8). If restricted access programs are eliminated the commercial benefits of the marine resource could be distributed to a broader base. However, even if access programs are not eliminated, the continuation of the race-for-fish will tend to increase overall costs to capture commercial benefits of the resource. Higher costs could be offset to some extent if the requirements of the Observer Program are relaxed. Currently the Observer Program is estimated to cost the industry approximately $12 million per year (see Appendix F-10).

If access restrictions are relaxed, the greater number of participants and vessels in the fishery would also create additional demands for support industries, particularly in communities adjacent to fishing grounds (Hiatt et al. 2001). The emphasis on maximum production and the potential to revert to the race-for-fish is likely, however, to reduce product quality and the health and safety of participants. The alternative could also lead to increased bycatch and shorter seasons if the race-for-fish significantly increases. In addition, because the BSAI pollock fishery remains rationalized with AFA and CDQs, those participants may be able to increase their industry dominance in the long-run.

Because of the more aggressive harvest strategy, the removal of many of the controls on the industry, and the potential reduction in fishery data from the Observer Program, there could be much more uncertainty in the industry (Appendix F). The lack of certainty reduces the ability of commercial interests to plan their business activities, and therefore is likely to reduce profit potential. Furthermore, the emphasis on commercial activity and the lack of controls is likely to result in significantly lower non-market, recreational and tourism values attributed to the ecosystem by the American public. For further information, see the non-market discussion in Section 3.9.8 and discussion on ecosystem values in Section 4.10.3.3.

4.10.3.8 Increase Alaska Native Consultation

The Alternative 2 policy sets objectives to increase Alaska Native consultation, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Objectives • Continue to incorporate Traditional Knowledge in fisheries management • Continue current levels of Alaska Native participation and consultation in fishery management	Alaska Native Issues	Incorporate Traditional Knowledge in fisheries management through existing literature, on-staff anthropologist
		Advisory Panel and NPFMC representation
		Allow for subsistence uses consistent with Federal law

Impacts of Policy

Under Alternative 2, current management policies and measures used by NOAA Fisheries and the NPFMC regarding Alaska Native consultation would be continued. Through the resources of NOAA Fisheries staff anthropologists, the collection of existing Traditional Knowledge, expansion of an in-house Traditional Knowledge database, and informal consultation with individuals in Alaska Native communities would continue. Formal consultation with federally recognized tribal governments during NEPA compliance under EO 13175 would also continue at current levels during NEPA scoping activities and public comment periods on draft NEPA documents. Similarly, opportunities for Alaska Native participation in NEPA compliance and NPFMC deliberations would continue to be available during NEPA scoping, comment on draft NEPA documents, review of NPFMC documents, and at NPFMC meetings.

Alaska Native representation on the NPFMC and its Advisory Panel would remain the same. Currently one NPFMC seat and two Advisory Panel seats are held by Alaska Native representatives. Under Alternative 2, the increased emphasis on harvest levels and removal of some existing controls on the fishery could overshadow consideration of Alaska Native issues related to subsistence.

Alaska Native participation in groundfish fisheries through individual catcher vessels and CDQ groups would generally increase, resulting in benefits to those participants. While the allocation of multi-species harvest to CDQ groups would be eliminated, an increase in the CDQ pollock allocation would increase benefits overall. Similarly, benefits to affected Alaska Native communities would also continue and likely increase, particularly to CDQ communities, generating local employment, secondary economic activities that support of the fishing industry, and community revenue through fish taxes and service fees. Steller sea lion protection measures would remain in effect and subsistence harvest of sea lions is expected to stay at current levels. However, the increase in harvest would result in some adverse effects on Steller sea lion, and cumulative effects on sea lions would remain adverse. Therefore, effects on subsistence harvest of Steller sea lions would be potentially adverse. Direct and indirect adverse effects of groundfish fishing on subsistence resulting from salmon bycatch would increase for BSAI salmon stocks in western Alaska, which are depressed and remain a concern to Alaska Natives. As a result, this alternative would result in potential adverse Environmental Justice effects on Alaska Natives related to adverse subsistence impacts (see the Alaska Native Issues qualitative analysis paper in Appendix F-9).

Under Alternative 2, subsistence uses would continue consistent with federal law. Joint production of subsistence resources, where Alaska Natives who participate in groundfish fishing take advantage of their commercial fishing efforts to harvest subsistence resources, would continue at current levels.

4.10.3.9 Improve Data Quality, Monitoring and Enforcement

Alternative 2 maximizes economic yield under the assumption that fishing has few adverse effects on the environment, and those that are adverse are known and mitigated. The policy sets goals and objectives to address data quality, monitoring and enforcement, as well as recommending a range of management measures that would implement these objectives.

Impacts of Policy

The goal of the alternative is to use the best scientific information available to manage the fisheries and consider the effects of fishing, and to use all available resources (federal, state, and academic) to assist in research, administration, management, and enforcement.

The objectives under Alternative 2 continue the existing industry reporting requirements to provide catch estimates and biological information, and the ongoing efforts to improve economic impact assessments. Additionally, the repeal of the Observer Program is considered.

The existing reporting regulations require vessel captains to provide estimates of total catch and discards, limited species composition data, and haul times and locations. For further information, see the Data and Reporting Requirements paper in Appendix F-11. Industry is not currently required to report cost or revenue data necessary to accurately assess the economic impact of fishing on regional or community economies. Ongoing efforts to elicit voluntary cooperation of industry in researching these data has met with mixed success.

<table>
<tr><th rowspan="2">Goals, Objectives</th><th colspan="2">Corresponding Management Measures</th></tr>
<tr><th>FMP Component</th><th>Management Measure</th></tr>
<tr><td rowspan="5"><u>Goals</u>
• Management approach based on the best scientific information available
• Draw upon federal, state and academic capabilities in carrying out research, administration, management and enforcement
• Consider the effects of fishing

<u>Objectives</u>
• Continue existing reporting requirements to provide catch estimates and biological information
• Continue ongoing effort to improve community and regional economic impact assessments
• Consider repealing the Observer Program</td><td rowspan="2">Observer Program</td><td>Repeal/fixed 0/30/100% Observer Program coverage; 100/200% for AFA. and CDQ</td></tr>
<tr><td>Repeal/third party, pay-as-you-go service delivery model</td></tr>
<tr><td rowspan="3">Data and Reporting Requirements</td><td>Require economic data from industry participants</td></tr>
<tr><td>Repeal except for AFA./require appropriate scales</td></tr>
<tr><td>Repeal/require VMS for Steller sea lion prey species</td></tr>
</table>

Alternative 2 also has an objective to consider repealing the Observer Program. The repeal of the program would apply to all groundfish fisheries with the exception of AFA and CDQ pollock, thus representing an 80 percent cut in observer days (see the Observer Program paper in Appendix F-10). The implications of this repeal are also discussed in other policy sections under this alternative, relating to target species (Section 4.10.3.2), the food web (Section 4.10.3.3), bycatch (Section 4.10.3.4), and allocation issues (Section 4.10.3.7). Because the presumed risk of adversely impacting the environment is assumed in this alternative to be low, the costs to industry of funding the Observer Program to gather fishery data may not be considered necessary. However, observers provide additional information on commercial fishing harvests that may not be otherwise captured by survey vessels or vessel logbook information. Stock assessment data is collected by observers, such as age structures and stomach samples, and fishery scientists use the Observer Program as a platform from which to complete special projects. Also, interactions with marine mammals and endangered seabirds are recorded by observers. The repeal of the Observer Program would increase the reliance of fishery managers on industry data, which is less accurate in terms of total catch and discard estimates, and is not as precise in terms of species reporting. Although there would be less need for inseason management data under Alternative 2 through the repeal of groundfish and potentially PSC bycatch restrictions, accurate catch estimates are still required as part of the annual stock assessment process. As a result, stock assessment scientists may adapt to the lack of precision by generating more conservative catch limit estimates.

As a whole, the Alternative 2 policy emphasizes the maximization of economic yield. The specific goals and objectives require the collection of data to maintain a minimum level to meet conservation requirements. The goal to manage fisheries based on the best available science could potentially be compromised under this policy, as only the pollock fisheries would still be monitored for age-structuring of catch. However, because the presumed risk of adversely impacting the environment is low, the costs imposed on industry of additional monitoring efforts may not be worth the tradeoff in economic yield.

4.10.4 Analysis of Alternative 3

Alternative 3 consists of a management approach statement and a set of policy objectives. The management approach statement provides the key to the underlying rationale and assumptions for the policy, along with policy goals and additional guidelines for the policy.

The management approach statement for Alternative 3 represents the need to balance many competing uses of marine resources and different social and economic goals for fishery management. The management approach statement is summarized in Table 4.10-3. Under this approach, additional conservation and management measures will be taken as necessary to respond to social, economic or conservation needs, or if scientific evidence indicates that the fishery is negatively impacting the environment.

The Alternative 3 management approach statement also indicates that the NPFMC management process will:

- Utilize and improve upon existing processes to involve a broad range of the public in decision-making.

- Maintain the balanced goals of the National Standards Guidelines and other provisions of the MSA as well as the requirements of other applicable law.

A summary of the impacts of Alternative 3 follows below in Section 4.10.4.1. In the remainder of Section 4.10.4, the impacts of the alternative are analyzed in detail, in relation to eight policy subheadings: prevent overfishing, preserve food web, reduce and avoid bycatch, avoid impacts to seabirds and marine mammals, reduce and avoid impacts to habitat, allocation issues, increase Alaska Native consultation, and data quality, monitoring and enforcement. For each subheading, the impacts of the relevant goals and objectives from the management approach are analyzed, using as a guideline the range of implementing management measures for Alternative 3, identified in Section 4.2 and analyzed in Section 4.7.

4.10.4.1 Summary of Alternative 3

The key policy elements that predominantly influence the impacts under Alternative 3 are: the emphasis on rationalizing the fisheries (resulting in increased efficiency and flexibility); the incorporation of ecosystem considerations (increasing the uncertainty buffers in management accounting); and the likelihood of additional closure areas (which may result in a variety of impacts, depending how the closures are situated).

Predictions about the impacts under this alternative are difficult due to the uncertainty involved in defining ecosystem management and predicting the impacts of protecting areas. Increased emphasis on relatively less abundant species, through protection measures and increased monitoring, indicates a tendency towards ecosystem management but as the implications of such management are uncertain. The tendency is to manage cautiously while accelerating research and data-gathering. The large potential gain in flexibility from rationalization has the potential to create ecosystem benefits.

Alternative 3 prevents overfishing of target stocks and reduces the likelihood that stocks will become overfished, through precautionary harvest policies, and imposition of rebuilding regulations when stocks fall below the level capable of producing MSY. This alternative would formally define criteria for determining the status of stocks relative to an overfished condition in order to better satisfy the requirements of the National Standard 1 Guidelines. Efforts would be accelerated to identify methods for reducing the number of stocks where the status relative to an overfished condition is unknown.

This alternative is successful in making many improvements relative to the baseline in achieving the goal of preserving the food web. The emphasis of this alternative is not only on using the best scientific information available to determine catch levels but also on providing additional protection against uncertainty by designation of MPAs and reserves. If these improvements are implemented, this strategy is likely to provide protection to a broad range of food web components.

The bycatch and incidental catch reduction policies in Alternative 3 are consistent with accelerating precautionary management measures through additional bycatch constraints and monitoring. Bycatch reduction objectives and reductions in incidental catch are likely to be achieved without a major cost to industry due to the incentives for more efficient use of fishery resources under cooperatives, comprehensive rationalization of fisheries or other bycatch incentive programs implemented under this alternative.

The goal of minimizing human-caused threats to protected species is largely met in this alternative by actively adjusting protection measures, actively reviewing the status of marine mammal fishery interactions, and through research. This approach, which may provide additional conservation measures in response to scientific evidence, is likely to provide increased protection to marine mammals and seabirds.

This alternative has a potential to reduce and avoid impacts to habitat by careful placement of closures. Placement of closures in lightly fished or not fished areas could result in avoidance of future habitat impacts if fisheries were to move effort into surrounding areas. Placement of closures in heavily fished areas can mitigate impacts, reduce unintended consequences, and achieve overall benefits to habitat if closures do not encompass entire habitat types or areas of fishing intensity. In the short-term, information from the Observer Program could be used to locate such closures. In the long-term, scientific information gained from this policy can potentially lead to modification of the placement of MPAs and help meet the policy objective to assess the necessary and appropriate habitat protection measures. Cumulatively, the alternative results in a split impact rating, as the adverse condition of the baseline is coupled with continued damage and mortality to living habitat, however the alternative has strong potential to mitigate these adverse impacts.

Alternative 3 promotes increased social and economic benefits through the elimination of the race-for-fish while also emphasizing the long-term economic value of the fishery through the promotion of rights-based allocations to individuals, sectors, and communities. In addition, this alternative promotes ecosystem-based management and is likely to increase non-market, recreational, and tourism values assigned to the ecosystem. It is not possible to determine the long-term effect on overall ecosystem value (commercial and non-market values combined) because it is not known whether the fishing sectors, even with rights-based allocations, will be able to adapt to the changes resulting from the increased emphasis on ecosystem tools and, in particular, the additional number and significance of closed areas.

The goals and policies for Alaska Native consultation and participation in fishery management under Alternative 3 would increase current levels by expanding informal and formal consultation between the NPFMC/NOAA Fisheries and Alaska Native participants and tribal governments. Traditional knowledge would be more formally incorporated in fishery management and additional data would be collected. Other goals and objectives in Alternative 3, such as reductions in PSC limits, may benefit subsistence salmon use by reducing bycatch levels in the groundfish fisheries.

Through data collection measures that will result in reducing uncertainty, Alternative 3 is likely to be effective in achieving the goal of accelerating the use of precautionary management measures. The objectives to improve the Observer Program and observer data will increase the quality of fishery data by implementing increased flexibility of, and potentially expanding, observer coverage. Additionally, the expanded economic data and potential for independent verification would allow for more accurate and credible economic impact assessments. A funding source would, however, need to be identified to implement improvements to these programs.

4.10.4.2 Prevent Overfishing

Alternative 3 would seek to accelerate the existing precautionary management measures through community or rights-based management, ecosystem-based management principles, and, where appropriate and practicable, increased habitat protection and additional bycatch constraints. Under this approach, additional conservation and management measures would be taken as necessary to respond to social, economic, or conservation needs, or if scientific evidence indicated that the fishery was negatively impacting the environment. This policy recognizes the need to balance many competing uses of marine resources and different social and economic goals for fishery management. The Alternative 3 policy is illustrated by FMP 3.1 and FMP 3.2. Each FMP contains a number of management measures that pertain to the sustainability of fisheries and fishery resources. The bookends represent a range of actions that alter constraints to fishery removals.

A detailed description of FMP 3.1 appears in Section 4.2. Briefly, FMP 3.1 continues precautionary practices seen in Alternative 1 where TAC is less than or equal to the ABC, and the ABCs are less than the OFL. Uncertainty corrections applied under Alternative 1 to BSAI and GOA Pacific cod and GOA pollock would not apply. OY restrictions would be identical to Alternative 1, where the OY range for the BSAI and GOA is capped at 2 million mt and 800,000 mt for the BSAI and GOA, respectively. The 2 million mt cap in the BSAI would limit the expansion of fisheries. The FMP would formally specify MSSTs for Tiers 1-3 in accordance with National Standard Guidelines. Sharks and skates would be removed from the other species complex and given their own TACs, and criteria to do the same for other target stocks would be developed. Efforts to develop ecosystem indicators to be used in TAC-setting, as per ecosystem management principles, would be accelerated.

In order to balance the needs of social and economic stability with habitat protection and resource conservation, the NPFMC would conduct a review of the existing system of closure areas in the BSAI and the GOA (for closure areas under FMP 3.1, see Figure 4.2-4), and evaluate them against a developed MPA methodology.

FMP 3.1 recognizes that the anticipated community or rights-based management programs may address bycatch reduction objectives (a review of bycatch in existing programs is initiated), but in the meantime accelerated precaution counsels a moderate reduction of PSC limits as an intermediary step. Additionally, in the GOA the FMP would add PSC limits for crab, herring and salmon to its specifications for halibut. Effective monitoring and timely reaction to change in the environment and the fisheries would be enhanced through improvements in the Observer Program and third party verification of economic data.

Goals, Objectives	**Corresponding Management Measures**	
<u>Goals</u> • Accelerate the existing precautionary management measures through community or rights-based management, ecosystem-based management principles • Where appropriate and practicable, increase habitat protection and impose additional bycatch constraints • Sound conservation of living marine resources <u>Objectives</u> • Adopt conservative harvest levels for multi-species and single species fisheries • Provide for adaptive management. • Continue to specify OY as a range or a formula • Initiate a scientific review of the adequacy of $F_{40\%}$ • Continue to collect scientific information and improve upon MSSTs including obtaining biological information necessary to move Tier 4 species into Tiers 1-3 in order to obtain MSSTs	Example Range: TAC $\leq$ABC$\leq$OFL, formal adjustments for uncertainty, automatic rebuilding, specific harvest policies for rockfish	Quota management based on a tier system. F_{ABC} set below F_{OFL} except at very low stock sizes protecting the stock from unintentional overfishing. Additional adjustments for uncertainty are incorporated into F_{ABC} under FMP 3.2. For tier 3 stocks, F_{ABC} is decreased linearly with biomass whenever biomass falls below a tier-specific reference level. For example purposes only, F_{ABC} for Tier 3 rockfish stocks would be set at $F_{60\%}$.
	Time/Area	For several species, fishing quotas are distributed across time and area in proportion to the expected underlying biomass of fish in the region at that time. These policies reduce the possibility of spatial temporal concentration of the catch. Relative to FMP 1 and FMP 3.1, FMP 3.2 imposes additional marine reserves and marine protected areas.
	Gear restrictions	For walleye pollock, Pacific cod, and sablefish, gear allocations partition catch to specific gear groups. Differences in gear selectivity are addressed in the stock assessment models and quotas reflect the expected age distribution of the catch by gear.
	OY caps	Under FMP 3.1, OY restrictions cap the aggregated groundfish catch in the GOA and BSAI at 800,000 mt and 2 million mt, respectively. These caps limit the expansion of fisheries (particularly in the BSAI). These OY caps would be replaced with species specific OYs under FMP 3.2
	Inseason Multi-species TAC and ABC monitoring	The catch of a given target species is limited by prohibited species bycatch caps and the TACs for other groundfish. The halibut bycatch caps serve as a constraint to BSAI and GOA flatfish expansion. Reduced bycatch allowances would further constrain target fisheries. Sharks and skates would be moved from the other species management category.

FMP 3.2 incorporates an uncertainty correction into the estimation of ABC for all species. This represents a significant acceleration of precautionary management. Additionally, OY would be specified separately for each stock or stock complex rather than for the groundfish complex as a whole (i.e., the 2 million mt OY cap would be eliminated), and would be set equal to the species-respective TAC. FMP 3.2 would also incorporate taxon-specific biological reference points in the tier system where scientifically justifiable. For example purposes, FMP 3.2 capped F_{ABC} at $F_{60\%}$ rather than $F_{40\%}$ for stocks managed in Tiers 1-3. In implementing this bookend, criteria would be developed for specifying MSSTs for Tiers 4-6, along with a list of priority candidate stocks; and a development of criteria for moving stocks from the other species and non-specified species categories would minimally result in sharks and skates being given their own TACs.

FMP 3.2 also reexamines the existing closure system in the BSAI and the GOA. The closures aim to provide protection for a wide range of species, from Steller sea lions to slope rockfish to prohibited species, as well as to respect traditional fishing grounds and maintain open area access for coastal communities. Additionally, the bookend would extend the existing bottom-trawl ban on pollock to the GOA.

To increase precaution regarding bycatch, PSC limits would be significantly reduced by the NPFMC (and set for all prohibited species in the GOA), but would not be expected to act as a proportionate restraint on the fisheries due to the incentives for bycatch reduction under cooperatives, or other bycatch incentive programs implemented as necessary under this bookend.

Impacts of Policy

Alternative 3 limits the impact of fishing mortality by setting an ABC less than the OFL. This alternative defines four management categories for which catch is constrained by various regulatory mechanisms: target species, other species, prohibited species and forage fish species. Alternative 3 harvest policies are consistent with ecosystem principles that call for in-season multi-species catch monitoring to ensure that catch does not exceed the OFL of groundfish. This catch monitoring is facilitated by at-sea observers, port samplers, weekly production reports and fish ticket information (Appendix F-10). Stocks can be moved from one management category into another only by FMP amendment. Within the target species category, stocks are managed either individually or as part of a stock complex. Stocks within the target species category can be added to or removed from a stock complex within the same category as part of the TAC-setting process (i.e., without an FMP amendment).

The bookends provide a range of potential impacts associated with this alternative. FMP 3.1 is similar to FMP 1 except that uncertainty corrections applied under Alternative 1 to BSAI and GOA Pacific cod and GOA pollock would not apply. FMP 3.2 imposes more constraints to fisheries removals and allows the OY caps for the GOA and BSAI to equal the sum of the ABCs of groundfish for the GOA and BSAI regions respectively.

Several measures associated with Alternative 3 could result in reductions in catch relative to baseline conditions. First, an uncertainty correction could be applied that would account for measurement and process error in the assessment (FMP 3.2). Second, the ABC for Tier 3 rockfish species could be set at $F_{60\%}$ (FMP 3.2). Third, a 0-10 percent (FMP 3.1) or 10-30 percent reduction (FMP 3.2) in bycatch would be imposed under this alternative. Finally, sharks and skates would be broken out of the other species complex. While the FMPs used to illustrate Alternative 3 demonstrate conservative harvest polices, it is important to note that the combinations of tools available under Alternative 3 could lead to a more aggressive harvest. For example, if the quota system described in FMP 3.1 and the OY system described in FMP 3.2 were adopted, the BSAI pollock fisheries could be expanded during periods of high abundance. Direct and indirect impacts analyses revealed that overfishing did not occur in the stocks or stock complexes modeled under FMPs 3.1 or 3.2 (Table 4.7-1). Relative to the comparative baseline, the expected fishing mortality under Alternative 3 would have no significant impact on any of the target groundfish stocks. Consideration of cumulative impacts does not change the expectations for direct or indirect impacts of this alternative on fishing mortality.

Relative to the comparative baseline, the likelihood of a stock falling below the level where the stock is capable of producing MSY is reduced under Alternative 3. Under FMP 3.1 and FMP 3.2 none of the stocks managed in Tiers 1-3 would be expected to become overfished. The direct and indirect impact of Alternative 3 on changes in biomass of all of the Tier 1-3 target groundfish stocks would be insignificant relative to the baseline (Table 4.7-1). The direct and indirect impact of commercial fishing on the biomass of target groundfish stocks managed in Tiers 4-6 is unknown because the status of such stocks relative to their respective MSSTs is unknown (Table 4.7-1). Consideration of cumulative impacts does not change the expectations for direct or indirect impacts of this alternative on changes in biomass.

Relative to the comparative baseline, FMP 3.2 adds several spatial/temporal restrictions on catch. These restrictions would decrease the spatial/temporal concentration of the catch. Under this policy, commercial fishing is expected to have insignificant impacts on the genetic makeup or the reproductive success of the 19 stocks managed in Tiers 1-3. The direct and indirect impact of commercial fishing on the genetic makeup or reproductive success of stocks managed in Tiers 4-6 is unknown because the status of such stocks relative to their respective MSSTs is unknown. Alternative 3 would initiate research to define MSSTs for stocks managed in Tiers 4-6. Once the MSST definition is established, the significance of commercial harvest on Tiers 4-6 stocks could be evaluated. Consideration of cumulative impacts does not change the expectations for direct or indirect impacts of this alternative on fishing mortality.

Relative to the comparative baseline, Alternative 3 would increase restrictions on the spatial temporal partitioning of catch and could reduce overall harvest of target groundfish. The direct and indirect impact of these changes on prey availability is expected to be insignificant or unknown for all stocks managed in Tiers 1-3 (Table 4.7-1). Direct and indirect impacts of commercial fishing on prey availability of all stocks or stock complexes managed in Tiers 4-6 are unknown because the status of such stocks relative to MSST is unknown (Table 4.7-1). Consideration of cumulative impacts does not change the expectations for direct or indirect impacts of this alternative on fishing mortality.

Harvest restrictions, spatial temporal constraints, and gear allocations all serve to mitigate the impact of commercial fishing on fish habitat. The closure system described in the FMP 3.2 would close approximately 18 percent of the EEZ to some form of MPA and designates approximately 3.1 percent of the EEZ as a no-take reserve (Figure 4.2-5). For the fishable area (depth to 1,000 m) of the EEZ, FMP 3.2 would designate approximately 8 percent of the fishable area as a no-take reserve and about 40 percent of the fishable area as some form of MPA. Relative to the comparative baseline, the impacts on target species resulting from habitat disturbance are considered insignificant or unknown for all stocks managed in Tiers 1-3 (Table 4.10-2a). The impacts are unknown for stocks or stock complexes managed in Tiers 4-6.

When taken in aggregate, Alternative 3 appears to accelerate the existing precautionary management measures through community or rights-based management, ecosystem-based management principles and, where appropriate and practicable, increased habitat protection and additional bycatch constraints.

Irreversible or long-term adverse effects on fishery resources are avoided by precautionary harvest policies and imposition of rebuilding regulations when stocks fall below the level capable of producing MSY. Strengths of Alternative 3 are that the FMPs will adopt formal criteria for status determination, and research will be accelerated to develop ecosystem-based harvest policies. The community or rights-based management would reduce the race-for-fish under Alternative 3. Efforts would be accelerated to identify methods for reducing the number of stocks where the status relative to an overfished condition is unknown. Alternative 3 would establish formal specifications for MSST whenever possible. Another strength of this policy is that FMP 3.2 would develop a list of priority candidate stocks for moving stocks from the other species and non-specified species categories. The catch of these species would be monitored. Until this system is developed, harvest policies may build and maintain the species complex, but it is still possible to over harvest a vulnerable member of the complex.

4.10.4.3 Preserve Food Web

The Alternative 3 policy sets goals and objectives to preserve the food web, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	**Management Measure**
Goals • Accelerate precautionary management measures through ecosystem-based principles • Promote sound conservation of living marine resources • Incorporate ecosystem-based considerations into management decisions • Take into account NAS Sustainable Fisheries policy recommendations Objectives • Incorporate ecosystem-based considerations into fishery management decisions • Develop indices of ecosystem health as targets for management • Improve the procedure to adjust ABCs as necessary to account for uncertainty and ecosystem factors such as predator-prey relationships and regime shifts • Initiate a research program to identify the habitat needs of different species that represent the significant food web	TAC-setting Process	Prohibit directed fishery for forage fish
		Procedures to incorporate precaution and uncertainty into ABCs
		Procedure to develop and use key ecosystem indicators in TAC-setting

Impacts of Policy

Impacts to food webs of the BSAI and GOA are mitigated through many of the goals and objectives and related management measures of this alternative, some of which are improvements beyond those provided in the baseline. In addition to objectives specifically for incorporating ecosystem considerations into fisheries management decisions and prohibition of directed fisheries for forage fish (which often form a central position in channeling energy through the food web) and precautionary adjustments to ABCs made to Tier 1 stocks that were part of Alternative 1, this alternative provides for the possibility of developing explicit procedures for incorporating predator/prey relationships and regime shifts in ABC adjustments and initiates a research program to identify the different habitat needs of species that are significant food web components. Other policies of this alternative such as preventing overfishing, reducing bycatch, avoiding impacts to seabirds and marine mammals, reducing impacts to habitat, and improving data quality, monitoring, and enforcement are critical to protection of food web components, which include target and non-specified species, PSC species, HAPC biota, and marine mammals and seabirds. Management measures such as revised procedures for ABC, MSST setting, incorporating precaution, and space/time allocation for TAC (Section 4.10.4.2); additional bycatch reduction measures (Section 4.10.4.4); further gear modifications for seabird protection and possible extension of fishery closure areas and seasonal take for marine mammal protection (Section 4.10.4.5); procedures to identify MPAs and no-take marine reserves (Section 4.10.4.6) and improvements to the Observer Program coverage (Section 4.10.4.9) that are proposed as improvements beyond the baseline in Alternative 3 provide increased protection to a variety of food web components. See the policy analysis in those sections for details on the level of protection provided by Alternative 3 to these individual components.

This alternative specifically attempts to incorporate ecosystem considerations into fishery management decisions through advancements in how uncertainty and ecosystem factors such as predator/prey relationships and regime shifts are used in ABC adjustment. It will continue to prohibit directed fisheries for forage fish, develop ecosystem indicators, and develop conceptual models of the food web. Analysis of the ecosystem effects of Alternative 3 involved selection of indicators that would show changes in key members or ecosystem characteristics that are important to the structure and function of marine food webs. Changes in pelagic forage, top predators, spatial/temporal availability of prey, exotic species introductions, energy removal and redirection through fishery catch removals and discards/offal production, and various measures of diversity were evaluated with respect to the potential of fishing to cause changes sufficient to bring these attributes below population, community, or ecosystem thresholds, if such thresholds could be defined. Most of these indicators showed there were insignificant impacts of this alternative on these ecosystem attributes. There were unknown effects of this alternative on top predator species and species diversity due to our lack of knowledge of abundance levels and life history characteristics of species such as skates, sharks, and grenadiers, although breaking these species out of the other species group and giving each its own TAC would provide additional protection. The additional area closures proposed in the FMP 3.2 of this alternative would result in improvements relative to the comparative baseline in spatial/temporal availability of forage to marine mammals and birds and protection of corals. Qualitative analysis of this alternative with respect to the ecosystem effects of the TAC-setting process (Appendix F-1) showed that increased protection is provided in this alternative to stocks that need it most, such as slower-growing, long-lived species such as rockfish, skates, and sharks and would thus reduce the possibility of adverse impacts to those groups and to their role in the food webs of these ecosystems. Thus, if these improvements are implemented, this alternative has the potential to decrease ecosystem impacts relative to the comparative baseline.

As a whole, through its goal to accelerate precautionary management measures through ecosystem-based principles and objectives to develop indices of ecosystem health and take ecosystem factors into account in ABC setting, and to initiate a habitat research program, this alternative is successful in making many improvements beyond the status quo in achieving the goal of preserving the food web. The emphasis in this alternative is on using the best scientific information available to determine catch levels but also on providing additional protection against uncertainty by designation of MPAs and reserves. If these improvements are implemented, this strategy is likely to provide protection to a broad range of food web components.

4.10.4.4 Reduce and Avoid Bycatch

Several policy changes adopted in Alternative 3 would change the incidental catch of target and non-target species and bycatch. The expected incidental catch of target and non-target species under Alternative 3 is difficult to project. The expected TAC under Alternative 3 could increase substantially if management adopted Amendment 56 as described in FMP 3.1 but modified the OY range as described under FMP 3.2. On the other hand, expected TAC could decrease if the uncertainty correction and reduced rockfish F_{OFL} described by FMP 3.2 were adopted. Breaking sharks and skates from the other species complex would ensure that these species are not harvested at rates above the Maximum Fishing Mortality Threshold. Criteria for defining the membership within species complexes and the circumstances when species should be broken out of complexes would be developed.

Many precautionary conservation benefits would be realized in FMPs 3.1 and 3.2 through the comprehensive rationalization of all fisheries (except those already part of a cooperative or IFQ program). Community or rights-based management programs may address bycatch reduction objectives (a review of bycatch in existing programs is initiated), but in the meantime a moderate reduction of PSC limits would be adopted as an intermediary step. The NPFMC would also be addressing habitat and bycatch concerns by reducing concentrated effort in the fisheries.

Effective monitoring and timely reaction to change in the environment and the fisheries would be enhanced through increases in coverage and improvements to the Observer Program, as well as an increase in the use of VMS and the range of economic data collected from industry. Alternative 3 would require 100 percent observer coverage for boats over 60 ft LOA. Additional observer coverage would reduce uncertainty in catch composition and demographic information collected at sea by observers. Improved species identification of other species and forage fish would be achieved under Alternative 3.

Impacts of Policy

Alternative 3 is expected to encourage the development of practical measures that reduce bycatch and incidental catch of target and non-target species. Relative to the comparative baseline, the impacts of mortality and change in biomass associated with the Alternative 3 policy would be insignificant for prohibited species that are currently in a depressed or overfished condition (BSAI and GOA chinook salmon, *C. bairdi* crab, *C. opilio* crab, BSAI and GOA red king crab, and BSAI blue king crab [Table 4.10-2a]). While cumulative impacts are considered conditionally significant, adverse impacts due to mortality are still expected for the species noted above as well as for BSAI and GOA chinook salmon. Alternative 3 is expected to have an insignificant impact on forage fish. The impact of Alternative 3 on other species and non-specified groups is unknown.

Alternative 3 policies as illustrated by FMPs 3.1 and 3.2 are consistent with the goal of accelerating precautionary management measures through additional bycatch constraints where appropriate and practicable. Alternative 3 policies are also consistent with the objective of monitoring prohibited species bycatch. Increased precaution regarding bycatch would be achieved through reductions in PSC limits. Bycatch reduction objectives (0-10 percent for FMP 3.1 or 10-30 percent for FMP 3.2) and reductions in incidental catch are likely to be achieved due to the incentives for more efficient use of fisheries resources under cooperatives, comprehensive rationalization of fisheries, or other bycatch incentive programs implemented under this alternative.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Goals • Accelerate precautionary management measures through additional bycatch constraints where appropriate and practicable • Promote sound conservation of living marine resources • Minimize human-cause threats to protected species Objectives • Continue and improve current incidental catch and bycatch management program • Develop incentive programs for incidental catch and bycatch reduction including the development of mechanisms to facilitate the formation of bycatch pools, vessel bycatch allowance, or other bycatch incentive systems • Encourage research programs to evaluate current population estimates for non-target species with a view to setting appropriate bycatch limits as information becomes available • Continue program to reduce discards by developing management measures that encourage the use of gear and fishing techniques that reduce discards	Spatial/ Temporal Management of TAC	Spatial/temporal distribution of TAC
	MPAs and EFH, Bycatch and Incidental Catch Restrictions, Gear Restrictions and Allocations	Seasonal, gear/fishery specific, and total closure areas identified to reduce bycatch; reviews to develop appropriate closure bycatch closure areas in the GOA
	Bycatch and Incidental Catch Restrictions	Reduce existing PSC limits for prohibited species, establish PSC limits for prohibited species other than halibut in the GOA
		Procedure to develop mortality rate-based approach to setting limits
		Retention standards for pollock and Pacific cod (IR/IU) and DSR
		Review bycatch reduction incentive programs (repeal/maintain VIP)
		Bycatch restrictions (including in-season)/ repeal or modify MRBs and establish system of caps and quotas

4.10.4.5 Avoid Impacts to Seabirds and Marine Mammals

The Alternative 3 policy sets goals and objectives to avoid impacts to seabirds and marine mammals, as well as recommending a range of management measures that would implement these objectives.

Impacts of Policy

This alternative seeks to provide conservation of living marine resources and minimize, to the extent practicable, human-caused threats to protected species. It will accomplish those goals through continued cooperation with USFWS to protect seabird species, initiation of a joint research program with USFWS to evaluate populations of seabirds that interact with groundfish fisheries, maintenance or possible adjustment of current protection measures for Steller sea lions to avoid jeopardy, and review of marine mammal/fishery interactions and development of appropriate fishery management measures for mitigation, if needed. Management measures that are improvements beyond those provided in the status quo include harvest control rules for Steller sea lion prey species, possible extension of seasonal/gear/fishery specific closures and total closure areas for walrus and Steller sea lion protection, and possible gear improvements to protect seabirds. Elimination of the race-for-fish in this alternative may also tend to decrease direct takes of marine mammals and seabirds. Impacts of the alternative with respect to seabirds were evaluated with respect to the potential for fisheries to cause direct mortality through fishing gear and vessel strikes, changes in prey availability (including offal), and changes in benthic habitat that might affect certain prey species of seabirds. Impacts for marine mammals were evaluated with respect to the potential for fishery incidental take or entanglement in marine debris, harvest of prey species, spatial/temporal concentration of fishing on prey, and fishing vessel disturbance.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	**Management Measure**
<u>Goals</u> • Promote sound conservation of living marine resources • Minimize human-cause threats to protected species <u>Objectives</u> • Continue to cooperate with USFWS to protect ESA-listed and other seabird species • Initiate joint research program with USFWS to evaluate current population estimates for all seabirds species that interact with the groundfish fisheries • Maintain or adjust current protection measures as appropriate to avoid jeopardy to ESA-listed Steller sea lions • Encourage programs to review status of other marine mammals stocks and fishing interactions (right whales, sea otters, etc.) and develop fishery management measures as appropriate	TAC-setting Process, Steller sea lion Measures	Steller sea lion prey species low biomass rules/ Steller sea lion prey species harvest control rule
	TAC-setting Process	Prohibit directed fishery for forage fish
	Spatial/ Temporal Management of TAC	Spatial/temporal distribution of TAC
	MPAs and EFH, Steller sea lion Measures, Gear Restrictions and Allocations	Maintain/extend as necessary seasonal, gear/fishery specific, and total closure areas identified to protect walrus and Steller sea lions
	Seabird Measures	Short-tailed albatross take restrictions
		Develop further gear modifications to protect seabirds

These indicators showed that Alternative 3 provides increased protection to seabirds and marine mammals relative to the comparative baseline. As in Alternative 1, incidental take of albatross, fulmars, shearwaters, and gulls is substantially reduced due to new mitigation measures in the longline fleet. In addition, mitigation measures for the trawl fleet are likely to reduce collisions with trawl third wires. The Seabird Protection Measures paper (Appendix F-6) noted that the Observer Program would be expanded under this alternative to improve the collection of seabird/fishery interaction data and to measure the effectiveness of mitigation measures. The groundfish fishery is not expected to have population level effects on any seabird species through mortality, changes in food availability, or benthic habitat. Although some piscivorous bird species such as glaucous-winged gulls might be gaining food subsidies from discards and offal in the baseline, other piscivorous birds would be negatively impacted by competitive interactions with gulls, thus offsetting any changes for the piscivorous bird group as a whole that might occur in this alternative.

Qualitative analysis of this alternative with respect to Steller sea lions (Appendix F-4) found that the additional proposed protection measures would function to further separate the groundfish fishery in space an time and would result in an additional buffer against uncertainty with respect to protection of Steller sea lions and some other marine mammals. Some improvements to marine mammal impacts are seen relative to the comparative baseline because of additional closures out to 15nm and designation of MPA under this alternative. Even though Alternative 1 showed no serious adverse impacts to marine mammals and seabirds, this alternative provides an additional buffer against uncertainty by providing additional protection.

The goal of minimizing human-caused threats to protected species is largely met in this alternative by actively adjusting protection measures, status review of marine mammal fishery interactions, and research. This approach, which may provide additional conservation measures in response to scientific evidence , is likely to provide increased protection to marine mammals and seabirds.

4.10.4.6 Reduce and Avoid Impacts to Habitat

The Alternative 3 policy sets goals and objectives to reduce and avoid impacts to habitat, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Goals • Accelerate precautionary management measures through increased habitat protection where appropriate and practicable • Promote sound conservation of living resources • Maintain a healthy marine resource habitat Objectives • Develop goals, objectives and criteria to evaluate the efficacy of MPAs and no-take marine reserves as tools to maintain abundance, diversity, and productivity of marine organisms • Consider implementation of MPAs if and where appropriate, giving due consideration to areas already closed to various types of fishing operations • Develop a research program to identify regional baseline habitat information and mapping • Evaluate the impacts of all gear on habitat through the implementation of a comprehensive research plan, to determine habitat protection measures as necessary and appropriate • Identify and designate EFH and HAPC	MPAs and EFH, Bycatch and Incidental Catch Restrictions, Gear Restrictions and Allocations	Existing system of closed areas including Sitka Pinnacles, modify based on MPA process
	MPAs and EFH	Develop procedure to identify MPAs and no-take marine reserves
		Identify and designate EFH and HAPC, EFH mitigation measures part of MPA development process

Impacts of Policy

Alternative 3 addresses impacts to habitat by having specific goals and objectives that focus on living marine habitat. This policy accelerates habitat protection where appropriate and practicable and could result in a gradual-to-rapid reduction and avoidance of impacts to habitat depending on how quickly management measures are implemented. Development of a procedure to identify MPAs and no-take marine reserves and identification of EFH mitigative features are identified as specific management measures.

In addition to the objectives specifically designed to address habitat concerns, Alternative 3 policies are designed to prevent overfishing, reduce and avoid bycatch, incorporate ecosystem considerations, and improve data quality and enforcement. These goals are important ancillary objectives that could provide reduced impacts to habitat. Management measures such as revised procedures for ABCs that incorporate greater precaution can potentially reduce impacts to habitat if fishing effort is reduced. Closures for marine mammal protection, especially if they are year round for all target species, can also provide protection to specific habitat types. Measures to avoid and reduce impacts could occur on a rapid time line, especially if precautionary measures are implemented before complete scientific information is available.

A composite of several different concepts for habitat protection and mitigation were qualitatively analyzed. After the concepts were analyzed, specific implementations of the concepts were analyzed and results compared to the comparative baseline. The basis for these conceptual closures is to illustrate how the effects of fishing on EFH can be mitigated by reducing the impacts caused by a particular fishery by closing specific areas. The conceptual strategies are:

- Reduce the impacts caused by a particular fishery by closing specific areas.

- Incorporate a "band-approach" where closures would be oriented perpendicular to depth contours from near shore to deep water assuring protection of a diversity of habitat types across a range of geographic areas.

- Develop a special conservation area in the Aleutian Islands to protect sensitive cold water coral communities.

- Create rotational closures.

All of these approaches are variations of MPAs. Concepts 1-3 have the most potential for benefits to habitat. However, careful placement of the MPAs is required to avoid unintended consequences. Displacement of effort to new areas with more sensitive habitat may be an unintended consequence. If closures are placed primarily in areas with high fish densities and displace effort into areas of low densities then increased effort in a given area could lead to more habitat impacts. For closures to be most effective they should be combined with some effort controls. Ancillary management measures associated with Alternative 3 that result in reduced effort could result in increased effectiveness of MPAs. However, closures alone, if they are strategically placed within historically fished areas, can provide benefits to habitat without necessarily requiring a reduction in TACs. Benefits to habitat could occur with closure areas strategically placed that do not encompass entire habitat types or clusters of fishing intensity. To be most effective, closure areas should include some portion of areas where high fishing intensity has occurred, but need not be so large that they encompass entire habitat types or clusters of fishing intensity. Placement of small closures within areas of high fishing intensity could also promote scientific understanding of the effectiveness of such management measures. The specific location of MPAs could have serious social and economic consequences. Determining where to locate MPAs for habitat goals should include consultation with the fishing industry and nearby communities.

Rotational closures could protect sea floor habitat while not permanently closing an area to fishing. However, rotational closures are not appropriate for highly structured sea floor habitats with long-lived species. For rotational closures to be effective, specific knowledge of indicator species' recovery times is required because if the rotation schedule is less than the recovery time then all areas may be maintained in a disturbed state with little benefits to habitat. If not carefully implemented, a more homogeneous distribution of fishing effort and habitat disturbance than in years prior to the closure could occur.

Analysis of specific management measures indicated mixed ratings relative to the comparative baseline for effects to mortality and damage to living habitat. These mixed ratings result from the specific location of bottom trawl closure MPAs and the uncertainty of how changes in TAC will interact with MPAs. For example, in the GOA many of the specific strategy (1) closed areas on the slope are encompass high effort areas which would be expected to have higher target fish densities. This could result in a much higher effort to catch fish in lower density open areas. This higher effort could result in enough of an increase in habitat impacts to negate impact reduction in the closed areas. Whether decreased TACs for some species will offset this increase in habitat impacts is uncertain. This uncertainty in predicted impacts led to a insignificant or possibly significantly adverse change to mortality and damage to living habitat relative to the baseline in the GOA.

This policy could lead to improved benthic community diversity and geographic diversity of impacts. Analysis of specific management measures in the Bering Sea indicated some improvement in the geographic diversity of impacts. Large expanses of high fishing intensity could still remain open in the Bering Sea, but there is at least one closure area that covers a portion of a high fishing intensity area, providing some improvement in the geographic diversity of impacts. In the Aleutian Islands, some closure areas bisect apparent historic clusters of fishing patterns, thus providing a diversity of impacts for the habitat being fished. In the GOA, closures also often encompass clusters of historically high fishing intensity, leaving little diversity or contrast of fishing intensity and thus leading to no improvement over the baseline.

From a cumulative impacts perspective, the baseline condition is adversely impacted due to historical impacts that have potentially caused long-term and possibly irreversible loss of living habitat, especially to long-lived, slow-growing species which are slow to recover. Although some benefits accrue to habitat within the proposed MPAs in FMP 3.2, impacts from fishing are not totally eliminated, and TAC/effort is likely to remain high. While there is an incremental expansion of no-take MPAs, the closures analyzed under this FMP 3.2 are not refined and may not be effective at preventing mortality or protecting benthic community structure. However, if properly designed and located, future closures could provide successful mitigation of the effects of fishing and, over time, adversely impacted habitat could recover. The cumulative impact predicted for this alternative is a split rating of conditionally significant adverse/conditionally significant beneficial. The adverse state of the baseline condition particularly with regard to slow-growing species would continue the cumulative adverse impact, however the alternative has the potential to provide mitigative benefits to affected habitat.

Overall, this policy has the potential to reduce and avoid impacts to habitat by careful placement of closures. Placement of closures in lightly fished or not fished areas could result in avoidance of future habitat impacts, if effort expands to new or lightly fished areas. Placement of small closures within heavily fished areas can potentially mitigate impacts, reduce unintended consequences, and achieve overall benefits to habitat and meet policy goals and objectives. Strategic placement of small closures will also help meet the policy objective of evaluating the efficacy of MPAs and implementation of a research program to evaluate impacts of gear. In the long-term, scientific information gained from this policy can potentially lead to modification of the placement of MPAs and help meet the policy objective to assess the necessary and appropriate habitat protection measures.

4.10.4.7 Address Allocation Issues

This policy would seek to accelerate the existing precautionary management measures through community or rights-based management and ecosystem-based management principles. Under this approach, additional conservation and management measures would be taken as necessary to respond to social, economic or conservation needs, or if scientific evidence indicated that the fishery was negatively impacting the environment. This policy recognizes the need to balance many competing uses of marine resources and different social and economic goals for fishery management.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	**Management Measure**
Goals • Accelerate precautionary management measures through community rights-based management • Take into account NAS Sustainable Fisheries policy recommendations • Provide socially and economically viable fisheries and fishing communities	Gear Restrictions and Allocations	Allocate by gear for certain directed fisheries
Objectives • Provide economic and community stability to harvesting and processing sectors through fair allocation of fishery resources • Maintain LLP program and further decrease excess fishing capacity and other adverse effects of the race-for-fish by eliminating latent licences and extending programs such as community or rights-based management to some or all groundfish fisheries • Provide for adaptive management by periodically evaluating the effectiveness of rationalization programs and the allocation of property rights based on performance • Extend the cost recovery program to all rationalized groundfish fisheries to support fishery management	Overcapacity	LLP program for groundfish fisheries Procedures and development of rights-based management programs for the groundfish fisheries, to include community quota programs or other community protections

Impacts of Policy

Alternative 3 promotes increased social and economic benefits through the promotion of rights-based allocations to individuals, sectors and communities. In addition, this alternative promotes ecosystem-based management which could increase the specificity of the species reporting, could increase the areas in which fishing is restricted, and places additional emphasis on the reduction on bycatch. For that reason this policy alternative has the potential to increase non-market value and the benefits derived from recreational, subsistence and tourism activities related to the BSAI and GOA marine ecosystems. See Section 3.9.8 and Section 4.10.4.3 for additional information on ecosystem values.

As the race-for-fish is eliminated, the alternative could result in positive effects in terms of producer net revenue, consumer benefits, and participant health and safety. For additional information on the effects of the race-for-fish and rights-based management see the Overcapacity qualitative analysis paper in Appendix F-8. The policy provides economic stability to fishery participants and communities by maintaining current allocation percentages to sectors. However, the elimination of the race-for-fish will likely result in a decrease in overall participation levels. In the long-run, communities are likely to see fewer persons employed in jobs related to the fishing industry (fishing, processing, or support sectors), but the jobs that remain could be more stable and provide higher pay.

With an end to the race-for-fish and implementation of rights-based allocations, participants are expected to be better able to adapt to the additional restrictions placed on the fishery because of increased emphasis on ecosystem management. To the extent participants are able to adapt, the rights-based allocations within the alternative are expected to decrease the number of direct participants and activities of support industries, Remaining participants however, are likely to have increased stability and incomes. The alternative's promotion of rights-based allocations is also expected to increase consumer benefits and health and safety of participants. Additionally, because the disincentives for bycatch reduction inherent in the race-for-fish are reduced, the alternative could reduce bycatch, even if additional bycatch regulations are not imposed.

It is not possible to determine the long-term effect on overall ecosystem value because it is not known whether the fishing sectors, even with rights-based allocations, will be able to able to fully adapt to the changes resulting from the increased emphasis on ecosystem tools, in particular the additional number and significance of closed areas. If the fishing sectors are unable to fully adapt to the additional restrictions, it is likely that commercial benefits from the fishery could decrease and could offset expected gains in non-market values, and subsistence, recreational, and tourism benefits.

The alternative also promotes more adaptive management and would very likely provide additional economic data as well as additional management funding through a cost recovery program. The additional funding could help to offset increases in management costs that could occur with additional closed areas and data collection requirements and the monitoring and enforcement of rights-based management. The collection of additional economic data could be critical in the development and eventual acceptance of additional ecosystem regulations. Regulations such as bycatch restrictions and the creation of MPAs have the potential to have negative effects at least in the short-term on industry participants; if additional data can reduce the uncertainty of social and economics effects associated with these types of restrictions, then it may increase the probability that these regulations could be approved and implemented. See the Data and Reporting Requirements qualitative analysis paper in Appendix F-11 for additional information the benefits of additional socioeconomic data.

4.10.4.8 Increase Alaska Native Consultation

The Alternative 3 policy sets objectives to increase Alaska Native consultation, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Objectives • Continue to incorporate Traditional Knowledge in fishery management • Consider ways to enhance collection of Traditional Knowledge from communities, and incorporate such knowledge in fishery management where appropriate • Increase Alaska Native participation and consultation in fishery management	Alaska Native Issues	Develop and implement procedures to incorporate Traditional Knowledge into fisheries management/ do Traditional Knowledge research
		Increase consultation with Alaska Natives
		Encourage increased participation/ representation of Alaska Natives in fishery management
		Allow for subsistence uses consistent with Federal law

Impacts of Policy

Under Alternative 3, there would be some changes to current management policies and measures used by NOAA Fisheries and the NPFMC regarding Alaska Native consultation. These changes increase efforts to collect Traditional Knowledge, and develop and implement measures to incorporate it into fishery management. NOAA Fisheries staff anthropologists would increase the collection of existing Traditional Knowledge, expand of an in-house Traditional Knowledge database, and continue informal consultation with individuals in Alaska Native communities. NOAA Fisheries and the NPFMC would work with Alaska Natives to evaluate and develop measures to incorporate Traditional Knowledge. Formal consultation with federally recognized tribal governments during NEPA compliance under EO 13175 would also continue at current levels during NEPA scoping activities and public comment periods on draft NEPA documents, but other forms of consultation would also be considered. Similarly, opportunities for Alaska Native participation in NEPA compliance and NPFMC deliberations would continue to be available during NEPA scoping, public comment periods on draft NEPA documents, review of NPFMC documents, and at NPFMC meetings. However, other forms of outreach and information exchange would be considered to increase participation.

Increased participation and representation of Alaska Natives in fishery management would be encouraged under Alternative 3. NOAA Fisheries and the NPFMC would work with Alaskan Natives to identify and develop measures that would increase participation and representation in fishery management.

Under Alternative 3, Alaskan Native participation in the fisheries will be affected by rationalization of fisheries and closure of areas to fishing. CDQ groups fishing in the BSAI would continue to benefit from rationalization. Non-CDQ Alaskan Native participants in the GOA would also benefit from rationalization of fisheries, although these benefits could be offset by closures of areas currently fished by smaller vessels. Benefits to Alaskan Native communities would be mixed, with CDQ communities receiving increased revenues, while on-CDQ Native communities could experience a reduction in employment and support services due to rationalization of fisheries.

Reduced levels of salmon bycatch and additional area closures could benefit subsistence harvest of Steller sea lion and salmon in western Alaska, although cumulative effects have a greater influence on the availability of both subsistence resources. The potential for Environmental Justice impacts as a result of this alternative would be limited to any adverse effects of rationalization on non-CDQ Alaskan Native communities.

Under Alternative 3, subsistence uses would continue consistent with federal law. Joint production of subsistence resources, where Alaska Natives who participate in groundfish fishing take advantage of their commercial fishing efforts to harvest subsistence resources, would continue at current levels, except where closure of fishing areas in the GOA could adversely affect joint production.

4.10.4.9 Improve Data Quality, Monitoring and Enforcement

Alternative 3 accelerates precautionary management of the groundfish fisheries. The policy sets goals and objectives to address data quality, monitoring, and enforcement, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Goals • Base management on the best scientific information available Objectives • Increase the utility of groundfish fishery observer data for the conservation and management of living marine resources • Improve Groundfish Observer Program, and consider ways to address the disproportionate costs associated with the current funding mechanism • Improve community and regional economic impact assessments through increased data reporting requirements • Increase the quality of monitoring data through improved technological means • Establish a coordinated, long-term ecosystem monitoring program to collect baseline information and compile existing information from a variety of ongoing research initiatives • Adopt the recommended research plan included in this document • Cooperate with research institutions such as the NPRB in identifying research priorities to address pressing fishery issues	Observer Program	Fixed 0/30/100% / 0/100/100% Observer Program coverage, scientifically based; 100/200% for AFA. and CDQ
		Address conflict of interest in funding
		Improve observer data, develop uncertainty estimates
	Data and Reporting Requirements	Require broader range of economic data from industry participants, verified through third party
		Require appropriate scales
		Require VMS for Steller sea lion prey species / Steller sea lion prey species and all vessels > 125 ft; modify to incorporate new technology and system providers

Impacts of Policy

The goal of Alternative 3, as with all the alternatives, is to base fishery management on the best scientific information available. The objectives specific to Alternative 3 are to increase the utility of observer data, and to improve the Observer Program; to improve economic impact assessments by changing data reporting requirements; to utilize advances in technology to improve the quality of monitoring data; to establish an ecosystem monitoring program; to adopt a plan for research priorities, and to work with research institutions to get these priorities addressed.

The Observer Program objective would be implemented through management measures that would either maintain or expand existing coverage but allow more flexible deployment of observers; improve observer data, including development of uncertainty estimates; and address the conflict of interest in funding. Building more flexibility into observer deployment, so that coverage can be adjusted rapidly to respond to monitoring needs for data or compliance, would be beneficial and was an original intent of the Research Plan that preceded the interim Service Delivery Model program currently in place (for further historical description, see the Observer Program paper in Appendix F-10). Merely expanding coverage from 30 percent to 100 percent on the 60 to 125 ft LOA component of the fleet, would provide more data on those vessels but would leave other issues, such as flexibility of observer placement and the lack of observer coverage on vessels less than 60 ft LOA, unaddressed.

Implementing improvements to observer data under Alternative 3 is accomplished through measures addressing observer sampling stations, the level of species identification in observer samples, and uncertainty estimates. Historically, observers have identified only fish that are managed to the species level; however, the Observer Program has responded to requests to further identify other organisms, most recently skates, sculpins, and some coral species. The program must maintain a balance in consideration of the amount of time to teach identification and to record these species in the field, so as not to sacrifice target species data. A pilot project to determine the recording time required in the field is currently underway, with the goal of understanding the cost-benefit relationships of increasing the specificity of identification. This program would be expanded under Alternative 3. Regarding the setting of uncertainty estimates, currently there are no established confidence intervals for observer data. A 1997 analysis has indicated, however, that while statistical procedures may be appropriate for the most abundant species in the catch, the statistical precision decreased for rarer species, and the adoption of statistical estimators may need to be paralleled with an increase in the current level of observer coverage and the amount of hauls sampled (for further discussion, see the Observer Program paper in Appendix F-10).

The Observer Program funding issue stems from the appearance of a conflict of interest arising from the direct financial relationship between the observer's employer and industry. Alternative 3 changes the funding mechanism in order to alleviate any taint on the credibility of observer data, and proposes a range of solutions that include full federal funding, industry fee-based funding and setting aside a portion of TAC (for further discussion, see the Observer Program paper in Appendix F-10).

The implementation of changes to the data and reporting requirements expands the range of economic data requested from industry participants, and potentially sets up a third party verification system for reported data. New information would include data on employment, variable harvesting and processing costs, and fixed/annual costs (see Appendix F-11, the Data and Reporting Requirements paper, for further discussion). This additional information would enhance the ability of analysts to provide accurate estimates of the costs and benefits of proposed regulatory actions. Additionally, third party data collectors would be able to verify revenue data currently submitted. While authenticated data would allow for more accurate and credible economic impact assessments, a funding source would need to be identified to support the independent verification system.

The use of available technology to improve monitoring data is implemented through the requirements for appropriate scales and for VMS requirements to be potentially extended to all vessels over 125 ft LOA. The requirement for scales would not create any immediate change; however, should VMS be required aboard vessels that are not already so equipped, this would impose a cost on those vessels in terms of installation, maintenance, and transmission costs. Additionally, new VMS technology and system providers will be explored, which may lead to a reduction in costs or improvements in technology and usage.

Establishing an effective ecosystem monitoring plan would accelerate precautionary management by providing an appropriate baseline against which to measure the impacts of fishing. Various ongoing research initiatives would contribute to this program, and new areas of research would be identified. The results would be compiled into a comprehensive monitoring plan. Funding for such a program would need to be identified, but the results would be a beneficial step in understanding the ecosystem impacts of fishery interactions.

Alternative 3 also adopts the recommended research plan included in Chapter 5 of this document, which identifies data gaps and research needs. Alternative 3 expands research efforts by seeking out partners, such as the North Pacific Research Board, to fund research on these data needs.

The Alternative 3 data quality, monitoring, and enforcement objectives conform with the overall policy intent of the alternative, namely to accelerate precautionary management in two ways: where appropriate, to take steps to incorporate uncertainty and ecosystem considerations into fishery management, and at the same time, to increase efforts to improve scientific understanding and diminish uncertainty. The objectives in Alternative 3 result in data collection on direct fishery impacts and interactions as well as on broader ecosystem relationships and indirect effects.

4.10.5 Analysis of Alternative 4

Alternative 4 consists of a management approach statement and a set of policy objectives. The management approach statement provides the key to the underlying rationale and assumptions for the policy, along with policy goals and additional guidelines for the policy.

The management approach statement for Alternative 4 represents an extremely precautionary approach to managing fisheries under scientific uncertainty, in which the burden of proof is shifted from a demonstration of adverse environmental impact to prohibit or proscribe a fishery to a demonstration of no adverse impact to authorize one. The management approach statement is summarized in Table 4.10-3. This policy is based on the assumption that fishing does produce adverse impacts on the environment but due to lack of information and uncertainty, we know little about these impacts.

The Alternative 4 management approach statement also provides further guidance about NPFMC management decisions:

- Management decisions assume that science cannot eliminate uncertainty and that action must be taken in the face of large uncertainties, guided by policy priorities and the strict interpretation of the precautionary principle.

- Management decisions will involve and be responsive to the public but decrease emphasis on industry and community concerns.

As well as the effects of the policy:

- The strategy will result in a number of significant changes to the FMPs that will significantly curtail the groundfish fisheries until more information is known about the frequency and intensity of fishery impacts upon the environment.

- Once more is known about fishery effects on the ecosystem, scientific information will be used to modify and relax the precautionary measures initially adopted.

A summary of the impacts of Alternative 4 follows below in Section 4.10.5.1. In the remainder of Section 4.10.5, the impacts of the alternative are analyzed in detail, in relation to eight policy subheadings: prevent overfishing, preserve food web, reduce and avoid bycatch, avoid impacts to seabirds and marine mammals, reduce and avoid impacts to habitat, allocation issues, increase Alaska Native consultation, and data quality, monitoring, and enforcement. For each subheading, the impacts of the relevant goals and objectives from the management approach are analyzed, using as a guideline the range of implementing management measures for Alternative 4, identified in Section 4.2, and analyzed in Section 4.7.

4.10.5.1 Summary of Alternative 4

The key policy element that influences impacts under Alternative 4 is the shift of the burden of proof to the user of the resource to demonstrate that the intended use will not have a detrimental effect on the environment, which raises the standard of justification required for fishery management actions. Key management objectives that implement this approach are: reduce the ABCs, and in turn the TACs, or consider temporarily suspending the fisheries, to account for uncertainty; institute extensive closure areas (resulting in the closure of traditional fishing areas and an increased emphasis on non-consumptive values); phase out fisheries with greater than 25 percent incidental catch and bycatch rates; develop a Fisheries Ecosystem Plan; and increase data collection and monitoring (in order to fill in data gaps and adjust restrictive measures as appropriate).

Predictions about the impacts under this alternative are difficult due to the uncertainty involved in defining ecosystem management and predicting the impacts of protecting areas. The emphasis is on instituting protective measures, particularly focusing on less abundant or economically valuable species, while at the same time imposing extensive monitoring and data-gathering to increase understanding of fishery impacts.

Alternative 4 establishes a very conservative harvest policy which is likely to prevent overfishing and reduce the chance that stocks would become overfished. Constraints to commercial harvest coupled with systems of closed areas would effectively reduce impacts from the race-for-fish and therefore from spatial/temporal concentration of catch. Catch monitoring would also increase under this alternative, resulting in more complete fisheries data. As with Alternative 3, this alternative would define criteria for determining the status of all managed stocks relative to an overfished condition in order to better satisfy the requirements of the National Standard 1 Guidelines. In the long-term, this alternative would protect the most vulnerable species of the complex, but the resulting management of many stocks with low biomass would be difficult to implement.

This alternative is very successful in meeting the goal of preserving the food web, by providing large buffers against scientific uncertainty about ecosystem impacts resulting from fishing. The assumption that the present level of scientific information is insufficient to manage fisheries without excessive risk to the ecosystem results in the implementation of highly precautionary measures. This strategy provides improvements over the baseline and achieves protection of virtually all food web components and thus ecosystem functions. Although the alternative is successful in producing a food web that is less influenced by fishing activity, predictions about the abundance changes of individual food web components that might result are uncertain due to the difficulty in accurately predicting predator-prey relationships.

The bycatch and incidental catch reduction policies under Alternative 4 are effective. Reduced bycatch and incidental catch would be achieved through extreme reductions in target groundfish catch and strong bycatch and incidental catch limits.

Alternative 4 is very successful at avoiding impacts to seabirds and marine mammals through its specific objectives to protect all seabirds from fishing interactions, and extending protection measures for Steller sea lion critical habitat and prey base. This largely increased level of protection provides a substantial buffer against uncertainty with regards to protection of marine mammals and seabirds.

The emphasis of the Alternative 4 policy on habitat provides large buffers against scientific uncertainty about the impacts of fishing on habitat. The combination of highly precautionary measures associated with increasing marine reserves and other closure areas will likely achieve protection and avoidance of impacts to habitat. Cumulatively, the alternative has a split rating, as the existing adverse condition of the baseline includes damage to slow-growing species unlikely to recover within the time period predicted in this analysis, however this alternative provides strong protection for habitat and potential for mitigation.

The Alternative 4 goals of incorporating and enhancing non-consumptive use values are met but at the expense of commercial value and potentially the continued viability of coastal communities. The precautionary policies in Alternative 4 could result in substantial reductions in allowable catches and could also result in the closure of large portions of traditional fishing areas. The alternative is likely to result in a substantial increase in the non-market values of the ecosystem, but is also likely to result in a substantial decrease in efficiency, net revenues, and the number of participants in the fisheries.

Alternative 4 would directly involve Alaska Natives in fishery management through the development of co-management or cooperative research programs. Consultation and participation objectives would focus on subsistence uses and cultural values of living marine resources. However, other goals and objectives in Alternative 4, that greatly reduce or eliminate commercial fishing, would adversely impact Native communities, including CDQ communities, through the loss of employment, economic activity, and community revenues.

Alternative 4 expands research and monitoring programs to obtain information necessary to fulfill the requirements of this alternative. The policy objectives are successful in increasing fisheries data by expanding the Observer Program to full coverage for vessels over 60 ft LOA, and instituting 30 percent coverage on smaller boats. Additionally, the requirements to improve the accuracy of data through technological means such as at-sea scales and VMS will improve monitoring and enforcement under this alternative.

4.10.5.2 Prevent Overfishing

This policy represents an extremely precautionary approach to managing fisheries under scientific uncertainty. It shifts the burden of proof to the user of the resource and the agency to demonstrate that the intended use would not have a detrimental effect on the environment. It would involve a strict interpretation of the precautionary principle. Management discussions would involve and be responsive to the public, but would decrease emphasis on industry and community concerns in favor of ecosystem processes and principles. This policy assumes that fishing does produce adverse impacts on the environment, but due to a lack of information and uncertainty, we know little about these impacts. The initial restrictive and precautionary conservation and management measures would be modified or relaxed when additional, reliable scientific information becomes available.

A detailed description of FMP 4.1 and FMP 4.2 appears in Section 4.2. FMP 4.1 illustrates a Fishery Management Plan where current levels of fishing are reduced and other precautionary restrictions are implemented until scientific research shows that the fisheries have no adverse effect on the resource and its environment. FMP 4.2 suspends all fishing until fisheries can be shown to have no adverse effect on the resource and its environment

Accordingly, FMP 4.1 would substantially reduce the impacts of the fishery. A modified TAC-setting process would create a more substantial buffer between ABC for selected species. and the OFL by setting the fishing mortality rate at $F_{75\%}$ for all Steller sea lion prey species (pollock, Pacific cod and Atka mackerel) and for rockfish (as long-lived, slow-growing species). Also, the *max* F_{ABC} for each stock or stock complex in Tiers 1-5 would be adjusted downward as a function of uncertainty in the biomass survey estimate for that stock or stock complex.

Under FMP 4.1, OY would be specified separately for each stock or stock complex rather than for the groundfish complex as a whole, and would be set equal to the respective TAC. The current precautionary practice of setting TAC less than or equal to ABC would be formalized in the FMP. For species managed as members of a stock complex, rather than setting TAC as the aggregate of the individual members' ABCs, the max_{ABC} value for each component stock would be determined and the TAC set equal to the lowest value. Where sufficient biological information is available, such as with EBS pollock, TAC would be distributed on a smaller spatial scale. Minimum stock size thresholds would be determined for all tiers.

To further mitigate the possibility of detrimental biological and environmental impact, 20 to 50 percent of the management area would be designated as no-take marine reserves (i.e., no commercial fishing) covering the full range of marine habitats within the 1,000 m bathymetric line (see Figure 4.2-6). As part of this area in the Aleutian Islands, a Special Management Area would be established to protect coral and other live bottom habitats. This area would also include spawning reserve areas for intensively fished species. Comprehensive trawl exclusion zones would be set to protect all Steller sea lion critical habitat, and trawling itself would be restricted to only those fisheries that cannot be prosecuted with other gear types (i.e, the flatfish fisheries.)

In an effort to reduce waste and the risk of adverse impact to the environment, existing PSC limits would be reduced by half under this bookend, as would bycatch and discard rates. IR/IU would be extended to all target species. Stringent PSC limits would be set for salmon, crab and herring in the GOA, and as information becomes available, bycatch limits would be set for non-target species also. Protection measures would be set for all seabird species.

As this policy alternative necessitates greater research and data-gathering efforts, FMP 4.1 would expand observer coverage to 100 percent for all vessels over 60 ft LOA and require 30 percent observer coverage on vessels presently exempted from observer coverage (i.e., vessels under 60 ft LOA). VMS would be made mandatory for all groundfish vessels, as would motion-compensated scales for weighing all catches at sea or at shore-based processors. Cooperative research and data-gathering programs would be initiated as well to expand the use of Traditional Knowledge in fisheries management.

FMP 4.2 extrapolates the precautionary principles of Alternative 4 by suspending all fishing until the fisheries can be shown to have no adverse effect on the resource and its environment. The TAC for all species would be set at zero. All areas of the EEZ (3 to 200 nautical miles) would be closed to all fishing (e.g. commercial, recreational, and subsistence) (see Figure 4.2-7). Bycatch and incidental catch, as well as the take of seabirds and marine mammals, would then necessarily be reduced to zero. Scientific research and data-gathering efforts would continue. When a fishery can be shown to pose no significant threat of adverse biological and environmental impacts, or if adverse effects can be successfully mitigated through use of fishery-specific regulations, the measures illustrated by this FMP would be relaxed to allow fishing to resume.

Under the FMP 4.2 illustration, we have assumed that each groundfish fishery currently conducted within the EEZ in the BSAI and GOA would be individually reviewed by the NPFMC and NOAA Fisheries. Upon completion of this review (up to 2 years), the agency would certify those fisheries that are found to have no significantly adverse impacts on the environment and authorize fishing under a specific set of regulations. If a fishery is found by this review to produce significantly adverse environmental effects, and mitigation measures cannot be designed to mitigate those effects, that fishery would not be certified and would remain closed until more scientific information is known.

Impacts of Policy

The harvest policies in Alternative 4 as illustrated by FMP 4.1 are consistent with ecosystem principles that call for in-season multi-species catch monitoring to ensure that catch does not exceed the OFL of groundfish. This catch monitoring is facilitated by at-sea observers, port samplers, weekly production reports, and fish ticket information (Appendix F-10). For several stocks managed in Tiers 4-6, direct and indirect impacts analyses reflect a shift away from unknown to insignificant. This change is possible because Alternative 4 requires that status criteria be established for stocks managed in these tiers. Cumulative effects considerations do not change the impact rankings for target stocks.

Goals, Objectives	Corresponding Management Measures	
<u>Goals</u> • Establish a fishery conservation and management program to maintain ecological relationships among exploited, dependent and related species as well as ecosystem processes that sustain them • Adopt an extremely precautionary approach to managing fisheries under scientific uncertainty • Shift the burden of proof to the user of the resource and the agency to demonstrate that the intended use would not have a detrimental effect on the environment <u>Objectives</u> • Prevent overfishing by transitioning from single-species to ecosystem-oriented management of fishing activities • Protect the productivity and genetic diversity of groundfish	Example Range: TAC ≤ABC≤OFL, formal adjustments for uncertainty, automatic rebuilding, specific harvest policies for rockfish	Quota management based on a tier system. Revised procedures to set ABC, TAC including precautionary fishing mortality rates for individual species and species complexes. For example purposes only, F_{ABC} for Tier 3 rockfish stocks would be set at $F_{750\%}$, F_{ABC} for Atka mackerel, BSAI and GOA Pacific cod, and BSAI and GOA pollock would be set equal to $F_{75\%}$. Uncertainty corrections based on the lower 90% confidence limits of the survey biomass indices would be applied to F_{ABC}.
	Time/Area	Spatial/temporal distribution of TAC on a smaller scale. These policies reduce the possibility of spatial temporal concentration of the catch. FMPs 4.1, and 4.2 create large marine reserves and marine protected areas. FMP 4.1 closes 20-50% of known spawning areas of target species across the range of the stock.
	Gear restrictions	For walleye pollock, Pacific cod, and sablefish, gear allocations partition catch to specific gear groups. Differences in gear selectivity are addressed in the stock assessment models and quotas reflect the expected age distribution of the catch by gear.
	OY caps	Under FMPs 4.1 and 4.2 Optimum Yield caps for the GOA and BSAI would be set at the sum of the ABCs for the GOA and BSAI.
	Inseason Multi-species TAC and ABC monitoring	The catch of a given target species is limited by prohibited species bycatch caps and the TACs for other groundfish. The halibut bycatch caps serve as a constraint to BSAI and GOA flatfish expansion. Reduced bycatch allowances would further constrain target fisheries. Procedures to break-out species from existing managed categories would be phased in.

The bookends provide a range of potential impacts associated with this alternative. Several management measures associated with FMP 4.2 would close all commercial fisheries in the short-term. Several constraints to commercial fisheries are imposed under FMP 4.1. First, an uncertainty correction would be applied that would account for measurement in the survey biomass estimates. Second, the F_{ABC} for Steller sea lion prey species and rockfish species would be set at $F_{75\%}$. Third, FMP 4.1 would impose a 30-60 percent reduction in bycatch. Fourth, FMP 4.2 would set the ABC for species managed as a complex equal to the lowest single species ABC for members of the complex. Finally, procedures for breaking species out of the other species complex would be established. Direct and indirect impacts analyses revealed that overfishing did not occur in the 38 stocks or stock complexes modeled under FMP 4.1 or FMP 4.2 (Table 4.10-2a). Relative to the comparative baseline, the expected fishing mortality under Alternative 4 would have no significant impact on any of the target groundfish stocks.

Relative to the comparative baseline, the likelihood of a stock falling below the level where the stock is capable of producing MSY is reduced under Alternative 4. Irreversible or long-term adverse effects on fishery resources are avoided by extremely precautionary harvest policies, and imposition of rebuilding regulations when stocks fall below the level capable of producing MSY. Under FMP 4.1 and FMP 4.2, none of the stocks managed in Tiers 1-3 would be expected to become overfished (Table 4.8-1). Adoption of FMP 4.1 would have a significantly beneficial impact on the ability of the stock to maintain itself above an overfished condition for BSAI Pacific cod, BSAI/GOA sablefish, BSAI Atka mackerel and BSAI Pacific ocean perch. Adoption of FMP 4.2 would have a significantly beneficial impact on the ability of the stock to maintain itself above an overfished condition for EBS pollock, BSAI and GOA Pacific cod, BSAI/GOA sablefish, BSAI Atka mackerel, and BSAI Pacific ocean perch. The direct and indirect impacts of Alternative 4 on Tiers 1-3 target groundfish stocks other than those mentioned above would be insignificant relative to the baseline (Table 4.8-1). With the exception of GOA Atka mackerel, the direct and indirect impacts of commercial fishing on the biomass of target groundfish stocks managed in Tiers 4-6 are considered insignificant because fisheries removals are constrained to very low levels (Table 4.8-1).

Relative to the comparative baseline, Alternative 4 adds several spatial/temporal restrictions on catch. These restrictions would decrease the spatial/temporal concentration of the catch. The direct and indirect impacts of spatial temporal concentration of the catch under Alternative 4 are unknown for GOA Atka mackerel. With the exception of GOA Atka mackerel, the direct and indirect impacts of commercial fishing on the genetic structure of the stock are considered insignificant (Table 4.8-1). Direct and indirect impacts of spatial temporal concentration of the catch on reproductive success are insignificant for most stocks or stock complexes. Significantly beneficial impacts of spatial temporal concentration of the catch on the reproductive success of BSAI Atka mackerel and BSAI Pacific ocean perch are expected.

Relative to the comparative baseline, Alternative 4 would increase restrictions on the spatial temporal partitioning of catch and could reduce overall harvest of target groundfish. The direct and indirect impacts of these changes on prey availability and predation mortality are expected to be insignificant for all stocks managed in Tiers 1-3 (Table 4.8-1). Direct and indirect impacts of commercial fishing on prey availability and predation mortality of all stocks or stock complexes managed in Tiers 4-6 are unknown because the status of the stock relative to MSST are unknown (Table 4.8-1).

Harvest restrictions, spatial temporal constraints, and gear allocations all serve to mitigate the impact of commercial fishing on fish habitat. The closure system described in the FMP 4.1 would close approximately 19 percent of the EEZ to some form of MPA and designates approximately 11 percent of the EEZ as a no-take reserve (Figure 4.2-6). For the fishable area (depth to 1,000 m) of the EEZ, FMP 4.1 would designate approximately 29 percent of the fishable area as a no-take reserve and about 51 percent of the fishable area as some form of MPA. FMP 4.2 assumes 100 percent of the EEZ would be designated as a no-take reserve (Figure 4.2-7). Relative to the comparative baseline, the impacts on target species resulting from habitat disturbance are considered insignificant for 37 of 38 stocks (Table 4.10-2a).

When taken in aggregate, Alternative 4 appears to impose an extremely precautionary approach to managing fisheries under scientific uncertainty. The policy establishes a fishery conservation and management program to maintain ecological relationships among exploited, dependent, and related species, as well as ecosystem processes that sustain them. Strengths of Alternative 4 are that the FMPs will adopt formal criteria for status determination. MSSTs would be formally specified in the FMPs whenever possible under Alternative 4 bringing this policy into compliance with NOAA Fisheries guidelines for National Standard 1. Status criteria would be established for stocks managed in Tiers 4-6. The constraints to commercial harvest coupled with systems of closed areas would reduce the race-for-fish under Alternative 4 and would reduce the spatial temporal concentration of the catch. Setting ABCs for species managed in complexes at the lowest single species ABC for members of the complex would curtail the impact of fishing some target groundfish stocks managed in Tiers 4-6. A weakness of this policy is that treatment of species complexes for Alternative 4 could be administratively cumbersome and practically difficult to implement. A second weakness of this policy is that the increased closed areas envisioned under FMP 4.1 could restrict commercial harvests to a very limited region of the Aleutian Islands and GOA. A third weakness of Alternative 4 is that implementing requirements to establish status criteria for stocks managed in Tiers 4-6 would require a substantial increase in funds to support catch monitoring, enforcement, collection of and analysis of demographic information, and additional surveys.

4.10.5.3 Preserve Food Web

The Alternative 4 policy sets goals and objectives to preserve the food web, as well as recommending a range of management measures that would implement these objectives.

<table>
<tr><th rowspan="2">Goals, Objectives</th><th colspan="2">Corresponding Management Measures</th></tr>
<tr><th>FMP Component</th><th>Management Measure</th></tr>
<tr><td rowspan="4"><u>Goals</u>
• Establish a fishery conservation and management program to maintain ecological relationships among exploited, dependent and related species as well as ecosystem processes that sustain them
• Incorporate and apply strict ecosystem principles
• Address the impact of fishing on predator-prey and other important ecological relationships in the marine environment

<u>Objectives</u>
• Develop and implement a Fishery Ecosystem Plan through the modification or amendment of current FMPs
• Conserve native species and biological diversity at all relevant scales of genetic, species, and community interactions
• Reduce the ABC to account for uncertainty and ecological considerations for all exploited stocks, including genetic, life history, food web and habitat considerations
• Set fishing levels in a highly precautionary manner to preserve ecological relationships between exploited, dependent, and related species</td><td rowspan="4">TAC-setting Process</td><td>Prohibit directed fishery for forage fish</td></tr>
<tr><td>Set F_{75} for Steller sea lion prey species and for vulnerable (e.g., long-life, slow-growing) species</td></tr>
<tr><td>Procedures to incorporate precaution, survey variance and uncertainty into ABCs</td></tr>
<tr><td>Evaluate a range of ABCs using the lower bound of a confidence limit to address uncertainties in stock assessment advice</td></tr>
</table>

Impacts of Policy

Impacts to food webs of the BSAI and GOA are reduced through most of the goals and objectives and the related management measures of this FMP. In addition to the objectives of developing a Fisheries Ecosystem Plan, conserving native species and biological diversity at all scales, and implementing highly precautionary fishing levels to preserve ecological relationships are all viewed as positive benefits of this policy.

Alternative 4 goals and objectives, which include the prevention of overfishing, bycatch reduction, avoidance of impacts to seabirds, marine mammals, and habitat, and improvements in data quality and monitoring, are critical to the protection of all food web components, which include target and non-specified species, PSC species, HAPC biota, and marine mammals and seabirds. The following management measures in FMP 4.1 provide increased protection to a variety of important food web components, relative to the baseline: revised procedures to set ABC that include much more precautionary *F* rates than in the baseline, procedures to incorporate precaution into ABCs, and finer scale spatial temporal distribution of the TAC (Section 4.10.5.2); larger reductions in PSC limits and extension of IR/IU to all target species (Section 4.10.5.4); more precautionary *F* limits for Steller sea lion prey species and gear modifications and fishing methods to reduce incidental take of all ESA-listed seabirds or species of concern to levels approaching zero (Section 4.10.5.5); establishment of large amounts of no-take MPAs, special Aleutian Islands coral management area, and additional bottom trawling restrictions (Section 4.10.5.6); and expansion of the data quality and monitoring goals through expanded observer coverage, VMS for all groundfish vessels, and uncertainty estimate development for all stocks (Section 4.10.5.9). At the alternative's most stringent application in FMP 4.2, fisheries would not be prosecuted until scientific research could show there was no significant ecological impact. See the policy analysis in those sections for details on the level of protection provided by Alternative 4 to these individual components.

This alternative specifically incorporates ecosystem considerations into fishery management decisions through development of a Fisheries Ecosystem Plan and application of ecosystem principles by modification of ABC to take uncertainty and ecological factors into account. Analysis of the ecosystem effects of FMP 4.1 involved selection of alternatives that would show changes in key members or ecosystem characteristics that are important to the structure and function of marine food webs. Changes in pelagic forage, top predators, spatial/temporal availability of prey, exotic species introductions, energy removal and redirection through fishery catch removals and discarding and offal production, and various measures of diversity were evaluated with respect to the potential for fishing to cause changes sufficient to bring these attributes below population, community, or ecosystem thresholds, if such thresholds could be defined. Virtually all of these indicators showed a beneficial change relative to the comparative baseline, although the amount and direction of change that would actually occur is uncertain because of difficulties in accurately predicting predator/prey interactions. This alternative shows potential significant improvements in pelagic forage availability through its more precautionary *F* limits on walleye pollock and Atka mackerel and significant improvements in spatial/temporal availability of forage through the designation of areas open to fishing outside foraging areas of mammals. By its TAC rules based on the least abundant group member, this alternative removes the uncertainty about protection of sensitive species such as sharks and skates that are managed in groups. Qualitative analysis of the alternative with respect to the ecosystem effects of the TAC setting process (Appendix F-1) shows that its management measures have the potential to make large reductions in TACs of several species that are key food web members such as walleye pollock and Atka mackerel and protection of sensitive, slow growing species through least abundant member TAC rules. These provide protection to food webs that rely on these pelagic forage species and to species diversity.

This alternative is very successful in meeting the goal of preserving the food web through its objectives of reducing ABCs to take uncertainty and ecological considerations into account and to set fishing levels in a highly precautionary manner to preserve food web relationships. The emphasis in this alternative is on providing large buffers against scientific uncertainty about ecosystem impacts of fishing through much more stringent *F* levels for some species and closures of large amounts of areas to fishing. It assumes scientific information is not sufficient to manage fisheries without excessive risk to the ecosystem, and thus prescribes these more highly precautionary measures. This strategy provides improvements, most significantly beneficial, from the comparative baseline and likely achieves protection of virtually all food web components and thus ecosystem function.

4.10.5.4 Reduce and Avoid Bycatch

Several policy changes adopted in Alternative 4 would impact the bycatch and incidental catch or target and non-target species. At the extreme, bycatch and incidental catch of target and non-target species would be zero under FMP 4.2. FMP 4.1 imposes several constraints to fishing that would reduce bycatch and the incidental catch of target and non-target species in groundfish fisheries. FMP 4.1 would substantially reduce the impacts of the fishery through a modified TAC-setting process. This FMP would also impose constraints to incidental catch of species managed as members of a stock complex by setting conservative TACs for the complex. FMP 4.1 creates no-take marine reserves (i.e., no commercial fishing) that would serve as a refuge for non-target species (see Figure 4.2-6). In an effort to reduce waste and the risk of adverse impact to the environment, existing PSC limits and bycatch rates would be cut in half. IR/IU would be extended to all target species. FMP 4.1 would expand observer coverage to 100 percent for all vessels over 60 ft LOA and require 30 percent observer coverage on vessels presently exempted from observer coverage (i.e., vessels under 60 ft LOA). VMS would be made mandatory for all groundfish vessels, as would motion-compensated scales for weighing all catches at sea or at shore-based processors. Cooperative research and data-gathering programs would be initiated as well to expand the use of Traditional Knowledge in fisheries management.

Impacts of Policy

Alternative 4 is expected to encourage the development of practical measures that reduce bycatch and incidental catch of prohibited species, target species, other species, forage fish and non-specified species. Relative to the comparative baseline, the impacts of mortality and change in biomass associated with the Alternative 4 policy would be conditionally significant beneficial impacts due to changes in fishing mortality for prohibited species that are currently in a depressed or overfished condition (BSAI and GOA chinook salmon and BSAI other salmon, *C. bairdi* crab, *C. opilio* crab, BSAI and GOA red king crab, and BSAI blue king crab [Table 4.10-2a]). In addition, conditionally significant beneficial impacts due to changes in fishing mortality are anticipated for GOA other salmon. Conditionally significant beneficial impacts due to changes in biomass and habitat are anticipated for crab stocks that are currently in a depressed or overfished condition. The impact of Alternative 4 on forage fish mortality is insignificant. The impact of Alternative 4 on all other non-target or unspecified groups is unknown.

Alternative 4 as illustrated by FMP 4.1 indicates that BSAI flatfish fisheries may expand relative to the comparative baseline. This expansion results from reductions in trawl fisheries for Pacific cod and rockfish. This expansion may by constrained by the policy objective of phasing out fisheries with >25 percent incidental catch and bycatch rates. However, in the short - term species typically caught in fisheries that target flatfish may experience higher rates of incidental fishing mortality.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Goals • Implement measures that avoid or minimize bycatch Objectives • Include bycatch mortality in TAC accounting and improve the accuracy of mortality assessments for target, non-target and PSC bycatch, including unobserved mortality • Reduce bycatch, incidental catch and PSC limits (e.g., by 10%/ year for five years) • Phase out fisheries with >25% incidental catch and bycatch rates • Establish PSC limits for salmon, crab and herring in the GOA • Set stringent bycatch limits for vulnerable non-target species based on best available information • Protect habitat and reduce bycatch, prohibit trawling in fisheries that can be prosecuted with more selective gear types and establish trawl closures areas	MPAs and EFH, Bycatch and Incidental Catch Restrictions, Gear Restrictions and Allocations	Establish gear closure areas and marine reserves to reduce and avoid bycatch
	Bycatch and Incidental Catch Restrictions	Reduce existing PSC limits for prohibited species, establish PSC limits for prohibited species other than halibut in the GOA
		Procedure to develop mortality rate-based approach to setting limits
		Extend retention standards for pollock and Pacific cod (IR/IU) to all target species
		Vessel incentive programs (VIP) and bycatch restrictions (including in-season)

Alternative 4 policies as illustrated by FMPs 4.1 and 4.2 are consistent with the goal of implementing measures that avoid or reduce bycatch. Alternative 4 policies are also consistent with the objectives of accounting for bycatch mortality in TAC accounting and improving the accuracy of mortality assessments for target, non-target and PSC bycatch, including unobserved mortality. Reduced bycatch and incidental catch would be achieved through extreme reductions in target groundfish catch and strong bycatch and incidental catch limits.

4.10.5.5 Avoid Impacts to Seabirds and Marine Mammals

The Alternative 4 policy sets objectives to avoid impacts to seabirds and marine mammals, as well as recommending a range of management measures that would implement these objectives.

Impacts of Policy

This alternative has objectives to set protection measures immediately for all seabird species; cooperate with USFWS to develop fishing methods that reduce seabird takes to levels approaching zero for all threatened, endangered, or USFWS species of management concern; initiate a joint research program with USFWS to evaluate populations of seabirds that interact with groundfish fisheries; and increase existing protection measures for Steller sea lions by further gear restrictions in critical habitat and more conservative harvest levels for key prey species. Management measures to accomplish these objectives include setting F_{75} for Steller sea lion prey species, continued prohibition of directed fishery for forage fish, comprehensive trawl exclusions zones to protected all designated Steller sea lion critical habitat, short-tailed albatross take restrictions, setting protection measures for all seabird species, and development of gear modifications and fishing methods to reduce incidental take of ESA-listed or seabird species of concern to levels approaching zero. Impacts of the alternative with respect to seabirds were evaluated with respect to the potential for fisheries to cause direct mortality through fishing gear and vessel strikes, changes in prey availability (including offal), and changes in benthic habitat that might affect certain prey species of seabirds. Impacts for marine mammals were evaluated with respect to the potential for fishery incidental take or entanglement in marine debris, harvest of prey species, spatial/temporal concentration of fishing on prey, and fishing vessel disturbance.

<table>
<tr><th rowspan="2">Goals, Objectives</th><th colspan="2">Corresponding Management Measures</th></tr>
<tr><th>FMP Component</th><th>Management Measure</th></tr>
<tr><td rowspan="6"><u>Objectives</u>
• Set protection measures immediately for all seabird species and cooperate with USFWS to develop fishing methods that reduce incidental takes to levels approaching zero for all threatened or endangered species and for USFWS' list of species of management concern
• Initiate joint research program with USFWS to evaluate current population estimates for all seabird species that interact with the groundfish fisheries and modify protection measures based on research findings
• Increase existing protection measures for ESA-listed Steller sea lions by further restricting gear in critical habitat and setting more conservative harvest levels for prey base species</td><td>TAC-setting Process, Steller sea lion Measures</td><td>Set F_{75} for Steller sea lion prey species</td></tr>
<tr><td>TAC-setting Process</td><td>Prohibit directed fishery for forage fish</td></tr>
<tr><td>MPAs and EFH, Steller sea lion Measures, Gear Restrictions and Allocations</td><td>Comprehensive trawl exclusion zones to protect all designated Steller sea lion critical habitat</td></tr>
<tr><td rowspan="3">Seabird Measures</td><td>Short-tailed albatross take restrictions</td></tr>
<tr><td>Set protection measures for all seabird species</td></tr>
<tr><td>Develop gear modifications and fishing methods that reduce incidental take for all ESA-listed seabirds or other species of concern to levels approaching zero</td></tr>
</table>

Qualitative analysis of the Steller sea lion protection measures and other policies of this alternative (Appendix F-4) found that the policies and measures provided large buffers against uncertainty and would provide substantially more certainty of marine mammal protection. Quantitative indicators showed that Alternative 4 provides significantly beneficial population level effects on Steller sea lions and potential improvements for northern fur seal and harbor seals due to increases in prey abundance and availability, although the amount and direction of change that would actually occur is uncertain because of difficulties in accurately predicting predator/prey interactions.

Although some piscivorous bird species such as glaucous-winged gulls might be gaining food subsidies from discards and offal in the baseline, other piscivorous birds would be negatively impacted by competitive interactions with gulls, thus offsetting any changes for the piscivorous bird group as a whole that might occur in this alternative. Incidental take of albatross, fulmars, shearwaters, and gulls would be greatly reduced from the baseline due to new mitigation measures and greatly reduced fishing effort for both the longline and trawl fleets. The risk of exceeding ESA-threshold mortality of short-tailed albatross would be greatly reduced from the baseline levels. The qualitative analysis paper entitled Seabird Protection Measures (Appendix F-6) noted that the Observer Program would be expanded under this alternative to cover all of the groundfish fleet and would play a vital role in seabird/fishery interaction research. As in Alternatives 1 and 3, this alternative is not expected to have any population level effects on seabird species through mortality, changes in food availability, or benthic habitat. Thus, this alternative provides much more protection to seabirds and marine mammals relative to the baseline, even though baseline determinations showed no serious adverse impacts of the groundfish fishery on these populations.

This alternative is very successful at avoiding impacts to seabirds and marine mammals by setting protection measures immediately for all seabirds, implementing further gear restrictions in critical habitat of Steller sea lions and setting more conservative harvest levels for Steller sea lion prey. This largely increased level of protection provides a substantial buffer against uncertainty with respect to protection of marine mammals and seabirds.

4.10.5.6 Reduce and Avoid Impacts to Habitat

The Alternative 4 policy sets a goal and objectives to reduce and avoid impacts to habitat, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Goals • Address the impacts of fishing on habitat Objectives • Zone and delimit fishing gear use in the action area and establish no-take marine reserves (both pelagic and nearshore) encompassing 20-50% of management areas to conserve EFH, provide refuges from fishing, serve as experimental controls to test the effects of fisheries, protect genetic and biological diversity, and foster regeneration of depleted stocks in fished areas • Protect habitat and reduce bycatch, prohibit trawling in fisheries that can be prosecuted with more selective gear types and establish trawl closures areas • Manage fisheries in an explicitly adaptive manner to facilitate learning (including large no-take marine reserves that provide experimental controls) • Protect marine habitats, including EFH, HAPC, ESA-designated critical habitats and other identified habitat types • Commit to funding a comprehensive research plan in order to a provide baseline habitat atlas	MPAs and EFH	Establish 20-50% of management area as no take MPAs covering the full range of marine habitats
		Establish Aleutian Islands Special Management Area to protect coral/live bottom habitat
		Identify and designate EFH and HAPC
	Gear Restrictions and Allocations	Restrict bottom trawling for flatfish to specific areas

Impacts of Policy

Alternative 4 represents a fundamental change in the management of fisheries by presuming that the current groundfish fisheries are producing large-scale adverse effects on the marine ecosystem including habitat. Current levels of fishing are reduced and 20 to 50 percent of the management area would be designated as no-take marine reserves (i.e., no commercial fishing) within the 1,000 m bathymetric line. A Special Management Area would be established in the Aleutian Islands to protect coral and living habitat. Bottom trawling would be restricted to only those fisheries that cannot be prosecuted with other gear types (i.e, the flatfish fisheries). Given these management goals and associated measures, impacts to habitat are expected to be significantly reduced and possibly eliminated relative to comparative baseline levels.

Alternative 4 addresses impacts to habitat by the presumption that current groundfish fisheries are producing adverse effects to habitat. The institution of large scale no-take marine reserves, restrictions to trawling, and reduced TACs should accelerate habitat protection and will cause rapid reduction and avoidance of impacts to habitat. For short-lived biota with fast recovery rates, recovery from past effects could occur quickly. For other species of living substrates such as long-lived corals and perhaps some sponges, increases over comparative baseline levels may not occur or may occur only after many years.

Implementation of this policy will result in large scale geographical shifts in fishing efforts or no fishing at all. At its most stringent application fisheries would not be prosecuted until scientific research shows there would be no significant impacts. At its less stringent application, reductions in target species catches should over-ride any negative impacts due to geographic shifts in fishing effort and result in less overall impacts and overall benefits to habitat. The reduction in TAC associated with this policy could even negate the need for closed areas. This policy also calls for a commitment to funding a comprehensive research plan which should enable meeting the policy goal of addressing impacts to habitat, adapting management to facilitate learning, and responding to new information.

From a cumulative impacts perspective, the baseline condition is adversely impacted due to historical impacts that have potentially caused long-term and possibly irreversible loss of living habitat, especially to long-lived, slow-growing species which are slow to recover. While benefits, in terms of decreased mortality and protection of community structure, accrue due to the extensive reductions in TACs and reduction in bottom trawling, it is uncertain whether these benefits will sufficiently mitigate the accumulated adverse impacts in the baseline. The cumulative rating is split between conditionally significant adverse, due to the fact that the baseline is already considered to be impacted and additional impacts both internal and external, cannot be eliminated, and conditionally significant beneficial as the alternative has the potential to provide significant mitigative benefits to affected habitat.

The emphasis of this policy is on providing large buffers against scientific uncertainty about impacts of fishing on habitat. Under this alternative, current scientific information is presumed to be insufficient to manage fisheries without excessive risk to habitat. Overall prescription of the highly precautionary measures associated with this policy will likely achieve protection of and avoidance of impacts to habitat.

4.10.5.7 Address Allocation Issues

This policy represents a highly precautionary approach to managing fisheries under scientific uncertainty. It shifts the burden of proof to the user of the resource and the agency to demonstrate that the intended use would not have a detrimental effect on the environment. Management discussions would involve and be responsive to the public, but would decrease emphasis on industry and community concerns in favor of ecosystem processes and principles. When fishing is allowed the policy could place additional controls on the fisheries through bycatch restrictions, gear restrictions, additional time and area closures or other traditional management measures.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Goals • Include the use of explicit allocative or cooperative programs to reduce excess capacity and allocate fish to particular gear types and fisheries • Identify and incorporate non-consumptive use values Objectives • Reduce excess fishing capacity and employ equitable allocative or cooperative programs to end the race-for-fish, reduce waste, increase safety, and promote long-term sustainability and benefits to fishing communities • Consider non-consumptive use values	Gear Restrictions and Allocations	Allocate by gear for certain directed fisheries
	Overcapacity	LLP program for groundfish fisheries, additional procedures to reduce effort such as seasonal exclusive area registration
		Rights-based management programs for certain directed fisheries, and community quota programs
		Effort-limiting regulations, such as limits on trips, gear size, vessel size or horsepower

Impacts of Policy

The principle policy goals of the Alternative, namely the incorporation and the implied enhancement of non-consumptive ecosystem values appears to be largely met by the management measures. The achievement of this goal however, appears to be at the expense of commercial benefits to the fishing and processing industry, coastal communities dependent on fisheries, and seafood consumers.

The precautionary policies in Alternative 4 could result in substantial reductions in allowable catches and could also result in the closure of large portions of traditional fishing areas. In fisheries that are allowed to continue, the policy calls for imposition of additional bycatch and incidental catch restrictions, as well as additional time and area closures, and gear restrictions. Together these additional controls on effort could have a substantial negative consequence on efficiency and the ability of the industry to create profits. Overall, we are unable to determine the net effect of values generated from the ecosystem. The alternative is likely to result in a substantial decreases in the commercial value from the ecosystem, and in the extreme could affect the continued viability of fishing communities as well as fishing and processing sectors. At the same time the alternative would likely result in substantial increases in non-market values attributed to the ecosystem by the American public and could increase recreational and tourism values. Benefits to recreation and tourism, however, could also be negatively affected to extent that Alaskan coastal communities dependent on groundfish are also involved in recreation and tourism. Additional information on ecosystem values can be found in Section 3.9.8 and Section 4.10.5.7.

The alternative would likely increase the controls placed on the participants in terms of allowable gears, trip lengths, and fishing periods and allowable bycatch, and therefore would result in declines in harvesting and processing efficiency, and could substantially alter the current distribution of catches and processing among sectors and communities. This alternative could also substantially decrease the number of participants in the fishery, community revenues, monies to support industries. Health and safety factors of participants could worsen because of increased distance to open fishing area, but because of the reduction in participants overall numbers of injuries would likely decline. Management costs for this alternative could be higher than the comparative baseline for the fisheries that continue because of the increased number of regulations, but to the extent that fisheries are shut down, overall management costs could be reduced.

4.10.5.8 Increase Alaska Native Consultation

The Alternative 4 policy sets goals and objectives to increase Alaska Native consultation, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Objectives • Utilize Traditional Knowledge in fishery management, including monitoring and data-gathering capabilities, through co-management and cooperative research programs • Increase participation of and consultation with Alaska Native subsistence users and explicitly address the direct, indirect and cumulative fishery impacts on traditional subsistence uses and cultural values of living marine resources	Alaska Native Issues	Initiate cooperative research programs to enhance Traditional Knowledge in fishery management
		Increase consultation with and encourage participation of subsistence users (Native and non-Native)
		Provide for traditional Native subsistence uses within protected areas

Impacts of Policy

Under Alternative 4, Alaska Native participation and consultation in fishery management would increase. NOAA Fisheries and the NPFMC would utilize Traditional Knowledge in fishery management, including investigating Native involvement in monitoring and data-gathering capabilities. Opportunities for co-management and cooperative research would also be evaluated and implemented. Consultation with subsistence users would increase, and their participation in fishery management would be encouraged. Direct, indirect, and cumulative fishery impacts on subsistence would be explicitly addressed through consultation and co-management.

Increased participation and representation of Alaska Natives in fishery management would be encouraged under Alternative 4. NOAA Fisheries and the NPFMC would work with Alaska Natives to identify and develop measures that would increase participation and representation in fishery management.

Alaska Native participation in commercial fishing would be greatly reduced or suspended under Alternative 4. This would contribute further to adverse cumulative effects resulting in trends in salmon and crab fisheries. Benefits to Native communities would also be adversely affected through loss of employment, economic activity and community revenues, including CDQ communities. Combined with trends in other fisheries and state funding programs, cumulative effects on Alaska Native communities would be adverse. Potential adverse groundfish fishing effects on Steller sea lion and salmon resources would be reduced or removed, resulting in potential beneficial effects, although adverse cumulative effects on the availability of these resources are a greater factor than effects related to fishing. There would be Environmental Justice impacts on Alaska Natives due to the reduction or elimination of the groundfish fishery and reductions in community benefits.

While subsistence activities would be allowed in protected areas, the ability to harvest subsistence through joint production would be reduced or eliminated, resulting in adverse subsistence effects.

4.10.5.9 Improve Data Quality, Monitoring and Enforcement

Alternative 4 places the burden of proof on NPFMC/NOAA Fisheries to demonstrate that the prosecution of the fisheries does not have an adverse effect on the environment. Therefore, fishery managers are required to justify that their management actions have no adverse impact on resources. This will result in the imposition of restrictive measures on the fisheries, which may be lifted or modified once appropriate evidence can be produced to show that the fishery will have no adverse impact. The policy sets goals and objectives to address data quality, monitoring and enforcement, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	**Management Measure**
<u>Goals</u> • Modify restrictive conservation and management measures as additional reliable scientific information becomes available • Draw upon federal, state, academic and other capabilities in carrying out research, administration, management and enforcement • Expand research and monitoring programs will fill critical data gaps <u>Objectives</u> • Increase the precision of observer data through increased observer coverage and enhanced sampling protocols, and address the shortcomings of the current funding mechanism by implementing either a federally funded or equitable fee-based system for a revamped Observer Program Research Plan • Improve enforcement and in-season management through improved technological means • Establish a coordinated, long-term monitoring program to collect baseline information and better utilize existing research information to improve implementation of the Fishery Ecosystem Plan • Adopt the recommended research plan included in this document	Observer Program	Expand observer coverage (30/100/100%), with 100% of hauls observed
		Address conflict of interest in funding
		Develop uncertainty estimates for all possible stocks
	Data and Reporting Requirements	Require economic data from industry participants
		Require motion-compensated scales
		Require VMS for all groundfish vessels

Impacts of Policy

The data quality, monitoring and enforcement goals for this policy are to expand research and monitoring programs to be able to fill data gaps and modify restrictive management measures as appropriate. Assistance in meeting these goals would be drawn from all areas, federal, state and academic. In order to further the Alternative 4 goals, several objectives are specified. The Observer Program would be reorganized to address current shortcomings of the funding mechanism, and the precision of observer data should be increased. Management would take advantage of the latest technology to assist inseason management and enforcement efforts. A coordinated effort to develop a baseline ecosystem monitoring plan should be developed, and the research priorities identified in Chapter 5 of this document should be pursued.

The Alternative 4 objectives for the Observer Program are implemented through expanded observer coverage; the development of uncertainty estimates for all possible stocks; and measures to address the conflict of interest in funding. The Observer Program paper in Appendix F-10 contains a detailed discussion of the changes under Alternative 4. Observer coverage would be increased to 100 percent on vessels greater than 60 ft LOA, and all hauls retrieved while the observer is aboard would be sampled for species composition. Vessels less than 60 ft LOA would be required to carry an observer for 30 percent of their fishing days. Expanded coverage would reduce the uncertainty from the effects of the fisheries on direct takes of target and non-target species. As with Alternative 3, the funding mechanism would be changed to address conflict of interest. However, the change in emphasis from industry and community concerns to ecosystem-oriented management would likely result in changes to the data collection protocols as well, which would increase the costs of the program. The emphasis on ecological relationships among species may emphasize the need for trophic interaction data, such as stomach collections, in addition to other critical observer data such as otolith collections, bycatch accounting, and total catch estimates. If the Alternative 4 policy is adopted in the form of FMP 4.2, however, there would be no need for the Observer Program until NOAA Fisheries could certify that a directed fishery has no adverse effect on the environment. Alternative 4 also calls for the use of technology to achieve more accurate monitoring and enforcement by requiring the use of motion-compensated scales on all vessels, and expanding VMS to all groundfish vessels. The Data and Reporting Requirements paper in Appendix F-11 contains a more detailed description of the implications of these management measures. The requirement to install motion-compensated scales on all vessels may become an obstacle to some vessels that are not large enough to accommodate the equipment. However, the use of motion-compensated scales on AFA and CDQ vessels has already increased the accuracy of reported catch, and could be expected to do the same in this application. Requiring VMS on all vessels (rather than only being used in certain directed fisheries, as is currently the case) would increase its utility as a management tool. Although such a program would increase costs for industry to install, maintain and transmit VMS data, and for NOAA Fisheries to track incoming data, it would prove an effective tool for monitoring the additional closure areas in place under this alternative. Additionally, as VMS software becomes more advanced, it could be linked with electronic logbook entries to record and verify the location of hauls, further improving the accuracy of fisheries data. A further description of the management implications of scales and VMS is included in Chapter 5.

The baseline ecosystem collection effort that would be initiated under Alternative 4 would be used to improve the implementation of the Fishery Ecosystem Plan developed under this alternative in accordance with the Ecosystem Principles Advisory Panel recommendations (EPAP 1999). This research initiative for baseline ecosystem information would likely be coordinated by NOAA Fisheries, but would require input from a wide variety of sources (e.g., industry, academic, federal and state). At its optimum, the program would provide the necessary evidence to determine the impact of the fisheries on resources, and thus allow for modification of the restrictive measures imposed on the fisheries as appropriate.

Alternative 4 also advocates the adoption of the recommended research plan included in this document. Research priorities and identified data gaps are included in Chapter 5 of this document. Alternative 4 seeks to expand research efforts to be able to collect these data.

The assumption of Alternative 4 is that fisheries do impact all aspects of the ecosystem through the complex relationships that link its elements. Until these relationships are more fully understood and downstream effects as well, there is an urgent need to manage interactions with the ecosystem, in terms of fishery removals, with great precaution. This fundamental assumption of Alternative 4 prioritizes the need for increased accuracy and breadth of monitoring and enforcement efforts on the one hand (e.g., to monitor and control fishing-related disruption to the ecosystem), and of research efforts on the other (e.g., to accelerate the scientific understanding of the ecosystem in order to determine what level of fishing is appropriate.)

4.10.6 Analysis of the Preferred Alternative

The preferred alternative (PA) consists of a management approach statement and a set of policy objectives. The management approach statement provides the key to the underlying rationale and assumptions for the policy goals and objectives, and additional guidelines for the implementation of the policy.

The management approach statement for the PA represents a precautionary approach, of applying judicious and responsible fisheries management practices, based on sound scientific research and analysis, proactively rather than reactively, to ensure the sustainability of fishery resources and associated ecosystems for the benefit of future, as well as current generations. This management approach statement is summarized in Table 4.10-3. Under this approach, the NPFMC and NOAA Fisheries intend to consider and adopt, as appropriate, measures that accelerate the stated precautionary, adaptive management approach through community or rights-based management, ecosystem-based management principles that protect managed species from overfishing, and increased habitat protection and bycatch constraints, where appropriate and practicable.

The PA management approach statement also indicates that the NPFMC and NOAA Fisheries management process will:

- Base management measures on the best scientific information available.
- Consider reasonable, adaptive management measures as described in the MSA in conformance with the National Standards, the ESA, NEPA, and other applicable law.
- Take into account the National Academy of Science's recommendations on Sustainable Fisheries Policy.

A summary of the impacts of the PA follows below in Section 4.10.6.1. In the remainder of Section 4.10.6, the impacts of the alternative are analyzed in detail, in relation to nine policy subheadings: prevent overfishing; promote sustainable fisheries and communities; preserve food web; manage, reduce and avoid bycatch and incidental catch; avoid impacts to seabirds and marine mammals; reduce and avoid impacts to habitat; promote equitable and efficient use of fishery resources; increase Alaska Native consultation; and improve data quality, monitoring and enforcement. For each subheading, the impacts of the relevant goals and objectives from the management approach are analyzed, using as a guideline the range of implementing management measures for the PA identified in Section 4.2 and analyzed in Section 4.9.

4.10.6.1 Summary of the Preferred Alternative

The key policy elements that predominantly influence the impacts under the PA are: the emphasis on rationalizing the fisheries (resulting in increased efficiency and flexibility); the incorporation of ecosystem considerations (increasing the uncertainty buffers in management accounting); and the likelihood of additional closure areas (which may result in a variety of impacts, depending how the closures are situated).

Predictions about the impacts under this alternative are difficult due to the uncertainty involved in defining ecosystem management and predicting the impacts of protecting areas. Increased emphasis on relatively less abundant species, through protection measures and increased monitoring, indicates a tendency towards ecosystem management but as the implications of such management are uncertain, the tendency is to manage cautiously while accelerating research and data-gathering. The large potential gain in flexibility from rationalization has the potential to create ecosystem benefits.

The PA prevents overfishing of target stocks and reduces the likelihood that stocks will become overfished, through precautionary harvest policies, and imposition of rebuilding regulations when stocks fall below the level capable of producing MSY. Efforts would be accelerated to improve the current harvest strategy, including in PA.2, additional procedures to incorporate uncertainty and develop spawning stock biomass estimates, in particular for Tiers 4-5.

The goal of promoting sustainable fisheries and communities under the PA is likely to be successful. The precautionary adjustments made to quota management decrease the risk of inadvertently overfishing managed species. Additionally, the transition to rights-based management under this alternative will promote the objectives of increasing efficiency, stability and safety in the long-term.

As a whole, through its goal to accelerate precautionary management measures through ecosystem-based principles, and its objectives to develop indices of ecosystem health and to take ecosystem factors into account in ABC setting, this alternative is successful in making many improvements beyond the status quo in achieving the goal of preserving the food web. The emphasis in this alternative is on using the best scientific information available to determine catch levels, but also on providing additional protection against uncertainty by designation of MPAs and reserves. If these improvements are implemented, this strategy is likely to provide protection to a broad range of food web components.

The bycatch and incidental catch reduction policies in the PA are consistent with minimizing human-caused threats to protected species and accelerating precaution through additional bycatch constraints, such as reduced PSC limits. Bycatch reduction objectives and reductions in incidental catch are likely to be achieved without a major cost to industry due to the incentives for more efficient use of fishery resources under cooperatives, comprehensive rationalization of fisheries or other bycatch incentive programs implemented under this alternative.

The goal of minimizing human-caused threats to protected species, and if appropriate and practicable, other seabird and marine mammal species, is largely met in the PA by actively adjusting seabird and marine mammal protection measures, and status review of endangered and threatened marine mammal fishery interactions. This approach, which may provide additional conservation measures in response to scientific evidence, is likely to maintain protection to ESA-listed marine mammals and seabirds, and may increase protection for other seabirds and marine mammals.

This alternative has the potential to reduce and avoid impacts to habitat by careful placement of closures. Placement of closures in lightly fished or not fished areas will provide mitigation and result in avoidance of future habitat impacts if fisheries were to move effort into surrounding areas. Closures in heavily fished areas should be small to minimize displaced efforts and reduce chances of unintended consequences. To achieve overall benefits, closures should not encompass entire habitat types or areas of fishing intensity. In the short-term, information from the Observer Program could be used to locate such closures. In the long-term, scientific information gained from this policy can potentially lead to modification of the placement of MPAs and help meet the policy objective to assess the necessary and appropriate habitat protection measures. Cumulatively, the alternative results in a split impact rating, as the adverse condition of the baseline is coupled with continued damage and mortality to living habitat, however the alternative has strong potential to mitigate these adverse impacts.

The PA promotes increased social and economic benefits through the elimination of the race-for-fish while also emphasizing the long-term economic value of the fishery through the promotion of rights-based allocations to individuals, sectors, and communities. In addition, this alternative promotes ecosystem based management and is likely to increase non-market, recreational, and tourism values assigned to the ecosystem. It is not possible to determine the long-term effect on overall ecosystem value (commercial and non-market values combined) because it is not known whether the fishing sectors, even with rights-based allocations, will be able to adapt to the changes resulting from the increased emphasis on ecosystem tools and, in particular, the potential addition to the number and significance of closed areas.

The goals and policies for Alaska Native consultation and participation in fishery management under the PA would increase current levels by expanding informal and formal consultation between the NPFMC/NOAA Fisheries and Alaska Native participants and tribal governments. Local and Traditional Knowledge would be more formally incorporated in fishery management and additional data would be collected. Other goals and objectives in the PA, such as reductions in PSC limits, may benefit subsistence salmon use by reducing bycatch levels in the groundfish fisheries.

Through data collection measures that will result in reducing uncertainty, the PA is likely to be effective in achieving the goal of accelerating the use of precautionary management measures. The objectives to improve the Observer Program and observer data will increase the quality of fishery data by implementing increased flexibility of, and potentially expanding, observer coverage. Additionally, the expanded economic data and potential for independent verification would allow for more accurate and credible assessments of economic impacts. A funding source would, however, need to be identified to implement improvements to these programs. The alternative also emphasizes the importance of enforcement concerns in fishery management.

4.10.6.2 Prevent Overfishing

The PA incorporates forward looking conservation measures that address differing levels of uncertainty. Under this approach, the NPFMC would seek to accelerate precautionary management measures through community or rights-based management, ecosystem-based management principles that protect managed species from overfishing, and, where appropriate and practicable, increased habitat protection and bycatch constraints. The PA policy is illustrated by PA.1 and PA.2. Each FMP contains a number of management measures that pertain to the sustainability of fisheries and fishery resources. The bookends represent a range of actions that alter constraints to fishery removals.

A detailed description of PA.1 appears in Section 4.2. Briefly, PA.1 continues precautionary practices seen in Alternative 1 where TAC is less than or equal to the ABC, and the ABCs are less than the OFL. Uncertainty corrections applied under Alternative 1 to BSAI and GOA Pacific cod and GOA pollock would also apply. OY restrictions would be identical to Alternative 1, where the OY range for the BSAI and GOA is capped at 2 million mt and 800,000 mt for the BSAI and GOA, respectively. The 2 million mt cap in the BSAI limits the expansion of fisheries. The FMP would formally specify MSSTs for Tiers 1-3 in accordance with National Standard Guidelines. Efforts to develop ecosystem indicators to be used in TAC-setting, as per ecosystem management principles, would be continued. Under PA.2, the calculation of OY caps would be revisited to determine their relevancy to the current environmental conditions and the current knowledge of stock levels.

PA.2 incorporates an uncertainty correction into the estimation of ABC for all species. This represents a significant acceleration of precautionary management. PA.2 would also develop and implement criteria for using key ecosystem indicators in TAC-setting, and other precautionary practices. As a proxy for a more conservative harvest strategy for rockfish, PA.2 capped F_{ABC} at $F_{60\%}$ rather than $F_{40\%}$ for rockfish stocks managed in Tier 3. In implementing this bookend, analysis and data collection would be initiated for specifying MSSTs for priority stocks in Tiers 4-6. The development of criteria to manage target and non-target species consistently, and for moving stocks from the other species and non-specified species categories, would begin with breaking BSAI and GOA sharks and BSAI skates out of the other species group for TAC-setting.

Impacts of Policy

As in Alternative 1, the PA limits the impact of fishing mortality by setting an ABC less than the OFL. This alternative defines four management categories for which catch is constrained by various regulatory mechanisms: target species, other species, prohibited species and forage fish species. The PA harvest policies are consistent with ecosystem principles that call for in-season multi-species catch monitoring to ensure that catch does not exceed the OFL of groundfish. This catch monitoring is facilitated by at-sea observers, port samplers, weekly production reports and fish ticket information (Appendix F-10). Stocks can be moved from one management category into another only by FMP amendment. Within the target species category, stocks are managed either individually or as part of a stock complex. Stocks within the target species category can be added to or removed from a stock complex within the same category as part of the TAC-setting process (i.e., without an FMP amendment).

The bookends provide a range of potential impacts associated with this alternative. PA.1 is similar to FMP 1, and harvest control rules would continue to be used and improved to maintain a spawning stock biomass with the potential to produce sustained yields on a continuing basis. PA.2 imposes more constraints to fishery removals and develops criteria for bringing non-specified species into a managed category.

Goals, Objectives	Corresponding Management Measures	
<u>Goals</u> • NPFMC intends to take appropriate measures to insure the continued sustainability of the managed species • Consider and adopt measures that accelerate ecosystem-based management principles that protect managed species from overfishing • Recognizes need to balance many competing uses of marine resources including protection of the long-term health of the resource and the optimization of yield • Seeks to provide sound conservation of living marine resources <u>Objectives</u> • Adopt conservative harvest levels for multi-species and single species fisheries and specify OY • Continue to use existing OY cap for BSAI and GOA groundfish fisheries as stated in current law. • Provide for adaptive management by continuing to specify OY as a range • Initiate a scientific review of the adequacy of $F_{40\%}$ and adopt improvements as appropriate • Continue to improve the management of species through species categories.	Example Range: ABC<OFL, sum of TACs within OY range, formal adjustments for uncertainty, automatic rebuilding, appropriate harvest policies for rockfish	Quota management based on a tier system. F_{ABC} set below F_{OFL} except at very low stock sizes protecting the stock from unintentional overfishing. Additional adjustments for uncertainty are incorporated into F_{ABC} under PA.2. PA.1 continues to use harvest control rules to maintain sustainable stocks. For example purposes only, F_{ABC} for Tier 3 rockfish stocks would be set at $F_{60\%}$ in PA.2.
	Time/Area	For several species, fishing quotas are distributed across time and area in proportion to the expected underlying biomass of fish in the region at that time. These policies reduce the possibility of spatial temporal concentration of the catch. Relative to FMPs 1 and PA.1, PA.2 imposes additional marine reserves and marine protected areas.
	Gear restrictions	For walleye pollock, Pacific cod, and sablefish, gear allocations partition catch to specific gear groups. Differences in gear selectivity are addressed in the stock assessment models and quotas reflect the expected age distribution of the catch by gear.
	OY caps	OY restrictions cap the aggregated groundfish catch in the GOA and BSAI at 800,000 mt and 2 million mt, respectively. These caps limit the expansion of fisheries (particularly in the BSAI). As a progressive measure, the calculation of OY caps would be revisited under PA.2 to determine their relevancy to the current environmental conditions and information on stock levels.
	Inseason Multi-species TAC and ABC monitoring	The catch of a given target species is limited by prohibited species bycatch caps and the TACs for other groundfish. The halibut bycatch caps serve as a constraint to BSAI and GOA flatfish expansion. Reduced bycatch allowances would further constrain target fisheries. Sharks and skates would be moved from the other species management category under PA.2.

Several measures associated with the PA could result in reductions in catch relative to baseline conditions. First, an uncertainty correction could be applied that would account for measurement and process error in the assessment (PA.2). Second, the development of appropriate harvest strategies Tier 3 rockfish species could result in a more conservative strategy (PA.2). Third, a 0-10 percent (PA.1) or 0-20 percent reduction (PA.2) in bycatch would be imposed under this alternative. Finally, sharks and skates could be broken out of the other species complex (PA.2). The FMPs used to illustrate the PA demonstrate conservative harvest polices. Direct and indirect impacts analyses revealed that overfishing did not occur in the stocks or stock complexes modeled under PA.1 or PA.2 (Table 4.9-1). Relative to the comparative baseline, the expected fishing mortality under the PA would have no significant impact on any of the target groundfish stocks. Consideration of cumulative impacts does not change the expectations for direct or indirect impacts of this alternative on fishing mortality.

Relative to the comparative baseline, the likelihood of a stock falling below the level where the stock is capable of producing MSY is reduced under the PA. Under PA.1 and PA.2 none of the stocks managed in Tiers 1-3 would be expected to become overfished. The direct and indirect impact of the PA on changes in biomass of all of the Tier 1-3 target groundfish stocks would be insignificant relative to the baseline (Table 4.9-1). The direct and indirect impact of commercial fishing on the biomass of target groundfish stocks managed in Tiers 4-6 is unknown because the status of such stocks relative to their respective MSSTs is unknown (Table 4.9-1). Consideration of cumulative impacts does not change the expectations for direct or indirect impacts of this alternative on changes in biomass.

Relative to the comparative baseline, PA.2 adds several spatial and temporal restrictions on catch. These restrictions would decrease the spatial/temporal concentration of the catch. Under this policy, commercial fishing is expected to have insignificant impacts on the genetic makeup or the reproductive success of the 19 stocks managed in Tiers 1-3. The direct and indirect impact of commercial fishing on the genetic makeup or reproductive success of stocks managed in Tiers 4-6 is unknown because the status of such stocks relative to their respective MSSTs is unknown. The PA would initiate research to collect information necessary to determine MSSTs, particularly for stocks managed in Tiers 4-5. Once the MSST definition is established, the significance of commercial harvest on those stocks could be evaluated. Consideration of cumulative impacts does not change the expectations for direct or indirect impacts of this alternative on fishing mortality.

Relative to the comparative baseline, the PA would increase restrictions on the spatial temporal partitioning of catch and could reduce overall harvest of target groundfish. The direct and indirect impact of these changes on prey availability is expected to be insignificant for all stocks managed in Tiers 1-3 (Table 4.9-1). Direct and indirect impacts of commercial fishing on prey availability of all stocks or stock complexes managed in Tiers 4-6 are unknown because the status of such stocks relative to MSST is unknown (Table 4.9-1). Consideration of cumulative impacts does not change the expectations for direct or indirect impacts of this alternative on fishing mortality.

Harvest restrictions, spatial temporal constraints, and gear allocations all serve to mitigate the impact of commercial fishing on fish habitat. The closure system described in PA.2 would close approximately 18 percent of the EEZ to some form of MPA and designate approximately 3.1 percent of the EEZ as a no-take reserve (Figure 4.2-9). For the fishable area (depth to 1,000 m) of the EEZ, PA.2 would designate approximately eight percent of the fishable area as a no-take reserve and about 40 percent of the fishable area as some form of MPA. Relative to the comparative baseline, the impacts on target species resulting from habitat disturbance are considered insignificant for all stocks managed in Tiers 1-3 (Table 4.9-1). The impacts are unknown for stocks or stock complexes managed in Tiers 4-6.

When taken in aggregate, the PA appears to increase existing precautionary management measures. Irreversible or long-term adverse effects on fishery resources are avoided by precautionary harvest policies and imposition of rebuilding regulations when stocks fall below the level capable of producing MSY. Strengths of the PA are that the FMPs will adopt formal criteria for status determination, and research will be accelerated to develop ecosystem-based harvest policies. Community or rights-based management adopted under the PA would reduce the race-for-fish. Efforts would be accelerated to identify methods for reducing the number of stocks where the status relative to an overfished condition is unknown. Another strength of this policy is that PA.2 would develop a list of priority stocks for moving stocks from the other species and non-specified species categories, using consistent criteria. The catch of these species would be monitored. Until this system is developed, harvest policies may build and maintain the species complex, but it is still possible to over harvest a vulnerable member of the complex.

4.10.6.3 Promote Sustainable Fisheries and Communities

The PA sets goals and objectives to promote sustainable fisheries and communities, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Goals • Ensure the sustainability of fishery resources and associated ecosystems for the benefit of future as well as current generations • Provide socially and economically viable fisheries and fishing communities • Recognize the need to balance different social and economic goals for sustainable fishery management including protection of the long-term health of the resource and the optimization of yield Objectives • Promote conservation while providing for OY in terms fo providing the greatest overall benefit to the nation with particular reference to food production, and sustainable opportunities for recreational, subsistence, and commercial fishing participants and fishing communities • Promote management measures that, while meeting conservation objectives, are also designed to avoid significant disruption of existing social and economic structures • Promote fair and equitable allocation of identified available resources in a manner such that no particular sector, group, or entity acquires an excessive share of the privileges • Promote increased safety at sea	TAC-setting Process	Quota management based on a tier system. F_{ABC} set below F_{OFL} except at very low stock sizes, protecting the stock from unintentional overfishing. Additional adjustments for uncertainty are incorporated in ABC setting.
		Optimum Yield restrictions cap the aggregated groundfish catch in the GOA and BSAI. These caps limit the expansion of fisheries (particularly in the BSAI).
	Overcapacity	Maintain existing restricted access programs while developing rationalization that includes benefits to rural communities

Impacts of Policy

The goal of promoting sustainable fisheries and communities is pursued through the following objectives: provide the greatest overall benefit to the nation, increase efficient use of fishery resources, avoid significant disruption of existing social and economic structures, promote fair and equitable allocation of resources, and promote increased safety at sea.

The impact of these goals and objectives for sustainable fisheries and communities would not be significantly different from the comparative baseline. To the extent that these goals are in the MSA, the objectives are also part of the status quo fishery management policy. Specific management actions that would further implement these goals under the PA are also captured in Section 4.10.6.2, Prevent Overfishing, and Section 4.10.6.8, Promote Equitable and Efficient Use of Fishery Resources. Management measures such as conservative quota management, and adjustments made under the PA to account for uncertainty, ensure the sustainability of the managed species by maintaining a spawning stock biomass for the target species with the potential to produce sustained yields. Improvements to the monitoring and data collection programs, as described in Section 4.10.6.10, Improve Data Quality, Monitoring and Enforcement, would allow fishery managers to achieve a more accurate understanding of the impact of fishing activity on the stocks and the ecosystem, and of the status of the stocks.

The acceleration under the PA of the move towards comprehensive rationalization of the groundfish fisheries is also an effective implementation tool for the objectives considered in this section. As discussed in further detail in Section 4.10.6.8, the implementation of rationalization, which allows for flexible fishing practices, is likely to improve efficient use of fishery resources while reducing unwanted incidental catch and bycatch, to increase overall benefit to the nation in terms of food production, and also to increase safe fishing practices. The transition to rationalization in the short-term could disrupt stability, however in the long-term, the stability of fisheries would be increased in comparison to a derby-style fishery. Likewise, communities would also tend to experience an increase in stability as a result of built-in community protections to the rationalization programs. The objective of equity would likely be met through allocating the resource based on historic participation in the fishery.

The goal of promoting sustainable fisheries and communities under the PA is likely to be successful. The precautionary adjustments made to quota management decrease the risk of inadvertently overfishing managed species. Additionally, the transition to rights-based management under this alternative will promote the objectives of increasing efficiency, stability and safety in the long-term.

4.10.6.4 Preserve Food Web

The PA sets goals and objectives to preserve the food web, as well as recommending a range of management measures that would implement these objectives.

Impacts of Policy

Impacts to food webs of the BSAI and GOA are mitigated through many of the goals and objectives and related management measures of this alternative, some of which are improvements beyond those provided in the comparative baseline. In addition to objectives specifically for incorporating ecosystem considerations into fisheries management decisions and prohibiting directed fisheries for forage fish (which often form a central position in channeling energy through the food web), and the precautionary adjustments to the ABCs of Tier 1 stocks that were part of Alternative 1, this alternative provides for the possibility of developing other precautionary ABC adjustments to account for ecosystem factors, and specifically develops indices of ecosystem health as targets for management. Other policies of this alternative, such as preventing overfishing, reducing bycatch, avoiding impacts to seabirds and marine mammals, reducing impacts to habitat, and improving data quality, monitoring, and enforcement, are critical to protection of food web components, which include target and non-specified species, PSC species, HAPC biota, marine mammals and seabirds. Management measures, such as revised procedures for ABC, MSST setting, incorporating precaution, and spatial/temporal allocation for TAC (Section 4.10.4.2); additional bycatch reduction measures (Section 4.10.4.4); further gear modifications for seabird protection (Section 4.10.4.5); procedures to identify MPAs and no-take marine reserves (Section 4.10.4.6) and improvements to the Observer Program coverage (Section 4.10.4.9), that are proposed as improvements beyond the baseline in the PA provide increased protection to a variety of food web components. See the policy analysis in those sections for details on the level of protection provided by the PA to these individual components.

Goals, Objectives	**Corresponding Management Measures**	
	FMP Component	**Management Measure**
Goals • Precautionary approach that incorporates forward looking conservation measures that address differing levels of uncertainty • Incorporate ecosystem-based considerations into management decisions • Accelerate precautionary management measures through ecosystem-based principles that protect managed species from overfishing • Take into account NAS Sustainable Fisheries policy recommendations • Promote sound conservation of living marine resources Objectives • Develop indices of ecosystem health as targets for management • Improve the procedure to adjust ABCs as necessary to account for uncertainty and ecosystem factors • Continue to protect the integrity of the food web through limits on harvest of forage species • Incorporate ecosystem-based considerations into fishery management decisions as appropriate	TAC-setting Process	Prohibit directed fishery for forage fish
		Procedures to incorporate precaution and uncertainty into ABCs
		Procedure to develop and use key ecosystem indicators in TAC-setting

This alternative specifically attempts to incorporate ecosystem considerations into fishery management decisions through advancements in how uncertainty and ecosystem factors are used in ABC adjustment. It will continue to prohibit directed fisheries for forage fish, and develop ecosystem indicators. Analysis of the ecosystem effects of the PA involved selection of indicators that would show changes in key members or ecosystem characteristics that are important to the structure and function of marine food webs. Changes in pelagic forage, top predators, spatial/temporal availability of prey, exotic species introductions, energy removal and redirection through fishery catch removals and discards/offal production, and various measures of diversity were evaluated with respect to the potential of fishing to cause changes sufficient to bring these attributes below population, community, or ecosystem thresholds, if such thresholds could be defined. Most of these indicators showed there were insignificant impacts of this alternative on these ecosystem attributes. There were unknown effects of this alternative on top predator species and species diversity due to our lack of knowledge of abundance levels and life history characteristics of species such as skates, sharks, and grenadiers, although breaking these species out of the other species group and giving each its own TAC (PA.2) would provide additional protection. The additional area closures, including the Aleutian Islands management area to protect corals and live bottom habitat, proposed in PA.2, would result in improvements relative to the comparative baseline in spatial/temporal availability of forage to marine mammals and birds and protection of corals. Qualitative analysis with respect to the ecosystem effects of the TAC-setting process in Appendix F-1, Alternative 3, which is similar to the PA in terms of the TAC-setting process, showed that increased protection would be provided to stocks that need it most, such as slower-growing, long-lived species such as rockfish, skates, and sharks, and would thus reduce the possibility of adverse impacts to those groups and to their role in the food webs of these ecosystems. Thus, if these improvements are implemented, this alternative has the potential to decrease ecosystem impacts relative to the comparative baseline.

As a whole, through its goal to accelerate precautionary management measures through ecosystem-based principles, and its objectives to develop indices of ecosystem health and to take ecosystem factors into account in ABC setting, this alternative is successful in making many improvements beyond the status quo in achieving the goal of preserving the food web. The emphasis in this alternative is on using the best scientific information available to determine catch levels, but also on providing additional protection against uncertainty by designation of MPAs and reserves. If these improvements are implemented, this strategy is likely to provide protection to a broad range of food web components.

4.10.6.5 Manage Incidental Catch and Reduce Bycatch and Waste

Several policy changes adopted in the PA would change the incidental catch of target and non-target species, and bycatch (regulatory and economic discards). Under PA.1, the cap on OY is maintained, so the absolute amount of target and non-target groundfish catch is unlikely to change. The calculation of OY caps would be revisited under PA.2 to determine if the caps are still relevant to environmental conditions and the current knowledge of stock levels. However, the amount of incidental catch of groundfish and subsequent discard of groundfish (bycatch) is likely to decrease due to the policy emphasis on rationalization. Other measures would likely lead to reductions of incidental catch for various species including prohibited species. These additional measures include the uncertainty correction and reduced rockfish F_{OFL} described in PA.2, and the separation of sharks and skates from the other species complex (PA.2). The latter would ensure that these species are not harvested above the maximum fishing mortality threshold. Furthermore, criteria for defining the membership within species complexes and the circumstances when species should be broken out of complexes would be developed.

The comprehensive rationalization of the groundfish fisheries, in PA.1 and PA.2, will address bycatch reduction objectives (a review of bycatch in existing programs is initiated), by eliminating the race-for-fish, and providing internal incentives to minimize catches of less valued groundfish and PSC. It is expected that with rationalization in all groundfish fisheries, incidental catch and discards (bycatch) may be reduced by as much as 20 percent. Even without predicted reductions in PSC resulting from rationalization, a moderate reduction of PSC limits would be adopted as an intermediary step. Habitat and bycatch concerns would also be addressed by reducing concentrated effort in the fisheries.

Impacts of Policy

The PA is expected to encourage the development of practical measures that reduce bycatch and incidental catch of target and non-target species. With respect to the impact on the sustainability of prohibited species that are currently in a depressed or overfished condition (BSAI and GOA chinook salmon, *C. bairdi* crab, *C. opilio* crab, BSAI and GOA red king crab, and BSAI blue king crab [Table 4.10-2b]). The impacts of mortality and change in biomass associated with the PA policy are likely to be positive, but are unlikely to be significant overall. Cumulative impacts are considered conditionally significant adverse due to mortality for BSAI chinook and other salmon and GOA chinook salmon. The PA is expected to have an insignificant impact on forage fish, but is none-the-less expected to reduce bycatch of these species. The impact of the PA on other species and non-specified groups is unknown.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	**Management Measure**
Goals • Accelerate precautionary management measures through increased bycatch constraints where appropriate and practicable • Minimize human-caused threats to protected species • Promote sound conservation of living marine resources Objectives • Continue and improve current incidental catch and bycatch management program • Develop incentive programs for bycatch reduction including the development of mechanisms to facilitate the formation of bycatch pools, VBAs, or other bycatch incentive systems • Encourage research programs to evaluate current population estimates for non-target species with a view to setting appropriate bycatch limits as information becomes available • Continue program to reduce discards by developing management measures that encourage the use of gear and fishing techniques that reduce bycatch which includes economic discards • Continue to manage incidental catch and bycatch through seasonal distribution of TAC and geographical gear restrictions • Continue to account for bycatch mortality in TAC accounting and improve the accuracy of mortality assessments for target, PSC bycatch, and non-commercial species • Control the bycatch of prohibited species through PSC limits or other appropriate measures • Reduce waste to biologically and socially acceptable levels	Spatial/ Temporal Management of TAC	Spatial/temporal distribution of TAC
	MPAs and EFH, Bycatch and Incidental Catch Restrictions, Gear Restrictions and Allocations	Seasonal, gear/fishery specific, and total closure areas identified to reduce bycatch; reviews to develop appropriate bycatch closure areas in the GOA
	Bycatch and Incidental Catch Restrictions	Reduce existing PSC limits, or other appropriate measures, for prohibited species, establish PSC limits for prohibited species other than halibut in the GOA
		Procedure to develop mortality rate-based approach to setting limits
		Retention standards for DSR, and IR/IU for pollock, Pacific cod, shallow-water flatfish in the GOA, and groundfish retention standard for other groundfish species in the BSAI
		Review bycatch reduction incentive programs (repeal/maintain VIP)
		Bycatch restrictions (including in-season)/ repeal or modify MRBs and establish system of caps and quotas

The PA policies as illustrated by PA.1 and PA.2 are consistent with the goal of accelerating precautionary management measures through increased bycatch constraints where appropriate and practicable. The PA policies are also consistent with the objective of controlling prohibited species bycatch. Increased precaution regarding bycatch would be achieved through reductions in PSC limits. Bycatch reduction objectives (0-10 percent for PA.1 or 0-20 percent for PA.2) are likely to be achieved due to the incentives for more efficient use of fisheries resources under cooperatives, comprehensive rationalization of fisheries, or other bycatch incentive programs implemented under this alternative.

4.10.6.6 Avoid Impacts to Seabirds and Marine Mammals

The PA policy sets goals and objectives to avoid impacts to seabirds and marine mammals, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
<u>Goals</u> • Minimize human-cause threats to protected species • Promote sound conservation of living marine resources <u>Objectives</u> • Continue to cooperate with USFWS to protect ESA-listed species, and if appropriate and practicable, other seabird species • Maintain or adjust current protection measures as appropriate to avoid jeopardy to ESA-listed Steller sea lions • Encourage programs to review status of endangered and threatened marine mammals stocks and fishing interactions and develop fishery management measures as appropriate • Continue to cooperate with NOAA Fisheries and USFWS to protect ESA-listed marine mammal species, and if appropriate and practicable, other marine mammal species	TAC-setting Process, Steller sea lion Measures	Steller sea lion prey species low biomass rules
	TAC-setting Process	Prohibit directed fishery for forage fish
	Spatial/ Temporal Management of TAC	Spatial/temporal distribution of TAC
	MPAs and EFH, Steller sea lion Measures, Gear Restrictions and Allocations	Maintain/modify as scientifically appropriate the seasonal, gear/fishery- specific, and total closure areas identified to protect walrus and Steller sea lions
	Seabird Measures	Short-tailed albatross take restrictions
		Develop further gear modifications to protect seabirds (trawl and longline)

Impacts of Policy

This alternative seeks to provide conservation of living marine resources and minimize human-caused threats to protected species. It will accomplish those goals through continued cooperation with USFWS to protect seabird species in the longline and trawl fleets, cooperation with NOAA Fisheries and USFWS to protect marine mammal species, maintenance or possible adjustment of current protection measures for Steller sea lions to avoid jeopardy, and review of endangered or threatened marine mammal and fishery interactions and development of appropriate fishery management measures for mitigation, if needed. Management measures that are improvements beyond those provided in the status quo include modification of closure areas for walrus and Steller sea lion protection as appropriate scientific information becomes available, and possible gear improvements to protect seabirds. Elimination of the race-for-fish in this alternative may also tend to decrease direct takes of marine mammals and seabirds. Impacts of the alternative with respect to seabirds were evaluated with respect to the potential for fisheries to cause direct mortality through fishing gear and vessel strikes, changes in prey availability (including offal), and changes in benthic habitat that might affect certain prey species of seabirds. Impacts for marine mammals were evaluated with respect to the potential for fishery incidental take or entanglement in marine debris, harvest of prey species, spatial/temporal concentration of fishing on prey, and fishing vessel disturbance.

These indicators showed that the PA provides increased protection to seabirds and marine mammals relative to the comparative baseline. As in Alternative 1, incidental take of albatross, fulmars, shearwaters, and gulls is substantially reduced due to new mitigation measures in the longline fleet. In addition, mitigation measures for the trawl fleet, currently under development through cooperation between industry and USFWS, are likely to reduce collisions with trawl third wires. The Seabird Protection Measures paper (Appendix F-6) analyzed components of Alternative 3 that are similar to the PA, and noted that the potential expansion of the Observer Program would improve the collection of seabird/fishery interaction data that measure the effectiveness of mitigation measures. The groundfish fishery is not expected to have population level effects on any seabird species through mortality, changes in food availability, or benthic habitat. The impact of the policy on Steller sea lions is likely to be similar to Alternative 1, except as new research indicates appropriate modifications will be made to existing protection measures.

The goal of minimizing human-caused threats to protected species, and if appropriate and practicable, other seabird and marine mammal species, is largely met in the PA by actively adjusting seabird and marine mammal protection measures, and status review of endangered and threatened marine mammal fishery interactions. This approach, which may provide additional conservation measures in response to scientific evidence, is likely to maintain protection to ESA-listed marine mammals and seabirds, and may increase protection for other seabirds and marine mammal species.

4.10.6.7 Reduce and Avoid Impacts to Habitat

The PA sets goals and objectives to reduce and avoid impacts to habitat, as well as recommending a range of management measures that would implement these objectives.

Impacts of Policy

The PA addresses impacts to habitat by having specific goals and objectives that focus on living marine habitat. This policy accelerates habitat protection where appropriate and practicable and could result in a gradual-to-rapid reduction and avoidance of impacts to habitat depending on how quickly management measures are implemented. Development of a procedure to identify MPAs and no-take marine reserves and identification of EFH mitigative features are identified as specific management measures.

In addition to the objectives specifically designed to address habitat concerns, the PA policies are designed to prevent overfishing, reduce and avoid bycatch, incorporate ecosystem considerations, and improve data quality and enforcement. These goals are important ancillary objectives that could provide reduced impacts to habitat. Management measures such as revised procedures for ABCs that incorporate greater precaution can potentially reduce impacts to habitat if fishing effort is reduced. Closures for marine mammal protection, especially if they are year round for all target species, can also provide protection to specific habitat types. Measures to avoid and reduce impacts could occur on a rapid time line, especially if precautionary measures are implemented before complete scientific information is available.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Goals • Accelerate precautionary management measures through increased habitat protection where appropriate and practicable • Maintain a healthy marine resource habitat • Promote sound conservation of living resources Objectives • Review and evaluate efficacy of existing habitat protection measures for managed species • Identify and designate EFH and HAPC pursuant to MSA rules, and mitigate fishery impacts as necessary and practicable to continue the sustainability of managed species • Develop an MPA policy in coordination with national and state policies • Encourage development of a research program to identify regional baseline habitat information and mapping, subject to funding and staff availability • Develop goals, objectives and criteria to evaluate the efficacy of MPAs and no-take marine reserves as tools to maintain abundance, diversity, and productivity • Implement MPAs if and where appropriate	MPAs and EFH, Bycatch and Incidental Catch Restrictions, Gear Restrictions and Allocations	Existing system of closed areas including Sitka Pinnacles, modify based on MPA process
		Establish Aleutian Island special management area to protect coral/live bottom habitats (PA.2)
	MPAs and EFH	Develop procedure to identify MPAs and no-take marine reserves, including definition of terms
		Identify and designate EFH and HAPC, determine extent of adverse effects from fishing, if any, and implement mitigation measures if necessary

The PA addresses habitat protection by developing and adopting a methodology for establishing MPAs and, in PA.2, adopting a MPA closure system. A composite of several different concepts for habitat protection and mitigation were qualitatively analyzed. After the concepts were analyzed, specific implementations of the concepts were analyzed and results compared to the comparative baseline. The basis for these conceptual closures is to illustrate how the effects of fishing on EFH can be mitigated by reducing the impacts caused by a particular fishery by closing specific areas. The conceptual strategies are:

- Reduce the impacts caused by a particular fishery by closing specific areas.

- Protect a diversity of habitat types across a range of geographic areas where closures do not encompass entire habitat types or areas of fishing intensity, incorporating a "band-approach" where appropriate with closures oriented perpendicular to depth contours from near shore to deep water.

- Develop a special conservation area in the Aleutian Islands to protect sensitive cold water coral communities.

- Limit size of closures in heavily fished areas to minimize displaced effort.

All of these approaches are variations of MPAs. Concepts 1-3 have the most potential for benefits to habitat. However, careful placement of the MPAs is required to avoid unintended consequences. Displacement of effort to new areas with more sensitive habitat may be an unintended consequence. If closures are placed primarily in areas with high fish densities and displace effort into areas of low densities then increased effort in a given area could lead to more habitat impacts. For closures to be most effective they should be combined with some effort controls. Ancillary management measures associated with the PA that result in reduced effort could result in increased effectiveness of MPAs. However, closures alone, if they are strategically placed within historically fished areas, can provide benefits to habitat without necessarily requiring a reduction in TACs. Benefits to habitat could occur with closure areas strategically placed that do not encompass entire habitat types or clusters of fishing intensity. To be most effective, closure areas should include some portion of areas where high fishing intensity has occurred, but need not be so large that they encompass entire habitat types or clusters of fishing intensity. Placement of small closures within areas of high fishing intensity could also promote scientific understanding of the effectiveness of such management measures. The specific location of MPAs could have serious social and economic consequences. Determining where to locate MPAs for habitat goals should include consultation with the fishing industry and nearby communities.

Analysis of specific management measures indicated mixed ratings relative to the comparative baseline for effects to mortality and damage to living habitat under PA.2. These mixed ratings result from the specific location of bottom trawl closure MPAs (see Figure 4.2-9) and the uncertainty of how changes in TAC will interact with MPAs. For example, in the GOA many of the specific strategy (1) closed areas on the slope encompass high effort areas which would be expected to have higher target fish densities. This could result in a much higher effort to catch fish in lower density open areas. This higher effort could result in enough of an increase in habitat impacts to negate impact reduction in the closed areas. Whether decreased TACs for some species will offset this increase in habitat impacts is uncertain. This uncertainty in predicted impacts led to an insignificant or possibly significantly adverse change to mortality and damage to living habitat relative to the baseline in the GOA.

This policy could, however, lead to improved benthic community diversity and geographic diversity of impacts. Analysis of specific management measures in the Bering Sea under PA.2 indicated some improvement in the geographic diversity of impacts. Large expanses of high fishing intensity could still remain open in the Bering Sea, but there is at least one closure area that covers a portion of a high fishing intensity area, providing some improvement in the geographic diversity of impacts. In the Aleutian Islands, the example closure areas that represent the established management area to protect coral and live bottom habitat, bisect apparent historic clusters of fishing patterns, thus providing a diversity of impacts for the habitat being fished. In the GOA closures also often encompass clusters of historically high fishing intensity, leaving little diversity or contrast of fishing intensity and thus leading to no improvement over the baseline.

From a cumulative impacts perspective, the baseline condition is adversely impacted due to historical impacts that have potentially caused long-term and possibly irreversible loss of living habitat, especially to long-lived, slow-growing species which are slow to recover. Although some benefits accrue to habitat within the proposed MPAs in PA.2, impacts from fishing are not totally eliminated, and TAC/effort is likely to remain high. While there is an incremental expansion of no-take MPAs, the closures analyzed under this FMP are not refined and may not be effective at preventing mortality or protecting benthic community structure. However, if properly designed and located, future closures could provide successful mitigation of the effects of fishing and, over time, adversely impacted habitat could recover. The cumulative impact predicted for this alternative is a split rating of conditionally significant adverse/conditionally significant beneficial. The existing adverse impact to the baseline condition coupled with continued damage and mortality to living habitat results in a conditionally significant adverse impact, because the extremely slow growing corals that have already been impacted are not likely to recover from their current impacted state. However, the alternative has strong potential to provide mitigative protection to habitat.

Overall, this policy has the potential to reduce and avoid future impacts to habitat by careful placement of closures. Placement of closures in lightly fished or not fished areas could result in avoidance of future habitat impacts, if effort expands to new or lightly fished areas. Placement of small closures within heavily fished areas can potentially mitigate impacts, reduce unintended consequences, and achieve overall benefits to habitat and meet policy goals and objectives. Strategic placement of small closures will also help meet the policy objective of evaluating the efficacy of MPAs. In the long-term, scientific information gained from this policy can potentially lead to modification of MPAs to help meet the policy objective to assess the necessary and appropriate habitat protection measures and reduce unnecessary impacts to the fishing industry.

4.10.6.8 Promote Equitable and Efficient Use of Fishery Resources

This policy would seek to accelerate the existing precautionary management measures through community or rights-based management and ecosystem-based management principles. Under this approach, additional conservation and management measures would be taken as necessary to respond to social, economic or conservation needs, or if scientific evidence indicated that the fishery was negatively impacting the environment. This policy recognizes the need to balance many competing uses of marine resources and different social and economic goals for fishery management.

Impacts of Policy

The PA promotes increased social and economic benefits through the promotion of rights-based allocations to individuals, sectors and communities. For this reason the alternative is likely to increase the commercial value generated from the groundfish fisheries. In addition, this alternative promotes ecosystem-based management which could increase the specificity of the species reporting, could increase the areas in which fishing is restricted, and places additional emphasis on the reduction of bycatch. For that reason this policy alternative has some potential to increase non-market value and the benefits derived from recreational, subsistence and tourism activities related to the Bering Sea and GOA marine ecosystems. Overall benefits derived from the ecosystem (the combination of commercial and non-commercial values) are likely to be positive. See Section 3.9.8 and Section 4.10.4.3 for additional information on ecosystem values.

As the race-for-fish is eliminated, the alternative could result in positive effects in terms of producer net revenue, consumer benefits, and participant health and safety. For additional information on the effects of the race-for-fish and rights-based management see the discussion under Alternative 3 in the overcapacity qualitative analysis paper in Appendix F-8. The PA provides economic stability to fishery participants and communities by maintaining current allocation percentages to sectors. However, the elimination of the race-for-fish will likely result in a decrease in overall participation levels. In the long-run, communities are likely to see fewer persons employed in jobs related to the fishing industry (fishing, processing, or support sectors), but the jobs that remain could be more stable and provide higher pay.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Goals • Accelerate precautionary, adaptive management measures through community or rights-based management • Take into account National Academy of Science Sustainable Fisheries policy recommendations • Provide socially and economically viable fisheries and fishing communities • Recognizes need to balance different social and economic goals for sustainable fishery management Objectives • Provide economic and community stability to harvesting and processing sectors through fair allocation of fishery resources • Maintain LLP program, and modify as necessary, and further decrease excess fishing capacity and overcapitalization by eliminating latent licences and extending programs such as community or rights-based management to some or all groundfish fisheries • Provide for adaptive management by periodically evaluating the effectiveness of rationalization programs and the allocation of access rights based on performance • Develop management measures that, when practicable, consider the efficient use of fishery resources taking into account the interest of harvesters, processors, and communities.	Gear Restrictions and Allocations	Allocate by gear for certain directed fisheries
	Overcapacity	Maintain existing restricted access programs (LLP and moratorium, AFA, IFQ sablefish, etc.)
		Development of rights-based management programs for the groundfish fisheries, to include protections that maximize benefits in rural communities

With an end to the race-for-fish and implementation of rights-based allocations, participants are expected to be better able to adapt to the additional restrictions placed on the fishery because of increased emphasis on ecosystem management. To the extent participants are able to adapt, the rights-based allocations within the alternative are expected to decrease the number of direct participants and activities of support industries, Remaining participants however, are likely to have increased stability and incomes. The alternative's promotion of rights-based allocations is also expected to increase consumer benefits and health and safety of participants. Additionally, because the disincentives for bycatch reduction inherent in the race-for-fish are reduced, the alternative could reduce bycatch, even if additional bycatch regulations are not imposed.

The alternative also promotes, in PA.2, expanding the range of data reporting required by industry. The collection of additional economic data could be critical in the development and eventual acceptance of additional ecosystem regulations. Regulations such as bycatch restrictions and the creation of MPAs have the potential to have negative effects at least in the short-term on industry participants; if additional data can reduce the uncertainty of social and economics effects associated with these types of restrictions, then it may increase the probability that these regulations could be approved and implemented. A further discussion of the benefits of additional socioeconomic data can be found under Alternative 3 in the Data and Reporting Requirements qualitative analysis paper in Appendix F-11.

4.10.6.9 Increase Alaska Native Consultation

The PA sets objectives to increase Alaska Native consultation, as well as recommending a range of management measures that would implement these objectives.

Goals, Objectives	Corresponding Management Measures	
	FMP Component	Management Measure
Objectives • Continue to incorporate local and Traditional Knowledge in fishery management • Consider ways to enhance collection of local and Traditional Knowledge from communities, and incorporate such knowledge in fishery management where appropriate • Increase Alaska Native participation and consultation in fishery management	Alaska Native Issues	Develop and implement procedures to incorporate local and Traditional Knowledge into fisheries management/ do local and Traditional Knowledge research
		Increase consultation with Alaska Natives
		Encourage increased participation/ representation of Alaska Natives in fishery management
		Allow for subsistence uses consistent with Federal law

Impacts of Policy

Under the PA, there would be some changes to current management policies and measures used by NOAA Fisheries and the NPFMC regarding Alaska Native consultation. These changes increase efforts to collect local and Traditional Knowledge, and develop and implement measures to incorporate it into fishery management. NOAA Fisheries staff anthropologists would increase the collection of existing local and Traditional Knowledge, expand an in-house local and Traditional Knowledge database, and continue informal consultation with individuals in Alaska Native communities. NOAA Fisheries and the NPFMC would work with Alaska Natives to evaluate and develop measures to incorporate Traditional Knowledge. Formal consultation with federally recognized tribal governments during NEPA compliance under EO 13175 would also continue at current levels during NEPA scoping activities and public comment periods on draft NEPA documents, but other forms of consultation would also be considered. Similarly, opportunities for Alaska Native participation in NEPA compliance and NPFMC deliberations would continue to be available during NEPA scoping, public comment periods on draft NEPA documents, review of NPFMC documents, and at NPFMC meetings. However, other forms of outreach and information exchange would be considered to increase participation.

Increased participation and representation of Alaska Natives in fishery management would be encouraged under the PA. NOAA Fisheries and the NPFMC would work with Alaska Natives to identify and develop measures that would increase participation and representation in fishery management.

Under the PA, Alaskan Native participation in the fisheries will be affected by rationalization of fisheries. CDQ groups fishing in the BSAI would continue to benefit from rationalization. Non-CDQ Alaska Native participants in the GOA would also benefit from rationalization of fisheries. Benefits to Alaska Native communities would be mixed, with CDQ communities receiving increased revenues, while non-CDQ Native communities could experience a reduction in employment and support services due to rationalization of fisheries.

Reduced levels of salmon bycatch and additional area closures under PA.2 could benefit subsistence harvest of Steller sea lions and salmon in western Alaska, although cumulative effects have a greater influence on the availability of both subsistence resources. The potential for Environmental Justice impacts as a result of this alternative would be limited to any adverse effects of rationalization on non-CDQ Alaska Native communities.

Under the PA, subsistence uses would continue consistent with federal law. Joint production of subsistence resources, where Alaska Natives who participate in groundfish fishing take advantage of their commercial fishing efforts to harvest subsistence resources, would continue at current levels.

4.10.6.10 Improve Data Quality, Monitoring and Enforcement

The PA accelerates precautionary management of the groundfish fisheries. The policy sets goals and objectives to improve data quality, monitoring, and enforcement, as well as recommending a range of management measures that would implement these objectives.

Impacts of Policy

The goal of the PA, as with all the alternatives, is to base fishery management on the best scientific information available. The PA objectives are to increase the utility of observer data, and to improve the Observer Program; to improve economic impact assessments by changing data reporting requirements; to utilize advances in technology to improve the quality of monitoring and enforcement data; to encourage an ecosystem monitoring program; to work with research institutions to identify research needs and to develop programs to address them; and to promote enforceability.

The Observer Program objective would be implemented through management measures that would either maintain or expand existing coverage but allow more flexible deployment of observers; improve species identification in observer data, and develop uncertainty estimates; and identify alternate funding mechanisms. Building more flexibility into observer deployment, so that coverage can be adjusted rapidly to respond to monitoring needs for data or compliance, would be beneficial and was an original intent of the Research Plan that preceded the interim Service Delivery Model program currently in place (for further historical description, see the Observer Program paper in Appendix F-10). Expanding coverage from 30 percent to 100 percent on the 60 to 125 ft LOA component of the fleet would provide more data on those vessels and address the issue of non-random coverage, but would not resolve lack of coverage issues with the <60 ft vessels.

Implementing improvements to observer data under the PA is accomplished through measures addressing the level of species identification in observer samples and uncertainty estimates. Historically, observers have identified only fish that are managed to the species level; however, the Observer Program has responded to requests to further identify other organisms, most recently skates, sculpins, and some coral species. The program must maintain a balance in consideration of the amount of time to teach identification and to record these species in the field, so as not to sacrifice target species data. A pilot project to determine the recording time required in the field is currently underway, with the goal of understanding the cost-benefit relationships of increasing the specificity of identification. This program would be expanded under PA.2. Regarding the setting of uncertainty estimates, currently there are no established confidence intervals for observer data. A 1997 analysis has indicated, however, that while statistical procedures may be appropriate for the most abundant species in the catch, the statistical precision decreased for rarer species, and the adoption of statistical estimators may need to be paralleled with an increase in the current level of observer coverage and the amount of hauls sampled (see discussion under Alternative 3 of the Observer Program paper in Appendix F-10 for additional information).

Goals, Objectives	**Corresponding Management Measures**	
	FMP Component	**Management Measure**
<u>Goals</u> • Precautionary approach that applies judicious and responsible fisheries management practices, based on sound scientific research and analysis • Base management on the best scientific information available <u>Objectives</u> • Increase the utility of groundfish fishery observer data for the conservation and management of living marine resources • Improve groundfish Observer Program, and consider ways to address the disproportionate costs associated with the current funding mechanism • Improve community and regional economic impact costs and benefits through increased data reporting requirements • Increase the quality of monitoring and enforcement data through improved technological means • Encourage a coordinated, long-term ecosystem monitoring program to collect baseline information and compile existing information from a variety of ongoing research initiatives • Cooperate with research institutions such as the NPRB in identifying research needs to address pressing fishery issues • Continue to cooperate and coordinate management and enforcement programs with state and federal agencies, the IPHC and other organizations • Promote enhanced enforceability	Observer Program	Observer Program coverage expanded or modified based on compliance or data needs, scientifically based; coverage to all vessels regardless of length (less than 60' or 60' or greater).
		Explore alternate funding mechanisms
		Improve observer species identification, develop uncertainty estimates (PA.2)
	Data and Reporting Requirements	Require broader range of economic data from industry participants, verified through third party (PA.2)
		Require VMS for Steller sea lion prey species; modify to incorporate new technology and system providers

The Observer Program funding objective issue stems from the appearance of a conflict of interest arising from the direct financial relationship between the observer's employer and industry. The PA explores changes to the funding mechanism in order to alleviate any taint on the credibility of observer data, and proposes a range of solutions that include full federal funding, industry fee-based funding and setting aside a portion of TAC (see discussion under Alternative 3 of the Observer Program paper in Appendix F-10 for additional information).

The implementation of changes to the data and reporting requirements under PA.2 expands the range of economic data requested from industry participants, and sets up a third party verification system, potentially in aggregate, for reported data. New information would include data on employment, variable harvesting and processing costs, and fixed/annual costs (see Appendix F-11, the Data and Reporting Requirements paper, Alternative 3). This additional information would enhance the ability of analysts to provide accurate estimates of the costs and benefits of proposed regulatory actions. Additionally, third party data collectors would be able to verify revenue data currently submitted. While authenticated data would allow for more accurate and credible economic impact assessments, a funding source would need to be identified to support the independent verification system.

The use of available technology to improve monitoring data is addressed in the FMPs through the ability to modify VMS to incorporate new technology and system providers. This may lead to a reduction in costs or improvements in technology and usage.

Establishing an effective ecosystem monitoring plan would accelerate precautionary management by providing an appropriate baseline against which to measure the impacts of fishing. Various ongoing research initiatives would contribute to this program, and new areas of research would be identified. The results would be compiled into a comprehensive monitoring plan. Funding for such a program would need to be identified, but the results would be a beneficial step in understanding the ecosystem impacts of fishery interactions.

The PA expands research efforts by seeking out partners, such as the North Pacific Research Board, to help identify research needs and to source funding for the research programs to address these data needs.

The objective to promote enhanced enforceability would encourage NPFMC to continue to prioritize enforcement considerations in designing management measure and program changes to the groundfish fisheries. It is likely that this objective may result in increased consultation with the Coast Guard in the design of management measures.

Cooperation, consultation, and coordination by the NPFMC and NOAA Fisheries with the State of Alaska agencies, federal agencies such as the USFWS and USCG, and organizations such as the IPHC, facilitate effective and efficient management and enforcement measures that promote conservation and sustainability.

The PA data quality, monitoring, and enforcement objectives conform with the overall policy intent of the alternative, namely to accelerate precautionary management in two ways: where appropriate, to take steps to incorporate uncertainty and ecosystem considerations into fishery management, and at the same time, to increase efforts to improve scientific understanding and diminish uncertainty. The objectives in the PA result in data collection on direct fishery impacts and interactions as well as on broader ecosystem relationships and indirect effects, and emphasize the importance of enforcement concerns in fishery management.

4.11 Comparison of Alternatives at the Policy Level

In Section 4.10 the impact analysis of the alternatives were summarized. In this section, we first compare the alternatives against the relevant requirements of Federal law, as well as other national recommendations that pertain to groundfish fishery management. Then, after summarizing the impact analysis of the alternatives from Section 4.10. Then the alternatives are compared against each other in regard to their impacts on the human environment.

4.11.1 Comparison of Alternatives Against Laws and National Recommendations

The alternatives developed for this Programmatic SEIS are policy statements that present a "vision"; one that is based on a management approach and a suite of goals and objectives, on how Alaska groundfish resources can be managed for the common good. Each policy alternative was designed to meet the minimum federal statutory requirements applicable to fisheries management and in most cases exceed those minimum requirements. The range of policy alternatives encompass the range of social values expressed by Congress, NOAA Fisheries, the NPFMC, and the public.

This section presents a policy review of each alternative against key federal laws that apply to fisheries management, national policy goals, and other recommendations for management of fishery resources in order to illustrate how well each policy alternative satisfies various statutory requirements. A detailed summary of all applicable federal laws and EOs is presented in Chapter 2 (Section 2.2.2) and will not be repeated here.

4.11.1.1 Federal Statutory Requirements

NOAA Fisheries is mandated by a variety of federal statutes to manage, conserve, and protect the Nation's living marine resources. Some of the main tenets of the agency's legislative mandates require a balancing of objectives. For instance, the MSA directs the agency to manage living marine resources for optimum sustainable utilization, while the MMPA prohibits exploitation of marine mammals and directs the agency to protect and maintain them at optimum sustainable population levels. The alternatives under examination in this Programmatic SEIS consider all of the statutory requirements and EO mandates relevant to fisheries management. The alternatives represent different ways in which the objectives embodied in the statutes and EOs can be balanced. The following statutes and EOs are at the heart of federal fisheries management and play an integral part in defining the scope of the policies, goals, and objectives contained in, and management measures that flow from, an FMP:

- The Magnuson Stevens Fishery Conservation and Management Act of 1976 (MSA).
- Endangered Species Act of 1973 (ESA).
- Marine Mammal Protection Act (MMPA).
- EO 12866 – Regulatory Planning and Review.
- EO 12898 – Environmental Justice Guidance Under NEPA.

- EO 13084 – Consultation and Coordination with Indian Tribal Governments.
- EO 13158 – Marine Protected Areas.

Table 4.11-1 compares the above-mentioned statutes and EOs with each alternative and describes how the alternatives take into account the statutory and EO requirements. The table also points out possible inconsistencies between the alternatives and the statutory and EO requirements.

4.11.1.2 NOAA Fisheries Strategic Plan

In 1998, the NOAA Fisheries published its strategic plan outlining its mission and its goals for guiding marine resource management decisions. In the spirit of the Government Performance and Results Act, the agency focused its plan on measurable results which were viewed as important to the American people, rather than on specific activities or programs. NOAA Fisheries intentionally set ambitious standards for itself against which its performance can be measured. The agency, after five years, could review its performance, celebrate its accomplishments, and learn from its shortcomings. NOAA Fisheries is currently conducting its five-year assessment and, based on its findings, will revise its strategic plan for the next five years.

In order to fulfill its stewardship mission, NOAA Fisheries has structured its divisions around three broad strategic goals:

1. Rebuild and maintain sustainable fisheries.
2. Promote the recovery of protected species.
3. Protect and maintain the health of coastal marine habitats.

Rebuild and Maintain Sustainable Fisheries

A sustainable fishery is one in which the rate of fishing mortality does not jeopardize the capacity of the stock to produce the maximum sustainable yield on a continuous basis. By building and maintaining sustainable fisheries, NOAA Fisheries ensures that fish stocks are available for many uses such as commercial, recreational, and subsistence. To realize this goal, they will:

- Maintain healthy stocks important to commercial, recreational, and subsistence fisheries.
- Eliminate overfishing and rebuild overfished stocks important to commercial, recreational, and subsistence fisheries.
- Increase long-term economic and social benefits to the nation from living marine resources.
- Promote the development of robust and environmentally sound aquaculture (where applicable).

Promote the Recovery of Protected Species

As part of its stewardship responsibility, NOAA Fisheries must ensure that our nation's living marine resources will be protected and enhanced for future generations. Protected species under the agencies' jurisdiction include all cetaceans and pinnipeds (excluding walruses) in addition to those marine species listed as threatened or endangered under the Endangered Species Act. NOAA Fisheries will provide effective leadership to conserve and recover marine species protected by statute or international treaty through conservation programs that are based on sound scientific research and decision-making. They will also provide for non-consumptive uses of protected resources which are compatible with their long-term conservation. To realize this goal, they will:

- Recover and maintain protected species populations.

- Reduce conflicts that involve protected species.

Protect and Maintain the Health of Coastal Marine Habitats

All living marine resources are vulnerable to habitat degradation, which can threaten the biodiversity on which they depend. These habitats are at risk from human activities which degrade or destroy habitat quality and quantity. NOAA Fisheries recognizes that protection of living marine resource habitat is crucial to the success of management and conservation efforts. To realize this goal, they will:

- Protect, conserve, and restore living marine resource habitat and biodiversity

<u>Evaluation of Policy Alternatives</u>

NOAA Fisheries is committed to achieving its strategic goals when making its management decisions. It will evaluate reasonable alternative management measures for achieving these goals and objectives, with appropriate consideration to competing interests and demands for fishery resource use. All the policy alternatives in this Programmatic SEIS comply with the strategic goals. The BSAI and GOA groundfish resources and their essential habitats can be destroyed if harvest is not carefully controlled or their important habitat goes unprotected. But with proper management, healthy stocks can be maintained, and diminished fish, Steller sea lion, and other populations can be restored to bring greater wealth to coastal communities. Policy Alternatives 1, 3, 4, and the PA provide the greatest management control over the harvest of groundfish. BSAI and GOA groundfish fisheries that are sustainable over the long-term allow United States citizens to reap the greatest economic and social benefits which include a continuing supply of high-quality seafood and recreational and subsistence fishing opportunities.

Sound scientific research is the basis for sustainable fisheries. However, unaccounted factors may unknowingly create or exacerbate stock declines, giving rise to crisis management of fisheries. Examples include the effects of noise on marine mammal health and behavior and the impact of habitat modification by fishing gear. Currently, NOAA Fisheries must make management decisions without having conducted sufficient investigations of the spectrum of ecological and anthropogenic factors that contribute to the equilibrium of natural systems. To help ensure productive future harvests, NOAA Fisheries scientists study the life history, stock size, habitat, and ecology of economically important fishes, and the effects of climate and ocean processes on their populations. This information is used by fishery managers to set TACs, fishing seasons, bycatch limits, and gear restrictions each year. All of the policy alternatives rely on continued scientific research and monitoring of the fisheries. Alternatives 3, 4, and the PA commit the agency to explore additional funding to support an expanded research program aimed at filling the scientific data gaps identified through preparation of this Programmatic SEIS. Such data is needed to measure progress in achieving policy goals and objectives and to answer the many questions about the effects of fishing on the marine ecosystem.

Many marine mammals, such as Steller sea lions, whales, and seals, as well as seabirds, listed albatross, salmon and sea turtles, are all protected by federal law. These valuable species comprise important members of the BSAI and GOA ecosystem. The protected species can be affected by fisheries, other human activities, and by environmental change. NOAA Fisheries seeks to reduce the impacts of fishing activities on protected species while ensuring the viability of valuable fisheries. All of the policy alternatives in this Programmatic SEIS include protection measures determined to avoid jeopardizing the recovery of Steller sea lions and short-tailed albatross and avoid adverse modification of critical habitat for Steller sea lions. Alternatives 1 and 2 commit the agency to its current protection plan and its continuing relationship with the USFWS. Policy Alternative 3 and the PA builds on this commitment by indicating it will adjust protection measures as appropriate based on new scientific evidence supporting a need for change. Policy Alternative 4 would result in immediate adjustments to the level of groundfish harvest and suite of other protection measures, including the possibility of temporary suspension of the fisheries as a precautionary measure, until scientific information is obtained that would support a relaxation of precautionary measures. All alternatives explicitly prioritize as a policy objective the recovery of threatened and endangered species.

Coastal habitats, such as estuaries, offshore pinnacles and gullies, and a variety of physical substrates, provide food and shelter for marine fish and shellfish during important stages of their life cycle. NOAA Fisheries monitors development, water and sediment contamination, dredging and filling activities, and oil development projects off Alaska. The agency is a major force in maintaining the health of marine ecosystems by leading research to identify and restore damaged habitat, and by recommending measures to offset development and use impacts. Alternatives 1, 2, 3, 4, and the PA all explicitly recognize through specific policy objectives the importance of protecting EFH and other marine habitat from human activities. Alternative 3 and the PA builds on current policy, legal requirements, and protection initiatives by recognizing the use of MPAs (in all their forms) as a legitimate management tool, and based on scientific review, the NPFMC and the agency will develop a MPA policy in coordination with national and state policies. Alternatives 3, 4, and the PA would establish large MPAs as a precautionary measure until scientific evidence shows they are not needed.

4.11.1.3 Ecosystem Principles Advisory Panel and National Research Council Recommendations

The SFA strengthened the MSA by mandating new conservation measures. One provision of the Sustainable Fisheries Act was the appointment of a NOAA Fisheries Ecosystem Principles Advisory Panel. The Panel was tasked with reporting to Congress the extent to which ecosystem principles are being applied in fishery conservation and management activities, including research activities, and to propose actions that should be undertaken to expand the application of ecosystem principles in fishery conservation and management. The Panel's report was published in 1999, and thus provides updated information on ecosystem-based management of fisheries (EPAP 1999).

The Panel developed a list of basic ecosystem principles and policies, and recommended that Fisheries Ecosystem Plans (FEPs) be developed as a first step towards a full ecosystem-based fisheries management approach. Components of the plan include food web models, habitat needs, estimates of total removals, an assessment of uncertainty and buffers, indices of ecosystem health and use, long-term monitoring plans, and an assessment of other elements. The basic principles outline the complex and dynamic nature of marine systems that are composed of interconnected groups of living organisms and their habitats and form the foundation of ecosystem based management strategies.

Building on these principles, the Panel developed six general ecosystem-based management policies to guide fishery managers. These policies reflect the importance of the ecosystem-based principles associated with the limitations on extraction, uncertainty, and the role of humans within ecosystems. A description of these six policies, as provided by the Panel, is listed below.

1. Change the burden of proof. – We live in a world where humans are an important component of almost all ecosystems. Thus, it is reasonable to assume that human activities will impact ecosystems. The modus operandi for fisheries management should change from traditional mode of restricting fishing activity only after it has demonstrated an unacceptable impact, to a future mode of only allowing fishing activity that can be reasonably expected to operate without unacceptable impacts.

2. Apply the precautionary approach. – The precautionary approach is a key element of the United Nations Agreement for Straddling Stocks and Highly Migratory Species (United Nations 1996) and the Food and Agriculture Organization of the United Nations (FAO) Code of Conduct for the Responsible Fisheries (FAO 1995). The U.S. is a signatory of both.

3. Purchase "insurance" against unforseen, adverse ecosystem impacts. – Even under the precautionary approach, there is a risk of unforeseen, adverse impacts on ecosystems. Insurance can be used to mitigate these impacts if and when they occur.

4. Learn from management experiences. – Management actions and policies can be considered as experiments and should be based upon hypotheses about the ecosystem response. This requires close monitoring of results to determine to what extent the hypotheses are supported.

5. Make local incentives compatible with global goals. – Changing human behavior is most easily accomplished by changing the local incentives to be consistent with broader social goals. The lack of consistency between local incentives and global goals is the root cause of many "social traps," including those in fisheries management (Costanza 1987). Changing incentives is complex and must be accomplished in culturally appropriate ways.

6. Promote participation, fairness, and equity in policy and management. – Ecosystem approaches to management rely on the participation, understanding and support of multiple constituencies. Policies that are developed and implemented with the full participation and consideration of all stakeholders, including the interests of future generations, are more likely to be fair and equitable, and to be perceived as such.

The overall recommendation of the Panel was to expand the application of ecosystem principles, goals, and policies to fishery management and research. The mechanism to accomplish this is through development of an FEP that would be developed for each major ecosystem. A requirement for regional councils to develop FEPs is being considered now by Congress. A comparison of the four policy alternatives in this Programmatic SEIS against these six recommended ecosystem-based management policies reveals that most of these principles are incorporated into the alternatives.

Change the Burden of Proof

Only Alternative 4 meets this principle in the strictest sense. This alternative represents a paradigm shift in management policy and in the near term would likely lead to significant restrictions placed on commercial groundfish fisheries off Alaska. However, Alternatives 1, 3 and the PA do informally meet the principle in certain circumstances. For example, the NPFMC does now restrict the development of certain fisheries for lack of information and concern over unknown impacts, thereby assuming some of the burden of proof due to uncertainty.

Apply the Precautionary Approach

Alternatives 1, 3, 4, and the PA all incorporate this management principle. Alternatives 3, 4 and the PA would accelerate precautionary measures to address uncertainty. Under the PA, the OY caps in the BSAI and GOA are kept in place even though the ABCs for many groundfish stocks would support greater harvests. Alternative 2 would pose the greatest risk to the ecosystem compared to the other alternatives.

Purchase "Insurance" Against Unforseen, Adverse Ecosystem Impacts

Alternatives 1, 3, 4, and the PA all apply the precautionary principle and therefore institute various buffers and other safeguards to reduce the risk of overfishing and to mitigate the adverse effects of fishing on the ecosystem. The aggressive harvest policy illustrated by Alternative 2 poses the greatest risk of harming the environment compared to the other alternatives.

Learn from Management Experiences

All five alternatives were structured based on a historical review of the lessons learned from over 25 years of groundfish fisheries management. Each alternative is adaptive and as new scientific information is obtained, changes to the groundfish FMPs are likely to occur.

Make Local Incentives Compatible with Global Goals

All five alternatives aim to achieve their policy objectives (e.g., "global goals") through use of specific FMP components and management measures. To varying degrees, the alternatives illustrate a range of potential management actions, many of which are designed to influence fishermen and processor behavior. The PA and Alternative 3 are similar in this regard. Past experience in managing the Alaska groundfish fisheries has shown the value of consulting with various stakeholders and the public to ensure that the eventual measures are meaningful and will achieve the intended goals and objectives.

Promote Participation, Fairness, and Equity in Policy and Management

The MSA and regional council process rely heavily on public involvement throughout the decision-making process. Public involvement would continue under all four policy alternatives. Under Alternative 1, the NPFMC has already begun to incorporate these ecosystem policies into its groundfish management program. The NPFMC has established a Ecosystem Committee, comprised of scientists, stakeholders, and interested public, to review the scientific literature and provide advice to the NPFMC. The Ecosystem Considerations Appendix to the SAFE report that is prepared annually by the NOAA Fisheries AFSC, together with what is provided in this Programmatic SEIS, already assembles most of the information required for an FEP. Should Congress require that councils prepare an FEP for their respective regions, the NPFMC has in many ways already gathered the necessary information to put such a document together under any of the four alternatives. Under Alternative 2, it may prove difficult to build on the information base needed to keep an FEP current. Alternative 2 policy presumes that there are no adverse effects of fishing on the ecosystem and such a presumption may serve as the basis for curtailing existing research and monitoring programs. Alternative 3, 4, and the PA would seek to expand on current data gathering programs, and the FEPs prepared under these alternatives would certainly be more thorough and easier to update over time.

Evaluation of Alternatives relative to National Research Council's Ecosystem Based Management Standards

In 1999, the NRC, an agency organized by the National Academy of Sciences, published new performance standards for fishery management in "Sustaining Marine Fisheries" (NRC 1999). The publication reviews the status of global fisheries, the problems facing fishery managers, and provides recommendations on how to improve management to achieve sustainable marine fisheries. The overall recommendation of the NRC was the adoption of an ecosystem-based approach for fishery management with the goal "to rebuild and sustain populations, species, biological communities, and marine ecosystems at high levels of productivity and biological diversity, so as not to jeopardize the wide range of goods and services from marine ecosystems, while providing food, revenue, and recreation for humans" (NRC 1999). To achieve an ecosystem-based approach, the NRC made several specific recommendations (see inset on this page).

Summary of the National Research Council's recommendations for ecosystem-based management to achieve sustainable fisheries.

1. Adopt conservative harvest levels for single species fisheries.
2. Incorporate ecosystem considerations into fishery management decisions.
3. Adopt a precautionary approach to deal with uncertainty.
4. Reduce excess fishing capacity and define and assign fishing rights.
5. Establish marine protected areas as a buffer for uncertainty.
6. Include bycatch mortality in TAC accounting.
7. Develop institutions to achieve goals.
8. Conduct more research on structure and function of marine ecosystems.

Although neither the MSA nor the NOAA Fisheries Strategic Plan has been amended to specifically incorporate the NRC's recommendations, a comparison of the alternatives to the NRC recommendations is useful.

Conservative Single Species Management of Commercially Important Fisheries

Relative to elsewhere in the world, the management of commercially important groundfish fisheries under Alternative 1 is conservative. Low harvest rates, combined with other management elements, provide for conservative single species management of commercially important species to achieve sustainable groundfish fisheries in the North Pacific. All groundfish stocks are considered relatively healthy after experiencing 20 years of sustained annual harvests of about two million metric tons. No fish stocks have been deemed overfished, approaching an overfished condition, or subject to overfishing in a recent evaluation of the status of U.S. fisheries (NOAA Fisheries 1999). Existing single species management of North Pacific groundfish meet the conservative and risk-averse approach standard recommended by the NRC. None of the groundfish stocks are subject to overfishing as defined under the MSA. The NPFMC is considering revising its harvest rate strategy for rockfish.

Alternative 2, which would adopt a more aggressive harvest policy, would seek to prevent single species overfishing while maximizing yield. Such a policy would increase the risk of overfishing, especially for those fish stocks where there is little information on stock status. Alternatives 3, 4 and the PA would all institute a more precautionary management policy where harvest strategies, if modified, would more likely be reduced. In the case of Alternative 4, reductions in single species ABCs and TACs would occur after adoption of policy by NOAA Fisheries until scientific information were available to show that a higher exploitation rate would not adversely impact the stock.

The North Pacific Fishery Management Council's Working Draft for Ecosystem-Based Management.

Definition: Ecosystem-based management, as defined by the NPFMC, is a strategy to regulate human activity towards maintaining long-term system sustainability (within the range of natural variability as we understand it) of the North Pacific, covering the GOA, the eastern and western Bering Sea, and the Aleutian Islands region.

Objective: Provide future generations the opportunities and resources we enjoy today.

Goals:
1. Maintain biodiversity consistent with natural evolutionary and ecological processes, including dynamic change and variability.
2. Maintain and restore habitats essential for fish and their prey.
3. Maintain system sustainability and sustainable yields of resources for human consumption and non-extractive uses.
4. Maintain the concept that humans are components of the ecosystem.

Guidelines:
1. Integrate ecosystem-based management through interactive partnerships with other agencies, stakeholders, and public.
2. Utilize sound ecological models as an aid in understanding the structure, function, and dynamics of the ecosystem.
3. Utilize research and monitoring to test ecosystem approaches.
4. Use precaution when faced with uncertainties to minimize risk; management decisions should err on the side of resource conservation.

Understanding:
1. Uncontrolled human population growth and consequent demand for resources are inconsistent with resource sustainability.
2. Ecosystem-based management requires time scales that transcend human lifetimes.
3. Ecosystems are open, interconnected, complex, and dynamic; they transcend management boundaries.

Incorporating Ecosystem Considerations into Fishery Management

The NPFMC has been actively developing an ecosystem-based approach to managing fisheries. A working draft of their approach is provided at right. The NPFMC's approach under Alternative 1 involves public participation, reliance on scientific research and advice, conservative catch quotas, comprehensive monitoring and enforcement, bycatch controls, gear restrictions, temporal and spatial distribution of fisheries, marine protection areas, and other biological and socioeconomic considerations. Management measures are also taken to minimize potential impacts of fishing activities on sea floor habitat and other ecosystem components such as marine mammals and seabirds.

The public, scientists, and policy makers have all contributed to the development of an ecosystem-based management strategy. Since 1995, the groundfish plan teams have added an Ecosystem Considerations section to their SAFE document that provides an annual assessment of the ecosystem, a review of recent ecosystem-based management literature, updates of ongoing ecosystem research, local observations from coastal people and fishermen, and available new information on the status of seabirds, marine mammals, habitat and other components of the North Pacific ecosystem. The NPFMC also has an Ecosystem Committee, which was established to discuss and recommend possible approaches to incorporating ecosystem concerns into the fishery management process. A major role of this committee has been to provide the NPFMC and stakeholders with information on ecosystem-based fishery management in the North Pacific. While a full understanding of North Pacific ecosystem dynamics remains beyond our grasp, the NPFMC and NOAA Fisheries are striving to achieve a better understanding of this system and, in the interim, are attempting to incorporate what we do know into the fisheries management process.

Although the NRC report provides some guidance on ecosystem-based management, there is no roadmap to follow or other examples to emulate. In a recent international meeting on the ecosystem effects of fishing, the NPFMC's efforts on ecosystem management (Witherell *et al.* 2000) were considered to be state-of-the-art.

All alternatives would incorporate ecosystem considerations into the fishery management decision-making process. The difference in alternatives is reflected in both the level of commitment toward ecosystem-based management principles (as illustrated by their stated management approach and objectives and further defined by their FMP bookends) and the commitment for expanded research. Alternatives 3, 4, and the PA more fully capture the NRC recommendations compared to Alternative 2.

A Precautionary Approach to Deal with Uncertainty

The primary sources of scientific uncertainty in fishery management are the uncertainty about fishing effects on ecosystems and the uncertainty associated with stock assessments. For stock assessments, uncertainty can be associated with catch statistics (e.g., observer estimation error, misreporting), biological parameters (e.g., maturity, mortality, growth), resource assessment survey measurement error, and natural variability in dynamics such as recruitment.

In the North Pacific fishery management arena, uncertainty under Alternative 1 is dealt with in several ways. In the case of establishing acceptable harvest rates the ABCs are based on a system of tiers corresponding to information availability on population dynamics parameters. The Pacific cod stock assessment went an additional step of evaluating uncertainty regarding specific model parameters. The ABC for the 2003 fisheries was based on a risk-averse optimization procedure that adjusts for uncertainty in the selectivity coefficients and natural mortality rate. This type of analysis will likely be expanded to other assessments in coming years.

Uncertainty regarding species interactions, environmental factors, and human actions is addressed with other management measures under Alternative 1. Regulatory changes that have to some degree addressed these sources of uncertainty include establishment of marine protected areas, the OY cap in the BSAI and GOA, the forage fish prohibition, and spatial/temporal restrictions to reduce adverse affects to Steller sea lions and walrus.

Alternatives 3 and 4 present two dramatically different approaches to applying the precautionary principle to fisheries management. Similar to Alternative 1, Alternative 3 presents an adaptive approach to management where the FMPs are modified as scientific information indicates that the ecosystem is stressed or that there are unacceptable environmental impacts caused by fishing. Alternative 3 differs from Alternative 1 by formalizing a procedure for addressing uncertainty in stock assessments and other information, where at present uncertainty factors are treated on an ad hoc basis. The PA commits to completing its scientific review of current harvest strategies and adopting any improvements necessary to provide protection to target groundfish species. The NPFMC will also look for ways to better manage species currently not targeted or managed using a species-assemblage approach. Alternative 4 shifts the burden of proof from demonstrating adverse impacts in order to prohibit or proscribe a fishery to demonstrating no adverse impacts in order to authorize a fishery. Under this policy, substantial restrictions on the current levels of harvest among other actions, would protect the resource until scientific information could be collected to determine whether a more liberal harvest could be authorized. Such information would have to possess a higher level of certainty than presently exists for most fisheries and stocks.

Reducing Excess Fishing Capacity and Assignment of Fishing Rights

There is no doubt that the groundfish industry in the North Pacific is overcapitalized due to limited quotas and the race-for-fish. The NRC report tends to link overcapacity with overfishing, because some fisheries (e.g., New England groundfish and scallops) have been traditionally managed with effort control, rather than quotas. Because catch is limited under Alternative 1 by TACs in the North Pacific, overcapacity does not necessarily increase the potential for overfishing. However, participants in overcapitalized fisheries can exert strong pressure for liberal catch quotas and other risk prone management measures, though there has been little evidence of that in fisheries under NPFMC jurisdiction. Also, in extreme cases, excess harvesting capacity may shorten seasons to a point that fishing quotas cannot be accurately monitored. The GOA pollock fishery is an examples of a fishery where quota overages have occurred in the North Pacific.

Under Alternative 1, the NPFMC has developed several programs to address overcapacity in the fisheries. Groundfish management programs generally limit the number of vessels that are allowed to fish off Alaska. In addition, halibut and fixed gear sablefish are managed under an IFQ program, which does not limit the number of vessels, but instead, grants permission to individuals to harvest a specified percentage of the TAC each year.

The AFA, passed in late 1998, among other things limited the number of harvesting and processing vessels that would be allowed to participate in the BSAI pollock fishery. Only harvesting and processing vessels that met specific requirements, based on their participation in the 1995-97 fisheries, are eligible to harvest BSAI pollock. Twenty-one catcher processors and 120 catcher vessels qualified under the AFA. Nine large capacity catcher processors were retired from the fishery by the AFA. Under the fishery cooperative structure now in place, not all 21 eligible catcher processors have chosen to fish in the late winter and early spring pollock seasons. The AFA also restricts eligible vessels from shifting their effort into other fisheries. “Sideboard” measures, as they have become known, prevent AFA eligible vessels from increasing their catch in other fisheries beyond their average 1995-97 levels. Sideboard restrictions reduce the likelihood that the fishing capacity of AFA eligible vessels will be increased to better compete in those fisheries. The fishery cooperative has proven to be an effective and efficient operating structure for fishermen and processors.

Adoption of Alternative 2 would result in a systematic review of existing license limitation and rights-based management programs (with the exception of those mandated under the AFA and MSA) and based on that review, the NPFMC and NOAA Fisheries could determine that such programs are not working and that these programs should be modified or eliminated. Such actions would not be consistent with the NRC recommendation to reduce excess fishing capacity and assign fishing rights. More consistent are Alternatives 3, 4 and the PA, all of which seek as a matter of policy to further reduce overcapacity and explore various means of achieving that objective. Alternative 3 and the PA seek to provide economic and community stability to the harvesting and processing sectors through fair allocation of fishery resources. This policy alternative also would seek to eliminate the race-for-fish in all groundfish fisheries by eliminating latent licenses and extending programs such as community or rights-based management cooperatives.

Alternative 4 emphasizes ecosystem considerations above economic and community considerations, but otherwise shares the objectives of Alternative 3 and the PA. One notable difference is that Alternative 4 formally incorporates the concept of non-consumptive use valuation into the fishery management decision-making process.

Marine Protected Areas

It has been long recognized that sea floor habitat is essential for maintaining productivity of fishery resources. Habitat that provides structural relief on an otherwise featureless bottom can be particularly important to fish for food, reproduction, and shelter from predators. Structural habitat includes boulders, corals, anemones, kelp, and other living organisms attached to the ocean bottom.

Because structural habitat has the potential for being disturbed by fishing gear, regulations have been implemented to protect areas where this habitat type is known to occur. Vast areas of the North Pacific have been permanently closed under Alternative 1 to groundfish trawling and scallop dredging to reduce potential adverse impacts on vulnerable habitat and to protect juvenile crab. Other closures occur on a seasonal basis, and additional closures to mobile fishing gear are under consideration. A unique nearshore pinnacle off Cape Edgecumbe in southeast Alaska has been closed to groundfish fishing for all gear types.

The NRC considers permanent marine protected areas to be an important and useful tool for fisheries managers. MPAs would provide a hedge against uncertainty, provide habitat protection, and allow for species and ecosystem protection. The NRC defines marine protected areas as those where all commercial fishing or activities are prohibited. Furthermore, the NRC suggests that 20 percent of the potential fishing area be considered for marine protected areas. In this Programmatic SEIS, we use the term "no-take marine reserves" rather than "marine protected area," to make clear that such an area would be closed to all commercial fishing. The term "marine protected area", or MPA, is used in this Programmatic SEIS to distinguish an area where some form of gear or fishery restriction is in place, but that it is not totally closed to all gear types or fisheries.

MPAs (as defined in the Programmatic SEIS; e.g., areas subject to some form of gear or fishery restriction but not totally closed) comprise a relatively large portion of the continental shelf (29 percent of the shelf and slope to a depth of 1,000 m; termed fishable area in this Programmatic SEIS; Figure 4.2-1). In the BSAI, MPAs encompass about nine percent of the EEZ, or about 22 percent of the fishable area. The GOA closures encompass about 14 percent of the EEZ, or 46 percent of the fishable area. Some environmental advocates and scientists have suggested that no-take marine reserves should be at least 20 percent of available habitat in order to be effective. The current suite of closed areas under both the BSAI and GOA falls far short of this objective, with less than one percent of the EEZ/fishable area closed to all groundfish fishing.

Alternative 2, the more aggressive harvest policy, assumes that there are no adverse impacts of commercial fishing on the environment and that there is no need to establish a Alaska groundfish MPA program. Adoption of this policy would be inconsistent with the NRC recommendation to establish a MPA program and EO 13158.

Adoption of Alternative 3, a more precautionary management policy, would at a minimum initiate a formal review of the applicability of an MPA program off Alaska and develop the necessary criteria and process for review of existing closed and restricted areas and to identify new areas as candidates under such a formalized program. This policy would also commit the agency to increased research on EFH. Under Alternative 3, both no-take reserves and MPAs would be considered viable management tools for achieving habitat protection and ecosystem-based management objectives. As such, this alternative is fully consistent with the NRC and Ecosystem Advisory Panel management standard.

Alternative 4 is also consistent with this standard. It differs from Alternative 3 by increasing policy emphasis on establishing no-take marine reserves as a means of ensuring that ecological processes and individual species protection objectives are met. It is recognized elsewhere in this Programmatic SEIS that considerable care is needed in determining where such reserves should be established and that such care requires considerable public and community involvement.

The PA is a modified version of the Alternative 3 policy in reference to habitat protection and the use of MPA and no-take reserves. Under the PA, the NPFMC would commit to developing a MPA policy for Alaska and coordinate its development with both state and federal MPA committees recently established. Under the PA, the NPFMC recommends that the agency maintain all existing closures until criteria can be developed for evaluating the effectiveness of all current closed areas in achieving habitat protection objectives as well as identify possibly new areas as candidates for MPA designation. For purposes of analysis and illustration, the PA uses the maps developed for Alternative 3 as examples of the range of concepts that will be pursued in the designation of EFH and HAPC and the development of MPAs (Figures 4.2-8 and 4.2-9). Figure 4.2-8 illustrates the system of closed areas and MPAs currently in effect. Figure 4.2-9 illustrates a expansion of closures up to 20 percent of the EEZ/fishable area. It should be noted that Figure 4.2-9 illustrates a true composite of MPA concepts that could be used to protect habitat as well as other closures to protect Steller sea lions and king and Tanner crab. It is not likely that all the concepts would be implemented simultaneously. It is also unlikely that all the areas shown as closed in the illustration would be implemented. Detailed analysis conducted in conjunction with this Programmatic SEIS revealed that some of these areas provided questionable benefits to habitat. In addition, the scale of the mapped closures are too crude to satisfy legal requirements and are only intended to provide conceptual representation of MPAs. [The reader should refer to the NPFMC's EFH EIS analysis for more detail on EFH and the range of possible mitigation alternatives.]

Bycatch and Discards

The issues of bycatch, discard, and waste of fish resources stem from social, economic, and conservation concerns. From an ecosystem perspective, mortality of unwanted and prohibited species may reduce spawning potential, reduce biodiversity, alter regular paths of energy flow and balance, enhance the growth of scavenger populations, and add uncertainty to estimates of total removals.

The NRC notes that conservation concerns are raised in world fisheries where bycatch and discards are treated as side effects of fishing. Under Alternative 1, all bycatch and discarded groundfish are counted toward the TAC established for individual stocks. Additionally, because observers sample the entire catch, not just the retained portion, the information on bycatch and discards is available and is directly incorporated into the annual stock assessments.

Fish are discarded for two reasons: either they are required to be thrown back due to regulations (prohibited species), or they are unwanted for market reasons. In the North Pacific, discards of unwanted groundfish (so-called economic discards) result when fishermen do not have markets, sufficient equipment, time, or economic return to retain and process the catch. In the 1997 BSAI groundfish fisheries, a total of 258,000 mt of groundfish were discarded, equating to about 15 percent of the total groundfish catch. Although this discard rate is much lower than most of the world's groundfish fisheries, which average about 19.9 percent discards, and it is deducted from the TAC, the sheer volume of discards is troublesome to many people who consider economic discards as a waste of food and as having an unnecessary impact to the ecosystem.

Bycatch management measures implemented for groundfish fisheries of the EBS under Alternative 1 have focused on reducing the incidental capture and injury of species traditionally harvested by other fisheries. These species include crab, herring, halibut, and salmon. Collectively, these species are called "prohibited species," as they cannot be retained as bycatch in groundfish fisheries and must be discarded with a minimum of injury.

In addition to bycatch limits, gear restrictions and other regulatory changes have also been implemented to reduce bycatch and waste. Biodegradable panels are required for pot gear to minimize waste associated with ghost fishing of lost gear. Tunnel openings for pot gear are limited in size to reduce incidental catch of halibut and crabs. Gillnets for groundfish have been prohibited to prevent ghost fishing and reduce bycatch of non-target species. With the implementation of an IFQ system for halibut and sablefish longline fisheries in 1995, bycatch and waste were reduced because the race-for-fish was eliminated, allowing for more selective fishing practices and significant reductions in actual gear deployment/loss. BSAI Amendment 57 prohibited the use of non-pelagic trawl gear for vessels targeting pollock in the Bering Sea, and made a concomitant reduction of allowable prohibited species bycatch of halibut and crabs.

To reduce groundfish economic discards, the NPFMC adopted an improved retention and utilization (IR/IU) program for all groundfish target fisheries. Beginning in 1998, 100 percent retention of pollock and Pacific cod was required, regardless of how or where it was caught. Only fish not fit for human consumption can be legally discarded. This measure has dramatically reduced overall discard of groundfish. For example, in 1997, about 22,100 mt of Pacific cod (8.6 percent of the cod catch) and 94,800 mt of pollock (8.2 percent of the pollock catch) were discarded. In 1998, discard amounted to only 4,300 mt of Pacific cod (2.2 percent) and 16,200 mt of pollock (1.6 percent). A proposed rule requiring full retention of all demersal shelf rockfish species (e.g., yelloweye rockfish) has been published.

Waste of salmon and halibut has been reduced by allowing bycatch of dead fish to be donated to food banks. The food banks in turn distribute the fish to needy people in the northwestern United States. Many fishing companies voluntarily participate in the donation program. Through 2001, over 4 million pounds of donated fish have produced an estimated 14 million meals for underprivileged persons.

Numerous regulations have been implemented to reduce bycatch and discards of groundfish and crabs. It is unlikely that discards can be significantly reduced below the 5 percent rate projected under current regulations, without requiring full retention of fish species unwanted for human consumption. In other words, a full retention requirement for sculpins and other species would likely result in less discards, but more fishmeal production. Bycatch and discard of crabs, halibut, and herring are a function of regulations. If full retention of all species was required, there would be virtually no bycatch or discard.

Adoption of Alternative 2 would result in a review and potential relaxing of bycatch control measures currently in effect. As mentioned previously, adoption of this policy alternative assumes that there are no adverse environmental effects of groundfish fishing and that bycatch at present levels is not adversely affecting the ecosystem. Under Alternative 2, groundfish harvests could be increased substantially, with little effort controls in place. Bycatch and discards are predicted to increase significantly under this alternative, even if the underlying assumption of no adverse effect to the ecosystem is proven true. Adoption of this policy would be inconsistent with this standard and NOAA Fisheries' own national bycatch reduction program.

Alternative 3 and the PA are similar to Alternative 1 but they further commit the NPFMC and the agency to achieving bycatch and waste reduction objectives. Bycatch accounting mechanisms would be improved and consideration given to establishing additional bycatch limits and/or reducing existing bycatch limits. As a result, the Alternative 3 and PA policies are consistent with this standard and national policy objectives.

Adoption of Alternative 4 would commit the NPFMC and NOAA Fisheries to much lower harvest rates and perhaps even temporary suspension of the fisheries until more information is known about the effects of fishing on the ecosystem. Such reductions in overall groundfish TACs would result in much lower fishing effort and lower bycatch of non-target groundfish and prohibited species.

Institutions

The NPFMC is one of eight regional councils established by the MSA to manage fisheries in the 200-mile EEZ. The NPFMC primarily manages groundfish in the GOA and BSAI, including Pacific cod, pollock, flatfish, Atka mackerel, sablefish, and rockfish species harvested mainly by trawlers, hook-and-line longliners, and pot fishermen. The NPFMC also makes limited entry decisions for halibut, though the U.S.-Canada IPHC biologically manages the resource, and has oversight for BSAI crab fisheries and the Alaska scallop fishery. The State of Alaska (specifically ADF&G) manages groundfish, crab, salmon, and herring fisheries in state waters, and also manages the BSAI scallop and BSAI crab fisheries on a day-to-day basis.

The NPFMC has eleven voting members, six from Alaska, three from Washington, one from Oregon, and a federal representative, the Alaska Regional Administrator of NOAA Fisheries. Voting members represent state fisheries agencies, industry, fishing communities, and academia. The NPFMC's four non-voting members represent the U.S. Coast Guard (USCG), U.S. Fish and Wildlife Service (USFWS) Department of State, and the Pacific States Marine Fisheries Commission. The NPFMC's staff resides in Anchorage, Alaska. The NPFMC receives advice at each meeting from an Advisory Panel representing user groups, environmentalists, recreational fishermen, and consumer groups, and from an SSC of highly respected scientists who review information brought to the NPFMC.

Each NPFMC decision is made by a recorded vote in a public forum following public comment. Final decisions then go to NOAA Fisheries formulated as recommendations for FMP or regulatory amendments. NOAA Fisheries reviews the Council's submission, issues proposed amendments and regulations for public review and comment, and then makes a decision on whether to approve, disapprove, or partially approve the action. Decisions must be consistent with the MSA, NEPA, ESA, MMPA, and other applicable law s including several EOs. Regulatory changes may take up to a year or longer to implement particularly if they are complex or contentious.

The NPFMC and NOAA Fisheries have successfully worked towards achieving the goal of sustainable fisheries. The structure of the NPFMC's numerous committees (e.g., Advisory Panel, SSC, Plan Teams, Ecosystem Committee) allows for incorporation of diverse views from interested parties. The NPFMC and NOAA Fisheries coordinate their activities with other institutions including the IPHC, ADF&G, USFWS, USCG, and others.

The NPFMC, its committees, and its well established public process described under Alternative 1 would continue under all of the policy alternatives. Specific changes to this existing institutional structure could occur under Alternatives 3, 4 and the PA. Under Alternative 3, the NPFMC and NOAA Fisheries would pursue ways to increase Alaska Native participation and consultation in fisheries management. Such methods may include adding more Alaska Native representatives on the NPFMC Advisory Panel and video conferencing. The agency might consider adding a tribal government coordinator to its staff to enhance its government-to-government consultation abilities and serve as a liaison to Native organizations and Native communities. Other options include establishing a student intern program to provide opportunities for Native students to learn more about fisheries management and to share information. Alternative 3 (and the PA) would also build on the existing relationship with USFWS and ADF&G to expand cooperative research programs. Alternative 4 would expand on these concepts by increasing participation of Native and non-Native subsistence users when making fishery management decisions.

Information Needs

While the fisheries in the North Pacific are managed with the best available science in the world, there is an ongoing need to increase our current understanding of the biological and socioeconomic factors in the fisheries. There is also a mandate to achieve some level of understanding of overall ecosystem dynamics and incorporate this into our management approach.

The NOAA AFSC, along with other institutions such as the University of Alaska, ADF&G, the Prince William Sound Science Center, and others have all been conducting ecosystem level research. This research is expected to continue at its current level unless funding is increased. An integral part of this Programmatic SEIS has been to identify data gaps and research needs for improved management of the Alaska groundfish fisheries. Due to the importance of this subject and the heavy reliance of any successful application of a management policy on adequate scientific information, NOAA Fisheries has prepared a separate chapter on this subject (Chapter 5) in this Programmatic SEIS.

Ongoing research and monitoring of the Alaska groundfish fisheries are essential to ensure the sustainability of these fisheries for future generations, regardless of which policy alternative or vision for management is adopted. Each of the four policy alternatives must be supported by research and monitoring. Alternative 2 requires decreased level of commitment, while Alternatives 1, 3, 4 and the PA all require expanded data quality, monitoring, and enforcement programs to ensure that policy goals are achieved. Such programs are typically funded by Congress through the federal appropriations process. Generally, NOAA Fisheries and the regional councils have been well funded though all research and agency expenditures are usually not. Decisions must be made by the agency as to what projects and programs get funding and which ones are put aside until funds become available. Recently, a new organization, the North Pacific Research Board, has been formed which could provide funds for ecosystem-related research. The fishing industry also has a long history of supporting research.

One area of anticipated growth and understanding is in the form of local and Traditional Ecological Knowledge. Local and Traditional Knowledge is comprised of historical observation of the environment accumulated over time by Native people who have relied on natural resources and the environment as a way of life. Recent sharing of this knowledge has begun to enter into the realm of fishery management decision-making. Under Alternative 1 and 2, these efforts would continue. Alternatives 3, 4, and the PA would seek to enhance collection and study of such information and consider new ways of incorporating local and Traditional Knowledge into the decision-making process. Such methods might include increasing Alaska Native involvement in fisheries management, through co-management agreements and cooperative research initiatives. All four policy alternatives are consistent with this ecosystem-based management standard.

4.11.2 Comparison of Alternative Impacts on the Human Environment

The alternatives are analyzed in detail from a policy perspective in Section 4.10 of this document. The sections below present the results of that analysis in a format that allows for comparison of the alternatives. The discussion is organized around the eight major goals identified as key components of North Pacific groundfish fishery management.

Table 4.11-2 presents the information summarized below in table format, and uses a color key to indicate the direction of effect associated with each alternative. The intent of the summary below, and in Table 4.11-2, is to provide a broad, policy-level understanding of the general impacts of the alternative. The analysis deals with effects at the population or fishery level, rather than calling out impacts to individual components (a more detailed analysis of the FMP bookends provides a basis for the policy-level analysis; see Section 4.10.1 for further information.) Where the impacts within a policy goal are substantially different for major component groups, the color key is split in half and two colors are assigned. The bulleted language in the table explains the rationale.

The colors assigned to the effects are red, yellow, light green, and dark green. Red indicates an adverse effect in the judgement of the analysts, but does not distinguish the degree of uncertainty associated with that effect. Yellow indicates that there is a high potential for adverse impacts if any of the assumptions used to manage the resource are wrong. Light green indicates a potentially beneficial effect is expected and that the rating incorporates some precaution against the potential that incorrect assumptions may result in an adverse effect. Dark green indicates a beneficial effect, and incorporates a high level of precaution against uncertainty.

Prevent Overfishing

Alternative 1 prevents overfishing of target stocks and thus meets the goal of ensuring the sustainability of the fisheries. Alternative 1 also includes automatic stock rebuilding provisions which have proven to be effective. A weakness of this alternative is that there is no incentive to research fishery impacts on Tier 4-6 stocks in order to change their management status. It is also possible under this alternative to overharvest a vulnerable member of a stock complex.

Alternative 2 would maximize economic yield while preventing overfishing of target stocks, but it is not effective at preventing stocks from becoming overfished. The weaknesses of this alternative are that it increases the chance of unintentionally overfishing a stock and that catch estimates may be uncertain under this alternative if the Observer Program is repealed. Also, as in Alternative 1, there is no incentive to change the management status of stocks where the impact of fishing is unknown, and it is still possible to overharvest vulnerable members of a managed stock complex.

Alternative 3 prevents overfishing of target stocks and reduces the likelihood that stocks will become overfished, through precautionary harvest policies, and imposition of rebuilding regulations when stocks fall below the level capable of producing MSY. This alternative would formally define criteria for determining the status of stocks relative to an overfished condition in order to better satisfy the requirements of the National Standard 1 Guidelines. Efforts would be accelerated to identify methods for reducing the number of stocks where the status relative to an overfished condition is unknown.

Alternative 4 establishes a very conservative harvest policy which is likely to prevent overfishing and reduce the chance that stocks would become overfished. Constraints to commercial harvest coupled with systems of closed areas would effectively reduce impacts from the race-for-fish and therefore from spatial/temporal concentration of catch. Catch monitoring would also increase under this alternative, resulting in more complete fisheries data. As with Alternative 3, this alternative would define criteria for determining the status of all managed stocks relative to an overfished condition in order to better satisfy the requirements of the National Standard 1 guidelines. In the long-term, this alternative would protect the most vulnerable species of the complex, but the resulting management of many stocks with low biomass would be difficult to implement.

The PA prevents overfishing of target stocks and reduces the likelihood that stocks will become overfished through precautionary harvest policies and imposition of rebuilding regulations when stocks fall below the level capable of producing MSY. Efforts would be accelerated to improve the current harvest strategy, including in PA.2, additional procedures to incorporate uncertainty and develop spawning stock biomass estimates, in particular for Tiers 4-5.

Promote Sustainable Fisheries and Communities[1]

Alternative 1 continues to provide economic and community stability within the current system, while adapting management programs if the need arises. Some fisheries and communities are stressed due to the negative effects of the race-for-fish.

---

[1] This policy goal was explicitly identified only in the PA; in other alternatives, this goal was addressed under the policy heading of "Allocation Issues".

Long-term sustainability of fisheries and communities may be problematic if Alternative 2 policies, as illustrated in FMP 2.1, are implemented. In the short-term, fisheries and communities will likely see improved economic conditions. If less aggressive actions are pursued, the alternative is likely to be no better or worse than Alternative 1.

The rationalization of the fisheries under Alternative 3 holds the promise of improved fishery and community sustainability. Extensive area closures associated with more aggressive ecosystem-based management may reduce small boat and Alaska community involvement in fisheries.

The extensive TAC reductions and area closures under Alternative 4 reduce the viability of fisheries and fishery-dependent communities. Some fisheries may survive if the assumptions of impacts are correct.

The goal of promoting sustainable fisheries and communities under the PA is likely to be successful. The precautionary adjustments made to quota management decrease the risk of inadvertently overfishing managed species. Additionally, the transition to rights-based management under this alternative will promote the objectives of increasing efficiency, stability and safety in the long-term.

Preserve Food Web

Alternative 1 is partially successful in achieving the goal of preserving the food web through its protection measures for dominant target species, forage species, and ESA-listed species. However, it will likely make slow, incremental progress in protecting food web components. Alternative 1 will likely protect food web components that are more well-studied than those that are not or those that are at critical population thresholds, but it is uncertain whether sufficient protection is provided to food web components where less comprehensive information is available.

There is a high potential to create adverse food web impacts under Alternative 2 through its lack of precaution, which leaves no room for uncertainty. The possible lack of catch monitoring results in the potential for adverse food web impacts to go undetected until dramatic food web changes are seen. This alternative provides less precautionary management to many components of the food web.

Alternative 3 is successful in making many improvements relative to the baseline in achieving the goal of preserving the food web. The emphasis of this alternative is not only on using the best scientific information available to determine catch levels but also on providing additional protection against uncertainty by designation of MPAs and reserves. If these improvements are implemented, this strategy is likely to provide protection to a broad range of food web components.

Alternative 4 would meet the goal of preserving the food web, by providing large buffers against scientific uncertainty about ecosystem impacts resulting from fishing. The assumption that the present level of scientific information is insufficient to manage fisheries without excessive risk to the ecosystem results in the implementation of highly precautionary measures. This strategy provides improvements over the baseline and achieves protection of virtually all food web components and thus ecosystem functions. Although the alternative is successful in producing a food web that is less influenced by fishing activity, predictions about the abundance changes of individual food web components that might result are uncertain due to the difficulty in accurately predicting predator-prey relationships.

As a whole, through its goal to accelerate precautionary management measures through ecosystem-based principles, and its objectives to develop indices of ecosystem health and to take ecosystem factors into account in ABC setting, the PA is successful in making many improvements beyond the status quo in achieving the goal of preserving the food web. The emphasis in this alternative is on using the best scientific information available to determine catch levels, but also on providing additional protection against uncertainty by designation of MPAs and reserves. If these improvements are implemented, this strategy is likely to provide protection to a broad range of food web components.

Reduce Incidental Catch, and Reduce Bycatch and Waste[2]

The bycatch management program under Alternative 1 is effective at limiting incidental catch of non-target species and reducing bycatch through incentive programs and monitoring. The weaknesses of Alternative 1 is that bycatch is often reported as a complex rather than as individual species, and that observers are not present to monitor catch on vessels less than 60 ft LOA, which may result in inaccurate estimates of bycatch. This alternative may therefore not provide adequate protection for non-target species.

Alternative 2, as illustrated in FMP 2.1, would not be consistent with the objective of monitoring prohibited species catch, as repeal of the Observer Program would negatively impact catch monitoring. Alternative 2 policies, as illustrated by FMP 2.2, would be less severe. As in Alternative 1, additional weaknesses of the alternative are that bycatch is often reported as a complex rather than as individual species and that the absence of observer monitoring of catch on vessels less than 60 ft LOA may result in inaccurate estimates of bycatch. Therefore, Alternative 2 may not provide adequate protection for non-target species.

The bycatch and incidental catch reduction policies in Alternative 3 are consistent with accelerating precautionary management measures through additional bycatch constraints and monitoring. Bycatch reduction objectives and reductions in incidental catch are likely to be achieved without a major cost to industry due to the incentives for more efficient use of fishery resources under cooperatives, comprehensive rationalization of fisheries or other bycatch incentive programs implemented under this alternative.

The bycatch and incidental catch reduction policies under Alternative 4 are effective. Reduced bycatch and incidental catch would be achieved through extreme reductions in target groundfish catch and strong bycatch and incidental catch limits.

The bycatch and incidental catch reduction policies in the PA are consistent with minimizing human-caused threats to protected species and accelerating precaution through additional bycatch constraints, such as reduced PSC limits. Bycatch reduction objectives and reductions in incidental catch are likely to be achieved without a major cost to industry due to the incentives for more efficient use of fishery resources under cooperatives, comprehensive rationalization of fisheries, or other bycatch incentive programs implemented under this alternative.

Avoid Impacts to Seabirds and Marine Mammals

Alternative 1 is effective at providing protection to listed seabirds and marine mammals as a result of its explicit objectives for ESA-listed species. Although not an explicit policy goal, some protection may also

---

[2] For Alternatives 1-4, this policy goal is worded as “Reduce and Avoid Bycatch”.

be provided to non-listed seabirds through reduced incidental take as a result of implementing additional seabird protection measures.

Alternative 2 retains seabird and marine mammal protection measures for ESA-listed species, but does not go beyond ESA-required protection measures. Additionally, other goals and objectives under this alternative remove management measures currently in place in the baseline. The more aggressive harvesting policy, the relaxation of area closures, and the possible repeal of the Observer Program create a high potential to increase fishery interactions with seabirds and marine mammals that may result in adverse impacts to those species.

The goal of minimizing human-caused threats to protected species is largely met in Alternative 3 by actively adjusting protection measures, by actively reviewing the status of marine mammal fishery interactions, and through research. This approach, which may provide additional conservation measures in response to scientific evidence, is likely to provide increased protection to marine mammals and seabirds.

Alternative 4 is very successful at avoiding impacts to seabirds and marine mammals through its specific objectives to protect all seabirds from fishing interactions, and extending protection measures for Steller sea lion critical habitat and prey base. This largely increased level of protection provides a substantial buffer against uncertainty with regards to protection of marine mammals and seabirds.

The goal of minimizing human-caused threats to protected species, and if appropriate and practicable, other seabird and marine mammal species, is largely met in the PA by actively adjusting seabird and marine mammal protection measures, and status review of endangered and threatened marine mammal fishery interactions. This approach, which may provide additional conservation measures in response to scientific evidence, is likely to maintain protection to ESA-listed marine mammals and seabirds, and may increase protection for other seabirds and marine mammals.

Reduce and Avoid Impacts to Habitat

Alternative 1 emphasizes incremental implementation of habitat protection measures as scientific information becomes available. As a result, impacts to habitat may be alleviated. This strategy is likely to be effective in protecting habitat components that are more well-studied than others, but it is uncertain whether sufficient protection will be provided to habitat components for which there is less complete information. Cumulatively, continued adverse impacts result from historical impacts that have potentially caused long-term and possibly irreversible loss of living habitat, especially to long-lived, slow-growing species that are slow to recover.

Alternative 2 could result in increased impacts to habitat because of less precautionary management measures. Possible elimination of current closed areas and increases in TAC have the potential to result in adverse impacts to habitat that could be hard to reverse, especially for long lived, slow-recovering living habitats. The policy goal of developing practical measures to minimize adverse effects to EFH could be difficult to achieve if such irreversible impacts occur.

Alternative 3 has the potential to reduce and avoid impacts to habitat by careful placement of closures. Placement of closures in lightly fished or not fished areas could result in avoidance of future habitat impacts if fisheries were to move effort into surrounding areas. Placement of closures in heavily fished areas can mitigate impacts, reduce unintended consequences, and achieve overall benefits to habitat if closures do not encompass entire habitat types or areas of fishing intensity. In the short-term, information from the Observer Program could be used to locate such closures. In the long-term, scientific information gained from this policy can potentially lead to modification of the placement of MPAs and help meet the policy objective to assess the necessary and appropriate habitat protection measures. Cumulatively, the alternative results in a split environmental impact rating, as the adverse condition of the baseline is coupled with continued damage and mortality to living habitat, however the alternative has strong potential to mitigate these adverse impacts.

The emphasis of the Alternative 4 policy on habitat provides large buffers against scientific uncertainty about the impacts of fishing on habitat. The combination of highly precautionary measures associated with increasing marine reserves and other closure areas will likely achieve protection and avoidance of impacts to habitat. Cumulatively, the alternative has a environmental split rating, as the existing adverse condition of the baseline includes damage to slow-growing species unlikely to recover within the time period predicted in this analysis, however this alternative provides strong protection for habitat and potential for mitigation.

The PA has the potential to reduce and avoid impacts to habitat by careful placement of closures. Placement of closures in lightly fished or not fished areas will provide mitigation and result in avoidance of future habitat impacts if fisheries were to move effort into surrounding areas. Closures in heavily fished areas should be small to minimize displaced efforts and reduce chances of unintended consequences. To achieve overall benefits, closures should not encompass entire habitat types or areas of fishing intensity. In the short-term, information from the Observer Program could be used to locate such closures. In the long-term, scientific information gained from this policy can potentially lead to modification of the placement of MPAs and help meet the policy objective to assess the necessary and appropriate habitat protection measures. Cumulatively, the alternative results in a split environmental impact rating, as the adverse condition of the baseline is coupled with continued damage and mortality to living habitat, however the alternative has strong potential to mitigate these adverse impacts.

Promote Equitable and Efficient Use of Fishery Resources[3]

Alternative 1 is expected to continue to provide economic and community stability within the current management system while adapting management programs when the need arises. The alternative could eliminate the race-for-fish and, by doing so, would increase net-revenues to producers and provide benefits to consumers, but would create fewer, although possibly higher paying, fishery related jobs. Non-market, recreation, and tourism values could decrease in the short-run before the transition to rights-based systems is completed.

Alternative 2 has the potential to increase allowable catches to maximum biological levels and could eliminate the cushion between ABC levels and levels that result in OFLs. This alternative is expected to significantly increase revenues but would also increase operating costs with the elimination of the LLP and IFQ programs. While fishery production is maximized, product quality and the health and safety of participants suffer. Of particular importance may be the amount of variability in harvests, which could increase significantly and therefore make it much more difficult to make long-term business and infrastructure decisions. Finally, non-market, recreation, and tourism values that accrue to the ecosystem could be reduced substantially.

---

[3] For Alternatives 1-4, this policy goal is worded as "Allocation Issues".

Alternative 3 promotes increased social and economic benefits through the elimination of the race-for-fish while also emphasizing the long-term economic value of the fishery through the promotion of rights-based allocations to individuals, sectors, and communities. In addition, this alternative promotes ecosystem-based management and is likely to increase non-market, recreational, and tourism values assigned to the ecosystem. It is not possible to determine the long-term effect on overall ecosystem value (commercial and non-market values combined) because it is not known whether the fishing sectors, even with rights-based allocations, will be able to adapt to the changes resulting from the increased emphasis on ecosystem tools and, in particular, the additional number and significance of closed areas.

The Alternative 4 goals of incorporating and enhancing non-consumptive use values are met, but at the expense of commercial value and potentially the continued viability of coastal communities. The precautionary policies in Alternative 4 could result in substantial reductions in allowable catches and could also result in the closure of large portions of traditional fishing areas. The alternative is likely to result in a substantial increase in the non-market values of the ecosystem, but is also likely to result in a substantial decrease in efficiency, net revenues, and the number of participants in the fisheries.

The PA promotes increased social and economic benefits through the elimination of the race-for-fish while also emphasizing the long-term economic value of the fishery through the promotion of rights-based allocations to individuals, sectors, and communities. In addition, this alternative promotes ecosystem-based management and is likely to increase non-market, recreational, and tourism values assigned to the ecosystem. It is not possible to determine the long-term effect on overall ecosystem value (commercial and non-market values combined) because it is not known whether the fishing sectors, even with rights-based allocations, will be able to adapt to the changes resulting from the increased emphasis on ecosystem tools and, in particular, the potential addition to the number and significance of closed areas.

Increase Alaska Native Consultation

The Alternative 1 goals and policies for Alaska Native consultation and participation in fishery management would continue at the current levels and comply with relevant EOs and other federal law. Traditional Knowledge in fishery management would continue to be incorporated in environmental documents as available and appropriate. Subsistence uses would continue consistent with federal law.

As in Alternative 1, the goals and policies for Alaska Native consultation and participation in fishery management under Alternative 2 would continue at the current levels and comply with relevant EOs and other federal law. Traditional Knowledge in fishery management would continue to be incorporated in environmental documents as available and appropriate. Subsistence uses would continue consistent with federal law. Other goals and objectives in Alternative 2 would affect Alaska Natives by the increase in economic benefits accruing to participants in the fishery, particularly the CDQ pollock fishery. The increased fishing effort under this alternative may however result in increased salmon bycatch, which could have adverse effects on salmon fisheries particularly in the western Alaska Yukon-Kuskokwim river system.

The goals and policies for Alaska Native consultation and participation in fishery management under Alternative 3 would increase current levels by expanding informal and formal consultation between the NPFMC/NOAA Fisheries and Alaska Native participants and tribal governments. Traditional Knowledge would be more formally incorporated in fishery management and additional data would be collected. Other goals and objectives in Alternative 3, such as reductions in PSC limits, may benefit subsistence salmon use by reducing bycatch levels in the groundfish fisheries.

Alternative 4 would directly involve Alaska Natives in fishery management through the development of co-management or cooperative research programs. Consultation and participation objectives would focus on subsistence uses and cultural values of living marine resources. However, other goals and objectives in Alternative 4 that greatly reduce or eliminate commercial fishing would adversely impact Native communities, including CDQ communities, through the loss of employment, economic activity, and community revenues.

The goals and policies for Alaska Native consultation and participation in fishery management under the PA would increase current levels by expanding informal and formal consultation between the NPFMC/NOAA Fisheries and Alaska Native participants and tribal governments. Local and Traditional Knowledge would be more formally incorporated in fishery management and additional data would be collected. Other goals and objectives in the PA, such as reductions in PSC limits, may benefit subsistence salmon use by reducing bycatch levels in the groundfish fisheries.

Improve Data Quality, Monitoring and Enforcement[4]

The Alternative 1 policy would result in a data collection program that will continue to meet minimum acceptable standards for scientific management of the fisheries. Although aspects of the catch collection program could be improved, such as non-random coverage in the 30 percent component of the fleet, current practices do provide useful data for fishery management while remaining mindful of the cost burden on industry of the monitoring program.

Alternative 2 objectives maintain a minimum level of data collection to meet conservation requirements. The consideration to repeal the Observer Program may compromise management on the best science available as a result of reduced accuracy and breadth of fishery data. However, because the presumed risk of adversely impacting the environment is assumed in this alternative to be low, the costs to industry of funding the Observer Program to gather fishery data may not be considered necessary.

Through data collection measures that would result in reducing uncertainty, Alternative 3 is likely to be effective in achieving the goal of accelerating the use of precautionary management measures. The objectives to improve the Observer Program and observer data would increase the quality of fishery data by implementing increased flexibility of, and potentially expanding, observer coverage. Additionally, the expanded economic data and potential for independent verification would allow for more accurate and credible economic impact assessments. A funding source would, however, need to be identified to implement improvements to these programs.

Alternative 4 expands research and monitoring programs to obtain information necessary to fulfill the requirements of this alternative. The policy objectives are successful in increasing fisheries data by expanding the Observer Program to full coverage for vessels over 60 ft LOA, and instituting 30 percent coverage on smaller boats. Additionally, the requirements to improve the accuracy of data through

[4] For Alternatives 1-4, this policy goal is worded as "Data Quality, Monitoring, and Enforcement".

technological means such as at-sea scales and VMS will improve monitoring and enforcement under this alternative.

Through data collection measures that would result in reducing uncertainty, the PA is likely to be effective in achieving the goal of accelerating the use of precautionary management measures. The objectives to improve the Observer Program and observer data would increase the quality of fishery data by implementing increased flexibility of, and potentially expanding, observer coverage. Additionally, the expanded economic data and potential for independent verification would allow for more accurate and credible assessments of economic impacts. A funding source would, however, need to be identified to implement improvements to these programs. The alternative also emphasizes the importance of enforcement concerns in fishery management.

Chapter 5

This page intentionally left blank

Chapter 5 Research and Management

Preparing this Programmatic Supplemental Environmental Impact Statement (SEIS) has highlighted areas where scientists and managers need to pursue greater information about the resource, the effects of fishing, and the social and economic impacts of management decisions. Accordingly, this chapter reviews research and practical management components of the Bering Sea and Aleutian Islands (BSAI) and Gulf of Alaska (GOA) Fishery Management Plans (FMPs) and discusses the research and enforcement needs implicated by the alternatives.

Section 5.1 provides an overview of the existing data gaps and plans to fill those gaps. This section is intended to serve as a further reference for those impact ratings in the Chapter 4 analysis where the conclusion was 'unknown'.

Section 5.2 focuses on management and enforcement issues and examines the effects of each Alternative from the perspective of management complexity.

5.1 Information Gaps and Research Needs

The policy alternatives analyzed in this Programmatic SEIS all require that certain monitoring and research plans continue such that uncertainties associated with management and the environmental effects of the Alaska groundfish fisheries can be addressed. This section reviews current and planned research projects and identifies the information gaps and research needs for the BSAI and GOA marine ecosystem. Section 5.1.1 discusses the major research priorities, funding process and ongoing research. Section 5.1.2 then goes on to describe specific information gaps and research needs by resource category.

5.1.1 Major Research Priorities, Funding Process and Ongoing Research

The following sections outline the major research priorities, and ongoing research activities currently being conducted on groundfish and the marine and human environment of the North Pacific. Scientific research and the necessary funding in support of federal fisheries management in the Exclusive Economic Zone (EEZ) off Alaska, come from various sources in addition to National Marine Fishery Service (NMFS or National Oceanic and Atmospheric Administration [NOAA] Fisheries) own facilities and budget; the Alaska Department of Fish and Game (ADF&G), the North Pacific Research Board (NPRB), various academic institutions, industry groups, grant programs such as SeaGrant and the Saltonstall-Kennedy Program, and other public and private entities. To the extent that current funding continues, NOAA Fisheries will continue to conduct and avail itself of existing research activities. Expanded research to collect new information and fill existing data gaps in dependent on the agency's receiving additional research funding. While additional funds are not certain, NOAA Fisheries intends to pursue the funding necessary to meet future research needs and improve the scientific information available for managing the fisheries.

5.1.1.1 NOAA Fisheries

NOAA Fisheries is responsible for ensuring that management decisions are based on the best available scientific information relevant to the biological, social, and economic status of the fisheries. The agency strives for information that is comprehensive, objective, credible, and effectively communicated. Along these lines, the Magnuson-Stevens Fishery Conservation and Management Act (MSA), as amended by the Sustainable Fisheries Act of 1996, requires the Secretary of Commerce to develop and publish a strategic plan for fisheries research. The MSA mandates strong action to conserve and manage fishery resources that contribute to the food supply, economy, and health of the Nation. Furthermore, MSA provisions require NOAA Fisheries to end overfishing, rebuild all overfished stocks, and conserve essential fish habitat (EFH) through research and consultations on federal and state actions that may adversely affect such habitat. These are among the agency's primary stewardship responsibilities.

To meet these responsibilities, the agency developed and, in December 2001, published the *NMFS Strategic Plan for Fisheries Research* (the Strategic Plan) (http://www.st.nmfs.gov/st2/strategic_plan.html) (NMFS 2001c). This plan, which updates the original *Strategic Plan for Fisheries Research* released in 1998, outlines NOAA Fisheries' proposed research efforts for the subsequent five years. The scope of this plan includes fisheries, habitat, and protected species research that addresses requirements of the MSA. The mission of NOAA Fisheries scientific enterprise is to ensure that the science products produced and disseminated by NOAA Fisheries is of the highest quality. The Strategic Plan outlines the following broad goals and objectives for NOAA Fisheries: 1) to improve scientific capability; 2) to increase science quality assurance; 3) to improve fishery research capability; 4) to improve data collection; 5) to increase outreach/information dissemination; and 6) to support international fishery science. The following bulleted list details the actions called for in meeting these goals and objectives.

Improve Scientific Capability

- Implement National Research Council (NRC) recommendations (NRC 1998) to ensure state-of-the-art resource assessments through NOAA Fisheries' Stock Assessment Improvement Plan (NMFS 2001d).

- Continue to incorporate economic and social factors into the agency's decision-making. As part of this continuing effort, NOAA Fisheries will periodically publish the report *Our Living Oceans: The Economic Status of United States (U.S.) Fisheries.* The report will measure the economic health of U.S. fisheries relative to current conditions versus desired future conditions of long-term sustainability.

- Increase the agency's ability to predict natural living marine resource variation through improved data collection, improved understanding of how living marine resources respond to environmental variability and climate change, and coordinated bio-socioeconomic modeling, which will result in more accurate assessments and estimations of the uncertainty associated with them.

- Increase NOAA Fisheries' ability to identify, conserve, protect, and restore those habitats essential to managed fishery resources and to estimate the impact of pollution, wetland and estuarine degradation, and fishing gear on the abundance and availability of fish.

Increase Science Quality Assurance

- Implement policies to ensure that the agency's science programs, analyses, and products are sound, credible, and provide an objective basis for management.

- Improve the agency's professional standards for research and scientific advice by establishing national guidelines for technical program and staff performance evaluations, performance award programs, and professional career development opportunities.

- Expand and improve the agency's system for peer review of scientific advice by establishing panels of knowledgeable scientists from both within and outside government.

- Solicit input from external scientists in topical areas when identifying research initiatives for the various NOAA Fisheries' grant programs.

Improve Fishery Research Capability

- Implement NOAA Fisheries' fishery research vessel replacement plan (NMFS 1998a) that integrates government, university, and industry vessel capabilities to provide the state-of the-art facilities necessary for the accomplishment of the agency's varied at-sea research programs.

Improve Data Collection

- Implement NRC recommendations (NRC 2000) to improve the agency's data collection and analysis techniques and fishery data management systems.

- Provide a core fishery statistics program based on strategic and operational needs.

Increase Outreach/Information Dissemination

- Involve constituents in research programs. To the extent practicable, NOAA Fisheries will charter fishing vessels to participate in research projects, invite constituents to participate aboard NOAA Fisheries' research vessels during resource surveys, encourage frequent contact and cooperation between scientists and constituents, and develop methods to incorporate scientifically valid observations by fishers and others into fish stock assessments and other analyses related to living marine resources and their habitat.

- Coordinate with the NOAA Fisheries' Constituent Affairs and Outreach Team to develop an internet web-centralized resource for neutral science-based information to educate the public and user groups and answer questions on various topics on the status of the nation's fisheries, including how NOAA Fisheries research is conducted and how stock assessments are performed.

- Develop a new series of reports and presentations to communicate scientific results in simplified language that is easier to understand than traditional scientific publications.

Support International Fishery Science

- Participate in international scientific initiatives, such as the United Nations Intergovernmental Panel on Climate Change, Program for the Conservation of Arctic Flora and Fauna, Commission for the Conservation of Antarctic Marine Living Resources, Food and Agriculture Organization of the UN, Global Oceans Observing Program, North Pacific Marine Science Organization, International Council for the Exploration of the Seas, International Whaling Commission, United Nations Atlas of the Oceans, and Global Ocean Ecosystems Dynamics.

- Participate in bilateral scientific initiatives with neighboring countries, Canada and Mexico, and in scientific exchange programs with foreign countries that are developing their fishery resources.

Because fisheries are managed on a regional basis, the focus of NOAA Fisheries' research programs varies among the five regional science centers. Science center directors and their division chiefs develop annual research priorities, based upon regional and national needs, through dialogue with their Regional Administrator, regional councils, the program offices in NOAA Fisheries headquarters, and user groups and other interested parties. Teams of researchers at each science center work together to develop research plans.

NOAA Fisheries provide annual stock assessment information and management advice to support the their stewardship mission for the living marine resources in their regions. These cross-disciplinary efforts are undertaken in cooperation with other Federal and state agencies, international organizations, the fishing industry, and academia, and are based on long-standing cooperative research agreements. In addition to these basic responsibilities, each regional science center has unique capabilities to focus on special research needs.

The Alaska Fisheries Science Center (AFSC) is the research branch of NOAA Fisheries responsible for research on living marine resources in the coastal oceans off Alaska. The AFSC has research facilities in Alaska (Auke Bay and Kodiak Island), Washington (Seattle), and Oregon (Newport). Organizationally, the AFSC consists of the Auke Bay Laboratory, the National Marine Mammal Laboratory, the Resource Assessment and Conservation Engineering Division, the Resource Ecology and Fisheries Management Division, and other administrative units. The AFSC has a permanent staff of about 325 employees who conduct fisheries and marine mammal research in the coastal and offshore waters off Alaska. This marine region of nearly three million square miles includes over 50 percent of the U.S. coastline and over 70 percent of the U.S. continental shelf. The region supports some of the most important commercial fisheries in the world, particularly groundfish and Pacific salmon species, and is host to some of the world's largest populations of marine mammals and seabirds.

The 2001 *NMFS Strategic Plan for Fisheries Research* (NMFS 2001c) outlines the AFSC's research priorities for Fiscal Year (FY) 2001-2006. These priorities were developed in collaboration with state and other federal agencies, academic institutions, foreign research institutions, the fishing industry, and resource conservation organizations. Summarized below are the AFSCs research priorities grouped into four major research areas: research to support fishery conservation and management; conservation engineering research; research on the fisheries themselves; and information management research. The following list details the specific research being undertaken to support each of these major research areas.

I. Research to Support Fishery Conservation and Management

A. Biological research concerning the abundance and life history parameters of fish stocks

- Conduct an annual summer bottom trawl survey on groundfish and crabs in the eastern Bering Sea (EBS) shelf with chartered fishing vessels.

- Conduct Midwater trawl-acoustic surveys to assess the off-bottom component of pollock stock in the Bering Sea every two years (2002, 2004, 2006) and the GOA (2003, 2005) with the NOAA Research Vessel (R/V) *Miller Freeman.*

- Conduct an EBS slope survey on groundfish every two years (2002, 2004, 2006) with a chartered fishing vessel.

- Conduct an annual March survey on spawning pollock resources in the Bogoslof Island area by the NOAA Fisheries R/V *Miller Freeman* or with cooperating foreign research vessels.

- Conduct an annual spring survey of pollock resources in the Shelikof area by the NOAA Fisheries R/V *Miller Freeman.*

- Conduct a summer bottom trawl survey on groundfish in the GOA with chartered fishing vessels every two years (2001, 2003, 2005).

- Conduct a summer bottom trawl survey on groundfish in the Aleutian Islands region with chartered fishing vessels every two years (2002, 2004, 2006).

- Conduct an annual summer longline survey on sablefish resources in the GOA by a chartered vessel.

- Conduct a triennial summer bottom trawl survey on shelf groundfish off the Pacific west coast with two chartered vessels in 2001.

- Conduct an autumn bottom trawl survey on slope groundfish off the Pacific west coast with the NOAA Fisheries R/V *Miller Freeman* in 2001.

- Conduct a triennial summer hydroacoustic-bottom trawl survey on Pacific whiting off the Pacific west coast with the NOAA Fisheries R/V *Miller Freeman* in 2001.

- Conduct an annual April Fisheries Oceanography Coordinated Investigation egg-larvae survey in the GOA and a May survey on late-larvae by the NOAA Fisheries R/V *Miller Freeman*.

In addition to the above surveys, the AFSC is also planning to conduct many field operations to study marine mammal-fish interactions, with particular emphasis on sea lion-pollock/cod/Atka mackerel interactions in the GOA and the BSAI areas.

The following observer programs are planned for the groundfish fisheries that occur off Alaska:

- 100 percent observer coverage of fishing and processing vessels longer than 125 feet (ft).

- 100 percent observer coverage of most fish processing plants onshore.

- 30 percent observer coverage of fishing vessels that are 65-125 ft.

- 100 percent observer coverage (with multiple observers) of special category vessels that engage in community development quota (CDQ) and American Fisheries Act (AFA) fishing operations.

The AFSC will assess the status of stocks, estimate their biological production potentials (maximum sustainable yield (MSY), acceptable biological catch [ABC], overfishing levels [OFLs]), bycatch requirements, and other parameters required for their management. The following stocks will be assessed annually and be published in Stock Assessment and Fishery Evaluation (SAFE) reports:

- All BSAI and GOA groundfish stocks, including pollock, cod, sablefish, Atka mackerel, yellowfin sole, rock sole, flathead sole, Greenland turbot, other flatfish, Pacific ocean perch, and other rockfish species.

- King and Tanner crabs in the Bering Sea.

The National Marine Mammal Laboratory will assess the population dynamics, ecosystem interactions, and abundance of marine mammal stocks and their incidental take requirements. Some specific programs and activities that will be pursued are:

- Implement the Steller Sea Lion Recovery Plan.
- Implement the Steller Sea Lion - Fishery Interactions Research Plan.
- Implement the Northern Fur Seal Conservation Plan.
- Implement the Alaska Harbor Seal Research Plan.
- Analyze existing aerial survey data and harvest monitoring data on Alaskan ice seals.
- Analyze data collected during the international Antarctic pack ice seal cruise.
- Implement the Humpback Whale Recovery Plan.
- Implement the Northern Right Whale Recovery Plan as it pertains to the North Pacific.
- Implement an extended 5-year research and monitoring plan for the eastern North Pacific gray whale.
- Analyze data collected during the 1997-1999 small cetacean surveys in Alaska.
- Implement the West Coast Pinniped-salmonid Research Plan.
- Monitor the Makah gray whale harvest.

B. Social and economic factors affecting abundance levels

- Expand sociological and economic research and incorporate results into the fishery management process.
- Conduct research on vessel over-capitalization and impacts of their fishing effort levels on fisheries.

C. Compilation and analysis of data on harvesting and processing sector behavior

D. Interdependence of fisheries or stocks of fish

- Collect biological specimens of spawning pollock throughout its range for genetic marker studies through deoxyribonucleic acid (DNA) and other genetic techniques. Cooperation with foreign scientists is required for sampling non-U.S. waters.
- Analyze survey and observer data to determine spatial distributions of different species clusters that would indicate separation or interdependence of stocks.

- Develop genetic baseline information on salmonids to identify stocks or area of origin.

- Conduct winter surveys to estimate distribution and abundance of pollock (acoustic) and Pacific cod (bottom trawl) in Steller sea lion critical habitat areas in southeast Bering Sea, Shumagin Islands, and Kodiak Island to determine dependence of sea lions on localized food supplies and assess feasibility of annual time series.

E. Identifying, restoring, and mapping of EFH

- Conduct studies on the impacts of logging, urbanization, and mining on coastal salmon resources in southeast Alaska. NOAA Fisheries will work with the Corps of Engineers and local organizations to restore an urban impacted salmon stream.

- Conduct restoration studies related to the *Exxon Valdez* oil spill (EVOS) in Prince William Sound (PWS). The research will build upon the results reported in the accomplishments section, including a study of the effects of oil on the biology, homing, and survival of pink salmon.

- Impact of anthropogenic factors and environmental changes on fish populations

- Investigate mortality and pathogens of shellfish and groundfish.

- Conduct Fisheries Oceanography Coordinated Investigations: a cooperative research program with the Pacific Marine Environmental Laboratory of NOAA's Oceanic and Atmospheric Research Office to investigate the causes of variation in annual recruitment in fish stocks.

F. Assessment of effects of fishing on EFH and development of ways to minimize adverse impacts

II. Conservation Engineering Research

A. Continue to conduct research to measure direct effects of bottom trawling on seafloor habitat according to a five-year research plan.

B. Conduct fishing gear performance and fish behavioral studies to reduce bycatch and bycatch mortality of prohibited, undersized, or unmarketable species, and to understand performance of survey gear.

C. Work with industry and North Pacific Fishery Management Council (NPFMC) to develop bycatch reduction techniques.

III. Research on the Fisheries

A. Social and economic research

- Continue to build upon the economic data collection program, initiated by AFSC. This program collects cost, earning, and employment data for the Alaska groundfish fishery. AFSC will continue to work with the NPFMC, AFD&G, and the Alaska Fisheries information network to identify the elements of a broader program to collect economic and social data.

- Assess the economic impact of different fishing and conservation strategies that are proposed throughout the year by NOAA Fisheries and NPFMCs.

- Compile the economic status of Alaska's groundfish fisheries as part of the annual groundfish SAFE reports.

- Assess economic performance of the Alaska groundfish and halibut fisheries and research to improve these assessments.

B. Seafood safety research

- No research activities identified.

C. Marine aquaculture

- Study the growth, distribution, behavior, and early marine survival of salmon; conduct research on salmon biology and enhancement technology in Alaska.

IV. Information Management Research

- Continue to build data infrastructure and resources for easy access and data processing. The AFSCs key databases are its survey data bases from the 1950s (or earlier) and the scientific observer database that extends back to the foreign fishing days of the 1960s.

- Continue to provide information products based on experts and technical data that support NOAA Fisheries, the regional office, NPFMC, international scientific commissions, and the overall research and management community.

5.1.1.2 North Pacific Fishery Management Council

NPFMC relies on its Scientific and Statistical Committee (SSC) to assist NPFMC in interpreting biological, sociological, and economic information. The SSC also plays an important role in providing NPFMC with recommendations regarding research direction and priorities based on identified data gaps and research needs. At its March 2003 meeting, the SSC reviewed the list of research priorities as developed by NPFMC's BSAI and GOA groundfish plan teams in November 2002. The SSC used this list to develop the following short list of research topics needing immediate attention in 2003:

I. Critical Assessment Problems

A. For rockfish stocks there is a general need for better assessment data, particularly investigation of stock structure and biological variables.

- Supplement triennial trawl survey biomass estimates with estimates of biomass or indices of biomass obtained from alternative survey designs.

- Obtain age and length samples from the commercial fishery, especially for Pacific ocean perch, northern rockfish, and dusky rockfish.

- Increase capacity for production ageing of rockfish so that age information from surveys and the fishery can be included in stock assessments in a timely manner.

- Further research is needed on model performance in terms of bias and variability. In particular, computer simulations, sensitivity studies, and retrospective analyses are needed. As models become more complex in terms of parameters, error structure, and data sources, there is a greater need to understand how well they perform.

B. There is a need for life history information for groundfish stocks, e.g., growth and maturity data, especially for rockfish.

- There is a need for information about stock structure and movement of all FMP groundfish species, especially temporal and spatial distributions of spawning aggregations.

II. Stock Survey Concerns

- There is a need to explore ways for inaugurating or improving surveys to assess rockfish, including nearshore pelagics.

- There is a need to develop methods to measure fish density in habitats typically inaccessible to NOAA Fisheries survey gear, i.e., untrawlable habitats.

III. Expanded Ecosystem Studies

- Research effort is required to develop methods for incorporating the influence of environmental and climate variability, and their influence on processes such as recruitment and growth into population models, especially for crab stocks.

- Forage fish are an important part of the ecosystem, yet little is known about these stocks. Effort is needed on stock status and distribution for forage fishes such as capelin, eulachon, and sand lance.

- Studies are needed to identify essential habitat for groundfish and forage fish. Mapping of nearshore and shelf habitat should be continued for FMP species.

IV. Social and Economic Research

- Development of time series and cross-sectional databases on fixed and variable costs of fishing and fish processing.

- Pre- and post-implementation economic analyses of crab and GOA groundfish rationalization.

- Identification of data needed to support analyses of community level consequences of management actions.

- Development of integrated multi-species/multi-fishery models for use in analyses of large scale management actions, such as PSEIS and EFH.

V. Bycatch

- Identify sources of variability in actual and estimated bycatch rates.

VI. Monitoring

- Promote advance in video monitoring of otherwise unobserved catch for improved estimation of species composition of total catch and discrimination of retained and discarded catch

VII. Research Priorities Identified by the NRC Steller Sea Lion Committee

The SSC held a brief discussion on the research and monitoring recommendations of the NRC Steller Sea Lion Committee, as presented in the Executive Summary of their report. The SSC noted that their recommendations are consistent with recognized needs, but also that there is considerable ongoing Steller sea lion research. Among the NRCs recommendations, the SSC wishes to particularly identify their recommendation for a spatially-explicit, adaptive management experiment to definitively conclude whether fishing is playing a role in the current lack of Steller sea lion recovery. As noted in the SSCs February 2003 minutes, there are a number of scientific, economic, and Endangered Species Act (ESA) regulatory considerations that must be addressed before such a plan can be seriously considered for implementation. However, the SSC supports further exploration of the merits of this adaptive management approach.

5.1.1.3 North Pacific Research Board

The NPRB was created by Congress in 1997 to recommend research relating to fisheries or marine ecosystems in the North Pacific Ocean, Bering Sea, and Arctic Ocean, with emphasis on cooperative research designed to address pressing fishery management or marine ecosystem information needs. NPRB's long-term goal is to develop a high caliber, comprehensive research program for the regions and fisheries under its purview. The program's foundation rests on science planning, prioritization of pressing fishery management and ecosystem information needs, coordination and cooperation among research programs, competitive selection of research projects, increased information availability, and public involvement. NPRB strives to avoid duplicating other research.

NPRB uses an open, competitive process for gathering research proposals. Criteria for project submission and evaluation are specified in an annual request for proposals that is normally released each fall. NPRB's enabling legislation is quite broad in defining who can receive research grants. Research grants may be made available to federal, state, private or foreign organizations or individuals. NPRB receives advice from various panels and committees, and recommends grants based on the merits of the request and the extent to which the proposed research meets the priorities established by NPRB. Research recommendations of NPRB are reviewed by the Secretary of Commerce, through his designee, the Alaska Regional Administrator for NOAA Fisheries. The Secretary is not free to use the recommended funding amount in some other way; it can only be used to fund some other grant recommended by NPRB.

NPRB's research funds are based on the interest earned by the Environmental Improvement and Restoration Fund, also created by Congress and derived from the Dinkum Sands case. Each year, 20 percent of the interest is made available to the Secretary without further appropriation to carry out marine research activities. NPRB approved about $2.2 million in marine research beginning in 2002, and $7 million in new research in 2003. Of the 156 proposals submitted for research in 2003, thirty proposals were approved by NPRB on March 20, 2003. NPRB's recommendations for 2003, however, still need to be given final approval by the Secretary of Commerce acting through his designee, the Alaska Regional Administrator for NOAA Fisheries. The following 29 proposals were recommended by NPRB for funding in 2003:

- Evaluation of emergent structure in low-relief benthic habitats as criterion for defining the EFH of juvenile North Pacific flatfish.
- A continuous plankton recorder survey of the North Pacific and southern Bering Sea.
- North Pacific Anadromous Fish Commission (NPAFC) Cooperative Research: salmon community structure and response to environmental change in the Bering Sea.
- Deep sea coral distribution and habitat in the Aleutian Archipelago.
- Monitoring and modeling predator-prey relationships.
- Species identity and life history of *Hematodinium*, the causative agent of vitter crab syndrome in Northeast Pacific snow (*opilio*) and Tanner (*bairdi*) crabs.
- Forage fishes in the western GOA: variation in productivity.
- Sperm whale and longline fisheries interactions in the eastern GOA.
- Estuaries as EFH for salmonids: assessing residence time and habitat use of coho and sockeye salmon in Alaska estuaries.
- NPAFC Cooperative research: genetic stock identification of chum salmon in the Bering Sea and adjacent waters.
- Establishing a statewide data warehouse of salmon size, age and growth records.

- Ice seal bio-monitoring in the Bering-Chukchi Sea regions.

- Effects of prey availability and predation risk on the foraging ecology and demography of harbor seals in PWS: development and test of a dynamic state variable model.

- Thermal habitat preferences of Pacific halibut and the potential influence of hydrographic variability on local coastal fishery.

- Continuation of long-term observations on the Bering Sea shelf: biophysical moorings at Sites 2 and 4.

- EFH for blue king crab, Phase I: development of cultivation techniques for blue king crab larvae.

- Pre-season forecast of Bristol Bay sockeye salmon migration timing based on oceanographic and biological variables.

- Pilot project for development of comprehensive baseline commercial fishing community engagement and dependency profiles for the BSAI and western GOA regions.

- Retrospective study of pigmented macrophage aggregates as markers of Pacific herring population health.

- Effects of inter-annual climate change on food availability, diet composition and productivity of planktivorous and piscivorous seabirds.

- Evaluation of alternative hypotheses to explain the collapse of the Kvichak sockeye salmon: a project to catalyze a comprehensive, hypotheses-driven research program.

- Spatial and temporal interactions between endangered short-tailed albatrosses and North Pacific commercial fisheries.

- Assessment of trawl third wires as a threat to seabirds, including the endangered short-tailed albatross.

- NPAFC cooperative research: use of genetic stock identification to determine the distribution, migration, early marine survival, and relative stock abundance of sockeye, chinook, and chum salmon in the Bering Sea.

- Bering Sea wintering grounds of beluga whales.

- Regime forcing and ecosystem response in the Bering Sea: Phase II.

- Video monitoring aboard Bering Sea factory trawlers—a pilot study.

- Enhancing rural high school involvement in North Pacific resource issues through participation in Alaska Regional National Ocean Sciences Bowl.

- Early marine ecology of juvenile chum salmon in Kuskokwim Bay, Alaska.

5.1.2 Specific Information Gaps and Research Needs by Resource Category

This section provides a brief summary of specific information gaps and research needs identified by PSEIS resource category. Most of these data gaps and research needs are fairly consistent across all of the alternatives; however, those data gaps and research needs pertaining to a specific alternative are highlighted and discussed. While the information gaps are many and the research needs important, it is beyond the scope of this section to examine the tradeoffs between the cost of collecting this new information versus the potential value of the new knowledge. As such, no attempts were made at prioritizing these research needs. However, expanded research to collect new information and fill existing data gaps is dependent on the agency's receiving additional research funding. While additional funds are not certain, NOAA Fisheries intends to pursue the funding necessary to meet future research needs and improve the scientific information available for managing the fisheries.

5.1.2.1 Physical Environment

At present, there is a considerable lack of environmental information from which to relate climate to the ecosystem in the North Pacific. NOAA is the primary steward for the living marine and protected resources and is responsible for the provision of long-term ecosystem observations. As such, a system should be developed for sustained measurement of climate and ecosystem variability; discern from those measurements significant changes; comprehend the underlying mechanisms for those changes; and develop and test prognostic ecosystem models. Research associated with the development of this system should focus on the following:

- Establish an observation system for the U.S. North Pacific marine environment for sustained monitoring of climate and ecosystem variability.

- Establish an infrastructure for the dissemination, interpretation and analysis of climate and ecosystem data.

- Conduct process studies to understand the underlying mechanisms relating climate change and ecosystem response.

- Integrate emerging scientific knowledge into prognostic models for resource management decisions.

- Provide annual reports on observed and predicted ecosystem changes.

- Improve understanding of interactions between the environment and society.

5.1.2.2 Target Groundfish Species

The significance of the impacts on target groundfish species were evaluated with respect to five effects: 1) fishing mortality; 2) change in biomass level; 3) spatial/temporal concentration of the catch; 4) prey availability; and 5) habitat suitability. When evaluating the significance of these effects, it was considered whether the impacts of effects could reasonably be expected to jeopardize the sustainability of each target species or species group. Related to this evaluation was the assignment of each species to one of six "Tiers" based on the availability of information about that stock (Appendix F-1). Tier 1 has the most information and Tier 6 has the least.

Species or species complexes that fall within Tiers 1 through 5 have estimates of the current fishing mortality rates and were evaluated with respect to exceeding the overfishing mortality rate (fishing mortality effect). Species or species complexes that fall within Tiers 1, 2, or 3 have reliable estimates of maximum stock size threshold (MSST) and were evaluated for the effects of spatial/temporal concentration of the catch, prey availability, and habitat suitability. The significance of these effects could not be evaluated for species or species complexes that fall within Tiers 4, 5, or 6, as these species do not have reliable estimates of MSST. This inability to evaluate the significance of the effects also occurs for the forage, prohibited and non-specified species. Additional research is needed so that the information base for Tiers 4-6 species will expand to the point where they can be move into Tiers 1-3. What follows are data gaps and research needs highlighted by many of the PSEIS target groundfish species authors.

Research is needed to reduce the uncertainty of survey biomass estimates for many of the target groundfish species. While there are adequate collections of biological data (e.g., lengths, weights, otoliths) for many of the target groundfish species from fishery independent bottom trawl surveys, these surveys may do a poor job of estimating abundance trends and biomass for some of the species. A major problem is that the survey's stratified random design for selecting haul locations may not be adequate for a species with a very patchy distribution. Biomass estimates in some years are greatly influenced by extremely large catches in just one or two hauls, and variance of these biomass estimates is consequently very high. This results in much uncertainty regarding abundance trends. Also, the surveys may not adequately sample rocky habitats where some target species may live, and so survey catchability *(q)* is uncertain.

A survey designed specifically for species with known patchy distributions (e.g., Pacific ocean perch, northern rockfish) would be an improvement. The objective of the present survey is to provide information on distribution and abundance of all groundfish species within the geographic area it covers. Because of the patchy distribution of some species, we need to sample many more locations than are possible given the constraints of the present survey methodology. It appears that a new survey that combines trawling with hydroacoustics may be the best future approach, but additional research is needed to determine how and if hydroacoustics can be used. Instead of the present survey net, a more up-to-date survey net equipped with tire gear on the footrope would also be useful for trawling over rougher bottoms.

Bayesian type analyses may be useful to quantify the effect of estimate uncertainty and improve stock assessments for target groundfish species. Particular attention should be given to estimates of q, and natural mortality (M) which have been shown to have a large influence on stock assessment model output. Also, updated studies on fecundity, size at maturity, age methodologies and validation, selectivity schedules at age, and weight at age information would be helpful in moving those groundfish species in Tiers 4-6 into Tiers 1-3.

Genetic research is needed to assess the risk of localized depletion on the genetic integrity of a given stock. Identification of stock structure is an essential part of examining whether a particular management scheme is providing the level of conservation as intended. Alternative 1 apportions ABC for many of the target groundfish species geographically among management areas in order to spread the effort and reduce the likelihood of localized depletion. However, information on stock structure for many of these species is inadequate, and for some species (e.g. many of the rockfish species), tag-and-release studies are not possible to elucidate stock structure. A number of genetic studies on Pacific ocean perch have been done, but the results have been equivocal. The most recent mitochondrial DNA studies suggest that some stock structure may exist, and additional studies are planned (Gharrett, personal communication 2000).

The development and application of molecular markers to studies of marine fish species have provided insight into the genetic connectivity of marine populations managed as stocks. Recent studies have focused on species supporting commercial fisheries, such as walleye pollock, using microsatellite, allozyme, mitochondrial DNA, and pantophysin markers. However, there is a considerable need to expand this approach to other directly exploited species (e.g., skates, flatfishes), species impacted as bycatch (e.g., sculpins), and ecologically important forage fishes (e.g., eulachon, capelin) in order to identify and assess the autonomy or connections among component stocks and their potential response to environmental or fishery-mediated changes.

Research is needed to assess the utility of rationalizing the fishery in order to reduce the risk of overfishing by eliminating the race for fish. Under Alternative 1, the groundfish trawl fishery is compressed in time and may increase the risk of overfishing. Consequently, the spatial concentration of catch could result in a negative impact on the reproductive success of the stock and subsequently on stock sustainability. However, more research is needed before the impacts can be fully known.

Research is needed to assess the utility of existing and proposed refugia to improve the reproductive success of various groundfish stocks. Under Alternative 1, a portion of the eastern Gulf is closed to trawling and may serve as *de facto* refugium allowing for increased survival of larger and older fish that produce significantly more eggs and larvae to replenish Gulfwide populations. Consequently, the spatial concentration of catch could result in a positive impact on the reproductive success of the stock and subsequently on stock sustainability, but more research is needed before the impacts can be fully known.

Research is needed to assess ecosystem considerations for single species management for many of the target groundfish species. There is currently insufficient information to conclude that existing trophic interactions would undergo significant qualitative change under Alternative 1. Consequently, the impacts of Alternative 1 on prey availability and the subsequent impact on stock sustainability can not be fully known without more research.

More research is needed to identify the habitat requirements of adult and juvenile target groundfish species and to assess impacts from fishing on habitat suitability. The habitat preferences of many of the groundfish species are poorly known. The trawl survey gear is able to sample flat, smooth substrates fairly well, but cannot sample rough, steep substrates. So for those species occupying the rougher substrates, the current trawl surveys may be doing an inadequate job of assessing them and their respective habitats. Juvenile habitat requirements are not known for many of the target groundfish species. For example, very few Pacific ocean perch less than 20 to 25 centimeters fork length are caught in the survey, and it is presumed these young fish live in habitats that cannot be sampled by the survey's nets.

Bottom trawling or other fishing gear in contact with the ocean could negatively impact the habitat of adult and juvenile groundfish species and may reduce survival of juvenile fish. Consequently, the change in habitat suitability could result in a negative impact on rearing success of the various groundfish stocks and subsequently on stock sustainability, but more research is needed before the impacts can be fully known.

5.1.2.3 Prohibited Species

Pacific herring populations in PWS are still recovering from the EVOS. It is unknown how, when, and if these populations will eventually recover and to what extent. Habitat contamination in PWS is also lingering but it has not been determined what the long-term effects of the EVOS will have on herring and its habitat. Additional research could be helpful in identifying physiological changes that may be occurring in those populations (some populations are showing signs of recovery while others are not). It is also unknown how the EVOS and its related lingering contamination have affected prey availability for herring, if at all.

It is known that Pacific herring form dense schools which make them more vulnerable to spatial/temporal effects of fishing. Currently the movement of herring schools throughout Alaskan waters has not been studied to the extent that one could predict their location and timing. Thus, additional research to elucidate the spatial/temporal characteristics of herring populations could prove extremely valuable in the management of this species.

There are data gaps for spawning habitat for all salmon. Since these fish spawn in fresh water, impacts from state subsistence fishing, sport fishing, and land management practices have not been studied to the extent that impacts are known. Degradation of watersheds (mainly from land management practices) used as salmon spawning grounds could impact reproductive success and stock sustainability, but no specific trends over time have been reported to date.

It has been thought that climatic changes are also playing a role in the current poor stock status of salmon runs in western Alaska, but specific effects are unknown. The potential for climate change, degradation of spawning habitat, change in prey availability, and increased mortality (fishing and natural events) to effect all species of salmon is recognized as a fruitful area for future research.

Determining relationships between prey catch and salmon prey availability is also a data gap and an area of potential research. Composition of prey for salmon are unknown. Identifying essential prey items in the diets of salmon could provide information to minimize prey competition between salmon and fisheries.

Focusing research efforts on depressed stocks of salmon in Alaska and chinook salmon originating in the Pacific Northwest that are currently listed species under ESA, may provide additional data that could help manage and protect this species until recovery begins to occur. Research collaboration between ADF&G and NOAA Fisheries could encompass the different phases of salmon's life cycles, thus, maintaining and improving the complex management of all species of salmon throughout Alaskan waters.

5.1.2.4 Other Species

NOAA Fisheries has increasingly been charged to conduct assessments on progressively more species. This is particularly true in the case of stock assessments for non-target species in Alaskan waters. A strong need exists for research in the following areas of concern regarding management of species that are caught as bycatch in other fisheries:

- When species are not identified as a single fisheries management unit, quotas may not adequately protect the reproductive potential of the less abundant members of a complex.

- When stocks are managed in complexes that include species with different life history characteristics, quotas may not adequately protect the reproductive potential of the slower growing, long-lived, less fecund members of a complex.

- Rare species may be vulnerable to overfishing because of their low stock size and patchy distributions.

- Traditional fishery independent assessment surveys are not designed to assess rare species and biomass estimates for these species may be uncertain.

The AFSC has collected specimens of skate species from previous surveys conducted in the BSAI and GOA that are difficult to classify. Some samples exhibit characteristics that may be indicative of a new species. Research funds are needed to allow staff to travel to various museums to compare EBS/GOA skate specimens with museum specimens for verification of species identification. This work will not only improve assessment of skates but will also improve the assessment of new fisheries in the GOA targeting on skates. Research is also needed on the biology and identification of North Pacific cephalopods. The life history and identification of these species are not well understood. Such research will improve the identification of cephalopods taken in commercial fisheries and during resource assessment surveys.

Detailed information on the age composition and fisheries catch are seldom available for bycatch species. This situation leads to increased reliance on survey biomass estimates. A catchability coefficient is needed to scale survey abundance estimates to total abundance. Research is needed to evaluate the catchability of non-target species to the EBS survey trawl used in the annual EBS bottom trawl survey.

5.1.2.5 Forage Species

The abundance of ecologically important forage species is unknown in much of Alaska. This information is critical for understanding the Alaska marine ecosystem and managing the commercially important species within this ecosystem. Research is needed to measure abundance of ecologically important forage species including: eulachon, herring, capelin, and in southeast Alaska: pollock. Assessment of forage species is difficult because of their diffuse, patchy distribution and unknown stock structure. Pre-spawning and overwintering aggregations, however, appear to be more discrete and concentrated, potentially enabling more efficient surveys (e.g., with acoustic and mid-water sampling) and stock-specific assessment data. As such, research should be conducted to determine where these winter aggregations of forage species occur in time and space.

Research should be conducted to measure how reliability of forage location and nutritional value affect susceptibility to predation. Different forage species appear to have different strategies to reduce predation. For example, overwintering herring concentrations occupy predictable depths, but are diffusely distributed. The numerical response of predator species affiliated with these prey can be collected simultaneously with measurement of forage species abundance.

The lack of population level assessments for some of the species in the forage species group means that species level effects on those are unknown. Better understanding of the factors influencing forage species dynamics and spatial/temporal distribution will help us better separate the role of climate and fishing in influencing the dynamics of these species.

5.1.2.6 Non-Specified Species

Non-specified species is a huge and diverse category encompassing everything not listed in the FMP as a target, prohibited, forage, or other species. Unfortunately, basic information is lacking for nearly all of the species in this group. They are caught in small or unknown amounts (due to a lack of reporting requirements in this category) and formal stock assessments are not conducted. Research is needed to gain a better information base (e.g., estimates of total biomass, spawning biomass, age and size structure, sex ratios, temporal and spatial distribution, fishing mortality rates, etc.).

Grenadier species represent the major catch from the non-specified FMP category. They are ecologically important and appear to be one of the most abundant species in the northeastern Pacific, but their true abundance and life history are poorly known. This information is critical for understanding the Alaska marine ecosystem and managing the commercially important species within this ecosystem. Only limited assessment work has been done for the grenadier species. Research should be conducted to examine avenues for preparing quantitative assessments for these species based on data from longline surveys.

5.1.2.7 Essential Fish Habitat

The largest fisheries in the continental U.S. occur in waters off Alaska. The region has five FMPs and encompasses the largest shelf and geologically most complex area of the U.S. coastal zone. There is a wide diversity of habitat types in this region ranging from the extensive soft-bottom areas of the Bering Sea shelf to the complex high-relief habitats of the Aleutian Islands and portions of the GOA. Alaskan fisheries that target groundfish, crab, and scallops all use gear that may adversely impact benthic habitat. This gear includes bottom trawls, longlines, pots, and dredges.

Since 1996, the AFSC has been conducting research on the effects of fishing gear on benthic habitat. This research has led to important findings that increase our understanding of fishing gear effects on benthic habitat. Research has focused on 1) understanding the direct effects of bottom trawling on seafloor habitat; 2) the associations of fish and invertebrate species with habitat features that may be affected by fishing gear; 3) the evaluation of technology to determine gear effects and benthic habitat features; and 4) retrospective analyses of spatial/temporal patterns of bottom trawling. Most of the field-oriented studies (i.e., 1-3 above) have focused on small geographic areas in specific habitat types.

Research efforts over larger geographic areas and a variety of habitat types will provide fisheries managers the information needed to develop measures for minimizing the adverse impacts of fishing gear, as required in the MSA.

During a three-day workshop held in January 2000 in Juneau, Alaska, research projects were identified and a time-table for completion was drafted. This plan has been subsequently revised as research is completed or priorities change. The suite of projects identified takes a comprehensive and scientific approach to the issue of fishing gear effects on habitat. During the initial phase of this research, the focus is on identifying the effects of the various gear types on fish habitat for a range of habitat types, mapping habitat, examining the associations between habitat features and fish utilization, and defining the geological processes that will allow comparison of natural versus gear effects processes. After this initial phase, studies will transition to those that establish the connections between habitat and fish production and population dynamics. This research plan will be implemented through collaborative projects with the ADF&G, the University of Alaska, and others.

Two themes emerged in this research plan: (A) The need to better determine the effects of fisheries on benthic habitat; and (B) The need to study the spatial extent of fishing ten individual projects hve been identified that fall into three major categories: 1) effects of specific gear on specific habitat; 2) linkage of fishing induced disturbance to population dynamics of commercial and non-commercial species; and 3) mitigation related studies. Some of these projects represent continuance and expansion of existing projects and others are new projects.

I. Determine Effects of Fishing on Benthic Habitat

Three experimental approaches are applicable to this general research objective and suitable research sites are generally available in the BSAI and GOA.

(A) *Compare conditions in heavily fished and lightly fished/unfished areas that are in close proximity and otherwise similar.* This approach allows an assessment of long-term (chronic) effects of fishing activity on physical features of the seabed as well as effects on the structure and function of associated benthic invertebrate communities. High quality fishing effort data are required to identify appropriate experimental sites, which may or may not straddle closed area boundaries. Replicated biological sampling with grabs, trawls, and underwater video or submersible observations are needed to characterize relevant population and community-level attributes in the disturbed and undisturbed sites, such as biomass, numbers of individuals, body size, species richness, species diversity, and the physiological states of biostructure, prey, and resident FMP species. Acoustical surveys with multi-beam, side scan, or single beam devices, coupled with grab and video groundtruthing, would be the basis for comparison of physical features such as sediment texture and bedforms.

(B) *Compare conditions before and after fishing to identify effects on the benthos. Unfished controls are necessary to evaluate the effects of fishing where existing closures do not provide a necessary contrast in fishing intensity*. Recovery can be examined in unfished controls with continued sampling. Replication with multiple (paired) sites is required to avoid spurious outcomes. Otherwise, longer-lived individuals or species will be under-represented in the samples thereby biasing results. In addition to sampling methods and gears described in (1) above, effective contrasts of conditions before and after fishing requires highly accurate positioning of fishing and sampling gear within the disturbed (experimentally fished) and undisturbed (control) sites, especially when destructive sampling methods are used.

(C) *Determine rates of disturbance with repetitive fishing of specific grounds. Incremental and cumulative catch rates can be used to measure the rates of depletion of benthic fauna, changes in community structure, and alteration of seabed properties as a function of fishing intensity.* Similar to (2) above, these sites should have limited or preferably no prior fishing disturbance history in order to obtain a full measure of effects. Once again, careful positioning of fishing and sampling gear is required for meaningful results.

II. Specific studies:

A. Effects of specific gear on specific habitat

1. <u>Effects of bottom trawling on soft bottom habitat of the GOA</u>
Extensive trawling occurs over soft-bottom habitats in the GOA. Immediate and long-term changes in soft substrates and associated animal communities will be evaluated through comparisons of adjacent open and closed fishing areas and through intensive trawling experiments. In areas with soft substrates, sea whip colonies are vulnerable to gear damage. Sea whips can be removed, dislodged, or broken by fishing gear. Previous studies conducted by the AFSC on soft-bottom habitat have shown that areas with sea whips appear to have greater productivity (greater biomass and numbers of megafauna) than adjacent areas devoid of sea whips. Since sea whips are believed to be long-lived, recolonization rates may be very slow. Sea whip biological characteristics and their resistance to levels of trawling will be studied. The study will also provide an opportunity to assess recolonization in future years. The study will

provide information for evaluating measures to minimize fishing effects such as area closures or gear modifications.

2. Effects of bottom trawling on soft-bottom habitat of the Bering Sea shelf
The relatively recent and well-documented development of large-scale commercial fisheries in the EBS presents a rather unique opportunity for studying the potential impacts of trawling on benthic habitats. Areas closed to trawling are adjacent to heavily fished areas allowing for comparison of the effects of fishing activities on seabed habitat utilized by nationally important stocks of groundfish and crab. Physical and chemical characterizations of the seabed, in addition to biological assessments, are needed to evaluate fishing effects on these habitats. Current studies in the Bering Sea have identified possible adverse effects of bottom trawls on soft-bottom benthos, including chronic effects on community diversity and on individual megafauna populations. However, interpretation of these findings and effective use for management purposes requires some understanding of the underlying processes. To address this need, a multi-year study is required to investigate acute effects and recovery from bottom trawling. Project findings will address management issues related to the need for and efficacy of bottom trawl prohibitions, as well as operational considerations related to management of closed areas.

3. Effects of scallop dredging on benthic communities
A research program is urgently needed to examine the effects of scallop dredging on the scallop's life history, population dynamics, and associated benthic community and habitat. A scallop dredge is a heavy fishing gear with maximum contact with the seafloor. Worldwide, scallop dredges have been implicated in negative, neutral, and positive effects on benthic animals and habitats depending on local environments. Typically, dredges catch only 5 to 35 percent of scallops in their path, so dredge paths are towed repeatedly during intense fishing seasons before vessels move to new fishing areas. In Alaska, the main target species, the weathervane scallop, overlaps in geographic distribution and habitat with a number of other important commercial species, including Tanner crabs whose stocks are depressed and/or overfished throughout Alaska. In Alaska, large areas of the coast are permanently closed to scallop dredging without evaluation of potential effects. We propose a multi-agency program with industry cooperation to study the biological and physical effects of scallop dredging in Alaska. A carefully planned research program was developed by internationally acclaimed scientists during a workshop sponsored by the ADF&G and University of Alaska in Kodiak, during June 10-12, 1999. A set of integrated field and laboratory projects will focus on process-oriented research directed at individual, population and community levels.

4. Effects of longline and pot gear on sensitive habitats
Considerable attention and some research has been directed at the effects of bottom trawling on benthic habitat. However, large scale fisheries that target crab, sablefish, rockfish, and Pacific cod use longline or pot gear. These gears can have an impact on certain sensitive habitat as evidenced by limited underwater observations. The actual capture of gorgonian and stony corals, as examples, has been verified by commercial fisheries observers and NOAA Fisheries surveys. Damage can be caused to corals, sponges, and some other sessile organisms by hooking, by crushing and plowing by pots and anchors, and from shearing by groundlines upon retrieval. On the other hand, a large proportion of this gear is set on soft substrate where effects are

considered negligible. Estimating cumulative effects for a variety of substrates and the behavior of gear in contact with the bottom are two topics that require study. These studies will involve underwater observation of longline and pot deployment and retrieval with remote and manned submersibles.

5. Effects of fishing on hard-bottom habitat of the Aleutian Islands
The narrow shelf areas of the Aleutian Islands, characterized by swift currents and very irregular terrain, support a very diverse and lush community of benthic organisms, including commercially important fish and shellfish. The taxonomy, life history and ecology of many of the invertebrate species are poorly known. Initial studies in the Aleutian Islands focused on the Seguam Pass area, where a trawl fishery for Atka mackerel has operated over the past two decades. This research identified six distinct bottom habitats and documented potential impacts from the historical trawl fishery. This study also considered potential recolonization of coral following trawl closures established to protect sea lion foraging areas. Additional work is needed to investigate impacts from other fisheries (e.g. cod, halibut, crab and rockfish) and gears types that occur in other key areas of the Aleutians. Because of limited habitat data, extreme tides and currents, and overall high biodiversity throughout the Aleutian Archipelago, research in the area is challenging. More exploratory studies will be the basis for development of specific research hypotheses that will emerge as more knowledge and experience is gained in the region.

6. Impacts of fishing on crab resources and habitat
Crab populations that support major commercial fisheries are perceived to be highly vulnerable to bottom trawling, given crab life cycles and behavioral patterns. Over the past 30 years, crab stocks have undergone significant fluctuations in abundance and currently are at very low levels. Juvenile crab, particularly juvenile king crab, are dependent on a variety of epibenthic organisms which are themselves vulnerable to bottom trawls. Also, large pods of juvenile king crab and female Tanner crab form during the mating season in very localized areas, and substantial numbers could be removed or injured if bottom trawling were to occur at these locations. Fishery management regulations for crab and groundfish have been directed at protecting the productivity of the crab resources in order to expedite their recovery. Large areas have been closed to bottom trawling and restrictive bycatch limits for crab have been imposed. However, because of interactions with other fisheries, effective use of these measures requires a clear understanding of factors affecting spatial/temporal patterns of crab distribution. In particular, podding behavior must be thoroughly investigated so that protective time and area closures can be accurately devised not only to reduce unintended mortality but also to minimize consequences for trawl fisheries. Similarly, research is needed to observe and document species associations that are critical to juvenile growth and survival. Furthermore, impacts of lost crab pots on EBS habitats must be investigated. In some years, tens of thousands of crab pots are lost due to rapidly moving ice flows. Derelict crab pots may alter habitat by adding hard structure to an otherwise flat and featureless soft bottom. Traditional dump sites for trawl-caught derelict pots would serve as natural laboratories for documenting effects on the benthos, and controlled laboratory and/or in-situ field studies would subsequently evaluate long-term impacts on productivity.

7. Effects of bottom trawling on shelf break and upper continental slope habitats
   Some of the highest density of bottom trawl effort occurs in the narrow zone that constitutes the upper continental slope and shelf break. This zone is a geologically unique area used by species of high commercial value such as sablefish, shortraker and rougheye rockfish, and Pacific ocean perch. Studies are needed to understand how bottom trawls affect the habitats that constitute this zone. These studies will focus on determining effects of bottom trawling in this zone and identification of habitat types that are sensitive to fishing-induced disturbance.

B. Linkage of fishing induced disturbance to population dynamics

1. Laboratory and field studies
   In instances where fishing gear has measurable effects on the seafloor, follow-up research is required to quantify the biological responses. Overall productivity could change as a result of gear-induced disturbances. Individual rates of growth, survival, settlement and reproduction could also be affected. Except in instances where change is inherently unacceptable, it is paramount to know whether these changes are positive or negative in nature. The ecological relationships in affected areas will be extremely complex. Variation in the responses of different taxa, life history stages and even individuals can be expected. Thus, only the dominant linkages will be understood or practical to investigate, at least initially. Controlled experiments over the range of observed impacts will be required. Specific hypotheses will be designed in laboratory and field settings as dictated by the needs for specific environmental conditions or variability, treatment groups, controls, and statistical replication. Experimental work will be conducted in seawater laboratories or *in-situ* at selected sites in the BSAI or GOA. These sites may require protection from further human disturbances throughout the experimental period.

2. Modeling
   An understanding of the natural processes of seabed disturbance (storms, erosion, deposition, bioturbation, landslides etc.) is required for comparison with the disturbance effects of fishing gear. Once disturbed naturally or with fishing gear, does the habitat return to the original undisturbed state or to some new equilibrium condition? Models of natural seabed sediment dynamics and seafloor geologic and biologic disturbance will be developed and applied to different physical and biological settings to allow comparison with fishing gear disturbance.

   Because potential management decisions are typically evaluated with respect to their effect on the population attributes (stock size, recruitment, etc.) of specific stocks, it is necessary to consider the linkage between fishing-induced disturbances and population dynamics. This process would minimally require information on the critical life history stages where substantial mortality takes place, the habitats associated with those critical life history stages, and how changes in habitat quality affect mortality rates and other vital population parameters. The field projects identified in the other parts of this initiative should provide the basic information to guide modeling efforts.

C. Mitigation related studies

1. Evaluation of mitigation measures and impacts with research closures
The MSA mandates the protection of EFH of the Nation's fishery resources. As the regulatory agency for federally managed fisheries, the NOAA Fisheries is particularly responsible for adverse effects to EFH due to fishing activities. As a result of that responsibility NOAA Fisheries is in the process of determining alternative measures to minimize to the extent practicable the adverse effects to EFH. Due to a considerable lack of available information, there is a great deal of uncertainty about the type and extent of measures that would actually be necessary or effective. The EFH Final Rule instructs that establishment of research closures be considered to evaluate the impacts of fishing activities. This research plan is an attempt to design and utilize research closures as a method to obtain information needed to protect habitat in a practicable manner. We will first provide a design to be implemented under baseline conditions, then attempt to modify the design as needed for the various minimization alternatives being considered.

The long-term goal of this research is to understand effects of fishing on habitat and validate whether adopted minimization measures are necessary and effective. Objectives are to determine whether fishing does or does not reduce or alter benthic habitat and whether such alterations effect the shelter, food, species composition, and ultimately the productivity, or MSY of important FMP species. Specific objectives of the research closures would be to compare, under contrasting (fished versus not fished) levels of fishing, information such as habitat condition, the abundance, composition, and size of habitat forming organisms, and possibly local abundance of fish and prey. These research closures are not expected to be able to demonstrate differences in stock productivity due to fishing impacts on habitat, but are a first step in seeing whether habitat features that provide shelter, prey, and other functions are altered.

2. Reducing fishing gear effects through gear modification
The modification of fishing gear has potential to substantially reduce seafloor effects. Fishing gear research has greatly improved both the effectiveness and the selectivity of fish harvests and similar success is likely if efforts are turned toward reducing seafloor effects. Some promising concepts are already apparent (i.e., fishing trawl doors off-bottom and using lighter groundgear) while others would emerge from focused research and development. Since gear effects are habitat-and community-specific, appropriate gear modifications are likely to vary between fisheries and locations. Failing to develop such options would exclude an entire class of mitigation possibilities.

A survey of fishing gears and the ecosystems where they operate will be examined for situations where modifications could have greatest effect. Development of seafloor-friendly gear will start by identifying which parts of the fishing gear generate adverse effects and what characteristics of those components can be changed to make those effects less severe. From this information, appropriate modifications will be developed and tested. Methods will be developed to quantify component-specific effects to allow measurement of the resulting improvements. Expected is that most improvements will involve some reduction in catch rates. Measuring such losses will also be a component of testing. To maximize the relevance and acceptance of the resulting gears, this project will be conducted in cooperation with the fishers and fishing gear designers.

II. Spatial Extent of Fishing-Induced Disturbance

A. Habitat evaluation in current FMP fisheries

Of urgent need is the examination of benthic habitat in the vicinity of major FMP bottom trawl fisheries. Currently, NOAA Fisheries is the defendant in a lawsuit that claims NOAA Fisheries violated EFH provisions in the MSA. The lawsuit expresses concern that "in the North Pacific, bottom trawling and other fishing activities harm EFH in various ways" and cite evidence that bottom trawls will damage benthic marine life, such as sponges and sea whips. The suit claims practicable measures to minimize adverse impacts were not adopted and proposes that NOAA Fisheries prepare assessments of measures that could be taken to protect EFH from fishing effects. As very little is actually known about the bottom habitat where major FMP bottom trawl fisheries currently occur, particularly in the GOA there is little information to assess the necessity and effectiveness of any measures that may be proposed. While a variety of measures, such as further area closures, can be proposed without any information, ideally measures should be chosen that have a high likelihood of being effective while retaining benefits of the fishery.

Observations of the Alaska seafloor have been made with manned submersible and Remote Observation Vehicles; however, these observations have covered only limited areas. Because the costs and logistic limitations of manned submersible observations necessary to survey the fishery area are prohibitive, the AFSC has been developing remote camera devices to lower costs and reduce the limitations. The initial phase of this study would sample current heavily-fished grounds to see where and to what extent different habitat types occur. Habitat types that are physically vulnerable to fishing may be of particular concern. Subsequent phases of the study would provide groundtruth information on habitat type to complement NOAA/U.S. Geological Survey (USGS) mapping efforts (see item 3, below). Later phases of the study would be to survey fishing grounds to evaluate any measures that may have been adopted to protect EFH.

B. Mapping of habitat features of major fishing grounds

Little of the continental shelf and slope of the Alaska EEZ has been adequately characterized. This project proposes to target limited areas of the Alaska EEZ for geomorphic/geologic mapping using state-of-the-art technology. These areas would correspond with areas most at risk to FMP fishing activities. NOAA Fisheries will determine the essential benthic ecological characteristics from ground truth surveys to allow useful habitat characterization and classification. Geological aspects will include assessing sediment dynamics to allow comparison of natural processes versus gear impact processes. High-resolution multi-beam systems that include coregistered calibrated backscatter are capable of mapping the continental shelf at spatial resolutions of less than 4 meters (m). The deeper water depths of the upper continental slope can now be mapped at spatial resolutions of ~8 m. Together, accurate, high-resolution bathymetry and backscatter provide quantitative insights into the geology and distribution of the surficial sediments and rock outcrops of benthic habitats. The bathymetry and calibrated backscatter can be combined with accurately georeferenced groundtruth sediment, biota and rock samples to predict the sediment types and habitats in zones where no groundtruth exists.

C. Retrospective analysis of seafloor geologic and biologic character

An analysis of existing data sets can improve current management practices and guide future field studies. These analyses consist of identification of the spatial/temporal occurrence of target fisheries (defined by species composition), and identification of species assemblages using cluster analysis. The data available for this analysis include those collected from NOAA Fisheries observer program and the NOAA Fisheries surveys. The identification of target fisheries builds upon the previous analyses of bottom trawl effort in Alaska and would be extended to include other gear types. This study will also provide large regional perspective and retrospective of the character of the shelf and upper slope sediments and outcrops based on existing geological and biological data collected by the USGS and others. The identification of fish/invertebrate assemblages provides key information that, when combined with geological characteristics, reveals which habitats have particular biological significance. In cooperation with the USGS maps and data bases summarizing the present adequate and inadequate state of knowledge of the seafloor off Alaska will be produced and maintained. These products would form the basis for extrapolating site specific (postage stamp) studies and for targeting priority areas for high resolution habitat mapping and groundtruthing.

D. Quantify abundance of habitat types over large geographic areas

Essential for both fisheries managers and researchers are estimates of the amount of specific habitats by management area. Interagency consultations and evaluation of management alternatives require this information in order to evaluate habitat effects of permitted actions. However, given the immense shelf and upper slope areas of the GOA and the Aleutian archipelago a long-term, multi-year study is required. High-resolution multi-beam systems can cover relatively large areas of the continental shelf (>20 kilometers^2 per hour), collecting georeferenced bathymetry and backscatter. The initial effort for this task will be to design an approach to improve the ability to quantify habitat abundance over large areas. High-resolution habitat studies over large geographic regions are currently difficult with today's technological and likely funding limitations. The project will involve extensive acoustic and video transects that can map depth, substrate type, and benthic organisms. Currently available mapping databases will be used where practicable. The project will also tie into projects that intensively map small areas of high priority, such as intensively fished grounds and dense coral and sponge habitats. From this project will come area estimates by habitat type, improved description of fish and shellfish habitats, and a general overlay of habitats throughout the GOA and Aleutian Island areas.

E. Characterization of benthic habitat in habitat areas of particular concern

Recently adopted amendments to FMPs in Alaska address areas of the marine environment that provide habitat necessary for completion of part or all of a managed species' life history cycle. EFH that is especially sensitive to human-induced impacts (such as fishing) may be further classified as a habitat area of particular concern (HAPC). HAPCs that have been identified, or are currently being proposed, in Alaska include living substrates in shallow or deep waters, seamounts or pinnacles, and the continental shelf break. All three habitat types are characterized by a high degree of biological productivity, and living substrates also provide areas of high microhabitat diversity. Deep-water corals have been classified as an HAPC. NOAA Fisheries trawl surveys have identified several sites in Alaska that may harbor colonies of deep-water gorgonian coral. Gorgonians such as red-tree coral (*Primnoa* sp.) colonies provide complex benthic habitat, and may be ancient and extremely slow growing. That, coupled with their arborescent nature, makes them highly susceptible to damage by commercial fishing activities. The goal of this study is to use geomorphic and geologic mapping tools along with a research submersible or towed video imaging system to survey particular locations that are being considered for protection as HAPCs by NPFMC. Investigators will initially assess abundance and distribution of red-tree and other gorgonian coral, identify fish and invertebrate species associated with the colonies, document evidence of damage (if any) to the colonies from human and non-human influences, and ascertain substrate morphology and composition in areas of coral abundance. Research in outlying years will focus on characterizing and linking physical and biological aspects of the seabed on seamounts/pinnacles, and along the continental shelf break.

5.1.2.8 Seabirds

The Draft Programmatic SEIS (NMFS 2001a, pp 4.3-1 and 4.3-50) and the Ecosystem Considerations for 2003 report (NPFMC 2002) have identified the major gaps in our knowledge of seabird ecology with respect to the groundfish fisheries and recommend the following:

- Compile existing data on diet, distribution, and abundance of seabirds into a common, accessible database.
- Initiate new research on seabird diets and foraging ecology, especially during the non-breeding seasons.
- Update population estimates for all seabird species.
- Improve knowledge about the distribution, abundance, and ecology of forage fish, especially with regard to management of predatory groundfish and climate change.
- Initiate studies to examine potential fishery impacts at the breeding colony level.
- Analyze Observer Program data to identify particular areas and time periods with the most adverse seabird/fishery interactions.

- Continue to improve collection of species-specific incidental take data through the Observer Program and collaborative efforts to develop and test effective take reduction measures in the longline and trawl fleets.

- Quantitative modeling of fishery impacts on selected seabird species at the population level.

- Examine role of fishery discards and offal in seabird reproduction and survival as a function of the spatial/temporal distribution of fishing efforts.

- Employ new research techniques (i.e. satellite telemetry) to examine at-sea distributions of sensitive species like short-tailed albatross.

Many of these efforts are underway but will require long-term commitments of resources and patience on the part of administrators and the public before scientists can reach meaningful conclusions.

For the purposes of analyzing regional population trends, adequate data exists for only a few species of seabirds that breed in Alaska, notably black-legged kittiwakes, red-legged kittiwakes, common murres, and thick-billed murres. More limited population and reproductive data is available for several other species (Dragoo *et al.* 2001). Unless U.S. Fish and Wildlife Service (USFWS) receives substantial increases in their future research budgets, the murres and kittiwakes will most likely continue to be the most useful species for fishery impact assessments. Population trends for the three albatross species can also be monitored fairly accurately because of their limited number of tropical breeding colonies, although assumptions must be made regarding the number of non-breeders that do not return to the colonies every year. The albatross species in the BSAI/GOA traverse huge distances and are impacted by many different kinds of human activities across international boundaries. Their frequent interactions with the groundfish fisheries and the important management implications of the ESA necessitate ongoing cooperation with other regional and international conservation agencies and institutions.

In addition to basic reproduction and population trend data, fishery impact assessment also requires an explanation of the mechanism(s) of action. For species that are thought to be impacted primarily through direct fishery-related mortality, such as the albatross species, population modeling can be combined with measurements of incidental take in the fisheries to calculate the degree of population impact (Cousins and Cooper 2000). The accuracy and completeness of incidental take levels should continue to be monitored by independent observers and tracked over time as new seabird avoidance techniques are introduced. Several other factors that influence seabird incidental take, such as overall nutritional state of the birds and seasonal distribution of fishing effort, should be monitored as well so that the effectiveness of the new avoidance techniques can be assessed with less uncertainty. For species thought to be affected primarily through fishery-induced changes in food availability, quantitative changes in prey availability (which includes elements of prey abundance, schooling behavior, and the "patchiness" of distribution) are much more difficult to measure. The complexity of the issue may be best addressed by trying to measure and compare the physiological state of birds in areas that are fished versus areas that are not fished. While traditional studies of this nature require the collection of birds for stomach and tissue samples, newer serological methods only require live capture and drawing blood samples (Piatt *et al.* 1998, Suryan *et al.* 1998a, Suryan *et al.* 1998b, Suryan *et al.* 2000).

The key to this kind of comparative analysis is finding suitable study areas for comparison. The establishment of no-fishing reserves around selected breeding colonies would greatly facilitate such studies. Comparative studies of this nature could be conducted for both fish-eating and plankton-eating seabird species. Ideally, nutritional studies would be conducted in conjunction with reproductive and population trend studies in order to link the impact mechanism with the potential effect. While it would not eliminate all uncertainty about potential impacts, a system of research reserves offers some hope of scientifically deciphering the ecosystem complexities of marine life. It is important to note that no-fishing reserves that were within 3 nautical miles of shore would have to be established in conjunction with the State of Alaska. The effect of a federal reserve would obviously be nullified if state-managed fisheries were allowed to continue inside a no-take reserve boundary. This would be especially important if the no-fishing reserve encompassed a seabird breeding colony.

Several concerns have been raised about the Observer Program incidental take data, including the large number of birds that are reported under "unidentified" or group categories rather than individual species and the large variability in take estimates within and between years (public comments on Draft Programmatic SEIS, CAR 2001). The Observer Program is addressing some of these issues with improvements in field identification methods based on feet and bills, improvements in sampling design and data collection protocols, and improvements in observer seabird training programs. However, there will always be unidentifiable bird remains and there is some value in combining rarely taken species into groups for reporting and analysis purposes. The quality and quantity of seabird data coming out of the Observer Program is largely a function of how much emphasis is placed on collecting seabird data versus other kinds of fishery data. Some of the Alternatives in this PSEIS give the collection of seabird data a higher priority than others. For some types of seabird/fishery interaction data, it may be necessary to have dedicated seabird observers on a subset of vessels that already have fishery observers. These seabird observers would not have fish sampling duties and could collect other types of data not normally collected in the Observer Program. The development of video monitoring techniques may also be useful in this effort, especially on smaller boats that did not carry observers. Of course, the potential value of this data will need to be balanced by the cost of acquiring it.

One concern has been that observers were not accounting for birds that are hooked on longlines as they were deployed but fell off before they were retrieved on board. One study from Australia (Gales *et al.* 1998) indicated that 30 to 95 percent of the birds coming out of the water fell off or were shaken off the gangions before being hauled aboard and were thus missed by observers. However, that study was based on an observer program that did not actively watch the groundline as it was retrieved. In the North Pacific Groundfish Observer Program, observers actually watch the groundline as it is retrieved and do tally birds that fall off before being retrieved on board. This accounts for some of the "unidentified seabird" data. The question of how many birds are hooked as a line is deployed but fall off while the groundline is underwater is an issue that could perhaps be addressed by a series of experiments. These experiments could use birds already taken in the fishery or taken for other scientific purposes. The known numbers of seabirds placed on the line would then be compared to the number retrieved after the line soaked under normal fishing conditions. Such experiments may improve estimates of how many birds are actually taken in the fisheries. An alternative might be to use underwater video cameras to observe the longlines as they are being deployed. This technology is currently being developed to study the impacts of pelagic trawls (Kim Rivera, NOAA Fisheries seabird coordinator, personal communication) but it would probably require substantial research and development for longline applications. Again, the cost of developing this technology may be disproportionate to the value of the data, especially if new avoidance measures dramatically reduce incidental take on longlines.

Concerns for fishery impacts range from population level effects to local breeding colony effects. As a practical matter, population modeling efforts have been limited to those species most frequently taken incidentally in the longline fisheries (northern fulmars) and to species of special concern (the three albatross species). Even though most other species are not monitored closely enough to determine if impacts are occurring on a population level, recent survey trends have raised interest in trying to model possible colony-level impacts on species that breed near intensive fishing efforts. Considering the proximity of major trawl and longline fishing efforts around the seabird colonies of the Pribilof Islands, it seems that this would be an appropriate region to model potential impacts on diving species such as the murres and on surface-feeding species such as the kittiwakes. While the murres are taken incidentally in trawls, a potentially larger impact may take place through fishery-induced changes in predator-prey relationships and other food web interactions with forage fish and important invertebrate prey. This localized impact model would thus be part of and integrated with a larger ecosystem modeling effort called for in some Alternatives.

Many questions need to be addressed regarding how seabirds would factor into an ecosystem model. Recent work by Hunt *et al.* (2000) has attempted to quantify some of the prey consumption parameters for seabirds and marine mammals in the North Pacific. While such broad analyses are valuable for overall energy and mass flow estimates, more localized measurements and assumptions about seabird numbers, seasonal distribution, and diet will be needed for a mathematical model to reflect the dynamics that are important to seabird survival and reproduction. The impact of seabird foraging on prey species, especially around breeding colonies, would also be an important element in any modeling effort.

The ecosystem model would have practical applications in the Alternative 4 policy which requires the fishery management system to incorporate indices of “ecosystem health” in allocation decisions. The question of what these indices might be for seabirds deserves careful consideration. One candidate for a measurable index is the population densities of selected “indicator” species. There are two challenges with this approach. First, state-of-the-art seabird censussing techniques are still not very precise so there will always be a substantial amount of scientific uncertainty regarding population levels, especially over large areas. Second, populations of animals are never static, even in the absence of humans, so a certain amount of fluctuation should be seen as acceptable or even desirable in a “healthy ecosystem”.

Decisions will have to be made about how much change in an index is acceptable and at what point management should respond. One option is to develop different “levels of concern” based on the direction and amount of change over time, similar to the International Union for Conservation of Nature and Natural Resources’ “red list” ranking system for species, defined but for regions as biologically important to the fishery rather than global population. In any case, even if a set of ecosystem “warning signs” can be developed, the underlying mechanisms of change must be determined before appropriate mitigation can be taken. It must be acknowledged that there may be issues that NPFMC or NOAA Fisheries may not be able to address with changes to the fishery management system. For example, if the population of a seabird indicator species begins to decline because of persistent pesticide pollution from agricultural runoff in Asia, NPFMC will not be able to correct the situation by changing groundfish allocations.

Every impact analysis depends to some degree on knowledge about the distribution and abundance of seabird species in the BSAI/GOA, especially in areas away from breeding colonies and during the non-breeding season when most direct interactions with the fisheries occur. While a great deal of data has been collected over the years, much of it was collected in the 1970s and 1980s (Outer Continental Shelf Environmental Assessment Program) and is not readily accessible because it is stored in various places and formats. The USGS/Biological Resource Division, in cooperation with NOAA Fisheries, USFWS, and the Minerals Management Service, has recently begun compiling this information into a standardized database format that will eventually be available to the public. Preliminary results from this North Pacific Pelagic Seabird Database have been used to analyze the degree of distributional overlap between selected species and different groundfish fisheries in the Ecosystem Considerations for 2003 report (NPFMC 2002). This report contains several maps that are good examples of how graphic information system technology can be used to facilitate understanding and analysis of seabird/fishery interactions. However, the basic abundance and distribution data for all seabird species needs to be updated for these efforts to be most useful.

5.1.2.9 Marine Mammals

To unequivocally assess the effects of groundfish fisheries on marine mammal populations, definitions of marine mammal population parameters are needed to measure the intensity and direction of the effects. Population parameters and metrics needed include: current population size (n), population trajectory, definition of carrying capacity (K) and/or optimal population size for each species/stock.

To assess the effects of groundfish fishery harvests on the marine mammal prey field the following information is needed: marine mammal energetic requirements; contribution of each prey species to energetic requirements (proportion in diet); adequacy of existing standing biomass of prey (current K for each marine mammal population); standing biomass of prey before and after fishery; and point at which vital rates/K are affected due to food limitation. Currently, this level of information is not available. Some of these issues are under investigation through various research programs; the answers to some of these questions may never be known.

Research is needed to examine methods for quantifying fishery linked (i.e., human) disturbance on marine mammal populations. Specific examples include: rate at which various gear types are lost or discarded which present risk of entanglement; effects of disturbance on baleen whales caused by vessel traffic, fishing operations, or sound production.

Identification of Species Specific Research Needs :

Spotted Seals: Importance of EBS & Aleutian Islands pollock in the diet of spotted seals (diet information in Bristol Bay, Pribilof Islands, and eastern Aleutian Islands).

Elephant Seals: Research is needed into the diet of elephant seals in the GOA.

Killer Whales: Research is warranted to examine the consumption of groundfish by killer whales in the GOA and BSAI.

Steller Sea Lions: NOAA Fisheries has identified the following potential causes of the decline of Steller sea lions: nutritional stress related to competition with fisheries for prey or climate-related changes in prey distribution, abundance or quality; predation by killer whales; disease; contaminants; and other human-related direct mortality (e.g., illegal shooting, incidental takes in fisheries, subsistence hunting).

The largest information gaps in understanding what has caused the decline of Steller sea lions or preventing their recovery are in the area of nutritional stress. In particular, they involve the following issues: measuring nutritional stress in a random sample of the population; determining prey and prey field requirements to sustain healthy individual sea lions; understanding sea lion use of habitat and how this changes with age and season; discerning natural from fishery-induced changes in the prey field.

Research programs have been developed by NOAA Fisheries and our research collaborators in the North Pacific to address these gaps and others related to the remaining potential causes of the decline. This research, however, will not obtain answers quickly, and some questions, particularly regarding causes of the decline observed decades ago, may never be answered. The priorities for NOAA Fisheries AFSCs FY03 Steller sea lion research program are:

- Steller sea lion foraging and marine habitat use (particularly by older juveniles).
- Steller sea lion vital rate determination (survival, fecundity).
- Steller sea lion enumeration (pup counts).
- Steller sea lion diet studies.
- fishery effects on prey populations.
- killer whale assessment and trophic ecology.
- the role of climate change and oceanographic processes in prey distributions.
- development of forage fish assessment techniques.
- assessment of the effects of contaminants and disease.

While little evidence currently exists to suggest that contaminants and disease are contributing to the lack of recovery, there are research programs whose objective is to continue investigating their potential impact on the population. With regard to illegal shooting, however, there are virtually no data on which to base any estimate of mortality, and no programs currently in place to obtain them.

5.1.2.10 Socioeconomic

- Compile information on catch by area and catch per unit effort by area in order to more fully ascertain the effects of closing areas on the temporal and spatial distribution of the groundfish fisheries. This data would be most accurately and efficiently collected from catcher vessels and processors using electronic log books.

- Conduct historical analyses and develop models to explain and predict fishermen's responses to temporal and spatial closures.

- Collect and analyze information to provide a more accurate account of local and regional employment patterns in the harvesting and processing sectors of the groundfish fisheries.

- Perform post-implementation studies of management actions, such as closures. Collect and analyze economic and socio-cultural data to determine whether changes in the human environment were a result of management actions or caused by external factors.

- Conduct additional research to determine the non-market value of Bering Sea and GOA marine ecosystems using appropriate economic methodologies.

- Extend mandatory economic data reporting requirements to the groundfish fisheries, including reporting of fixed and variable cost data, as well as vessel and processors ownership information. Such mandatory economic data will be collected in accordance with confidentiality standards.

- Regularly update the sector and regional profiles, to examine changes over time, including post-action effects of different management regimes.

5.1.2.11 Ecosystem

The probability of introduction of non-native species through ballast water exchange from fishing vessels coming from areas where invasions have already occurred has been identified as a serious threat in the State of Alaska's Aquatic Nuisance Species Management Plan. This plan identifies the need for Alaska to develop mandatory ballast-water exchange laws.

Measures of diversity are subject to bias and we do not know how much change in diversity is acceptable (Murawski 2000). More research is needed to derive meaningful ecosystem indicators of change, including those related to diversity. Particularly, it is important to understand the natural range of variability in diversity measures and determine whether there are diversity thresholds that are important determinants of ecosystem function. It is important to conduct species-level work such as determining life history parameters and abundance of target and non-target species to ensure that species level diversity is being protected. Since we are unable to study every organism in sufficient detail, a system of prioritizing research on species should be devised that takes bycatch amounts in fisheries and sensitive life history characteristics into account in the research prioritization.

The lack of population level assessments for some of the species in the forage species group means that species level effects on those species are unknown. Better understanding of the factors influencing forage species dynamics and spatial/temporal distribution will help us better separate the role of climate and fishing in influencing the dynamics of these species.

More research is required to evaluate whether the amounts of pollock removed are having a population-level effect on the fur seals. Ongoing research is needed to quantify predator needs of mammals, birds, and other predators in space and time would improve our ability to evaluate the effects of fishing removals of prey.

Understanding the role of climate variability in species and ecosystem level production changes is needed. See NOAA Climate and Productivity Initiative for FY2005 and the ongoing NOAA Fisheries *Fisheries and the Environment* research plan for some details on this.

The effect of shark bycatch on shark populations reaching MSST is unknown at present and research directed at better assessment of population levels of these sensitive (late maturing, low fecundity, low natural mortality) species is needed to determine the potential for groundfish fisheries to impact these populations.

Further examination of the potential for fishery removals to induce changes in system level characteristics should be examined using ecosystem models of the BSAI and GOA. These system level characteristics are very difficult to assess outside of a modeling framework but more field research on predator/prey interactions and predator functional responses would improve the predictions of ecosystem and multi-species models. Evaluations of system maturity from these models rely heavily on our assumptions about primary productivity and benthic infauna biomass, two aspects of marine production that are not well studied in the BSAI and GOA baseline.

Some of the species in this forage group are not well studied (such as stichaeids and gunnels) and life history parameter determinations should be a priority in the future to better assess the risk of falling below acceptable population thresholds of abundance.

Many years of survey data and life history parameter determinations for skates, sharks and grenadier species may better define population trends and whether further protection might be warranted.

Members of the HAPC biota guild serve important functional roles in providing fish and invertebrates structural habitat and refuge from predation that are not well studied. The abundance of these structural species necessary to provide protection is not well known and it may be important to retain populations of these organisms that are well-distributed spatially in order to fulfill their functional role. Better understanding of the life history characteristics, distribution, and functional roles of these organisms is needed to better protect their role in the ecosystem.

Genetic diversity has not been well assessed in the baseline, more genetic work on target species that may have more localized spawning concentrations would be important.

Relative to Alternative 2: If a target fishery were to develop on forage species such as capelin, there is potential for the combined effects of fishing on many forage species to affect predators. However, the amounts of forage needed by predators is uncertain. More research is needed to determine predator forage needs and level of forage biomass necessary for successful foraging.

The amount of seabird mortality induced by trawl third wires is not well-known and requires further study.

Relative to Alternative 3: More research on developing ecosystem indicators; enhancing collection of data on climate, ecosystem production, and predator/prey interactions; defining predators needs; and defining the role of climate variability in population fluctuations are needed in order to adopt and use ecosystem-indicators in a total allowable catch (TAC)-setting, and for using ecosystem considerations in setting biological reference points. See the NOAA FY2003 Climate and Productivity Initiative and the Stock Assessment Improvement Plan for details on some of the research that might be required.

Relative to Alternative 4: A substantial research program would need to be initiated to determine foraging needs of dependent species; life history parameters, genetics and abundance and distribution of species proposed for target fisheries. Fishery bycatch of nontarget species and gear effects on habitat would also be evaluated before a fishery could be opened. Natural levels of ecosystem variability and the influence of climate on ecosystem production would also need to be determined.

5.2 Management and Enforcement

This section begins with a discussion of management and enforcement considerations in the groundfish fisheries (see Section 5.2.1), and the factors influencing management complexity (see Section 5.2.2). Section 5.2.3 provides the basis for comparing the alternatives under discussion in this Programmatic SEIS. The effects of the alternatives, including the preferred alternative, on management and enforcement are analyzed for each alternative in Sections 5.2.4-5.2.8. The comparative effects of the alternatives are summarized in Section 5.2.9.

5.2.1 Management and Enforcement Considerations

This section provides information about the effects of the alternatives on management and enforcement for the groundfish fisheries off Alaska. For this discussion, management and enforcement responsibilities include the following:

- Data collection, research, and analysis to prepare annual stock assessments.
- The annual groundfish specifications process through which TAC limits and prohibited species catch (PSC) limits are established.
- The ongoing process of amending the FMPs and regulations to implement fishery management measures recommended by NPFMC or NOAA Fisheries.
- Monitoring of commercial fishing activities to estimate the total catch of each species and to ensure compliance with fishery laws and regulations.
- Actions to close commercial fisheries once catch limits have been reached.
- Actions taken by NOAA Fisheries Enforcement, the U.S. Coast Guard (USCG), and NOAA General Counsel to identify, educate, and, in some cases, penalize people who violate the laws and regulations governing the groundfish fisheries.

Management of the groundfish fisheries in the BSAI and GOA and enforcement of management measures governing those fisheries comprise a complex system for overseeing fisheries that range geographically over an extensive area of the North Pacific Ocean and Bering Sea. Management of these fisheries is more fully described in Appendix B.

NOAA Fisheries manages the fisheries off Alaska based on TAC amounts for target species and PSC amounts for species that may not be retained. The TAC and PSC amounts are further subdivided by gear type, area, and season. As the complexity of the management regime has grown, the number of TAC and PSC subdivisions has grown as well. For example, in 1995 for the BSAI there were 40 TAC allocations, 38 PSC allocations and two CDQ allocations. In 2003 for the BSAI, there were 152 TAC allocations, 78 PSC allocations, and 34 CDQ allocations. Each allocation represents a possible need for NOAA Fisheries to take management actions, such as closing fisheries, reallocating incidental catch amounts, or investigating overages. When a directed fishery in one area is closed, the boats that participated in the fishery often move to another area or change to another target. This, in turn, often leads to the need for additional management actions.

Though the number of allocations has increased, the quantity of fish available for these allocations has not, and NOAA Fisheries is required to manage increasingly smaller blocks of fish. To do this adequately requires the use of increasingly sophisticated catch-monitoring tools, such as observer coverage, electronic reporting, vessel monitoring systems (VMS), and the use of at-sea scales. Though these tools increase the quantity, quality, and timeliness of the data available to NOAA Fisheries management, they also increase the demands on staff to effectively make use of a larger and more complex data system.

Current fishery management recognizes that a meaningful enforcement program must accompany management measures for them to be effective. As management becomes more complex, the difficulty of adequately enforcing the regulations grows. As the size and complexity of the regulatory environment increases, the burden on enforcement personnel to fully understand the nuances and implications of regulations increases as well. NOAA Fisheries/Alaska Region enforcement maintains approximately 36 agents and officers stationed in nine Alaskan ports for monitoring groundfish landings: Juneau, Anchorage, Dutch Harbor, Homer, Ketchikan, Kodiak, Petersburg, Seward, and Sitka. In addition, enforcement personnel regularly travel to other Alaskan ports to monitor landings and conduct investigations. Enforcement personnel associated with NOAA Fisheries, Northwest Region assist in the monitoring of Alaska Region groundfish harvest, primarily individual fishing quota (IFQ) sablefish, landed at ports in the Northwest Region. Also, USCG personnel conduct enforcement activities, monitor vessel activity, conduct at-sea boardings and aircraft overflights, and assist NOAA Fisheries enforcement personnel in monitoring dockside landings.

A key component of management and enforcement is education and outreach. Complex management programs are accompanied by a regulatory structure that can be difficult for the fishing industry to understand and comply with. This is exacerbated when regulations change rapidly. When fishermen believe that regulations are unduly burdensome or unnecessary, they are less likely to comply voluntarily. Thus, successful implementation of the regulations is dependent on outreach programs that explain the goal of regulations and why they are necessary. NOAA Fisheries Management, NOAA Fisheries Enforcement, and the USCG all conduct extensive outreach and education programs that seek not only to explain the regulations, but to help the fishing industry understand the rationale for those regulations.

5.2.2 Factors Influencing Management Complexity

Complexity of Quota Management

Annual groundfish TAC amounts and PSC limits are either established in regulations or through the annual groundfish specification process (described in further detail in the TAC-setting Process paper, in Appendix F-1). These area-specific TACs may be further apportioned by harvesting or processing sector, season, gear, or vessel size class.

NOAA Fisheries initially estimates how much of each groundfish species will be caught as incidental catch in other directed groundfish fisheries throughout the year. The amount available as a directed fishing allowance is determined by subtracting the estimated incidental catch needs from the total amount available for the species or species group. For some species, such as rockfish, NOAA Fisheries usually determines that the entire TAC will be needed as incidental catch and no directed fishery will be allowed. These species are closed to directed fishing at the beginning of the year through a notice in the Federal Register (FR). For other species, sufficient TAC exists to authorize directed fisheries in most management areas.

NOAA Fisheries must conduct real-time monitoring of the catch of groundfish to predict when a catch limit will be reached and close the directed fishery before the directed fishing allowance is exceeded. Closure notices must be published in the FR, which requires NOAA Fisheries to decide on a closure date from one to five days before the closure must be effective. The office of the FR is closed on weekends and Federal holidays. The requirement to publish closures in the FR is an important reason why NOAA Fisheries is limited in how quickly it can assess catch data and close a fishery. In-season closure notices are not required for individual quota programs such as the halibut and sablefish IFQ Program or the CDQ fisheries, because individual quota holders are responsible for maintaining catch within assigned quota limits.

In general three types of closures are triggered by in-season actions. The first is a target species quota closure issued when a TAC, or apportionment of a TAC, is harvested. The second is a prohibited species closure in which vessels participating in a fishery approach a prohibited species bycatch allowance before harvesting all of the groundfish species available to them. The third is closure of a target species fishery when the catch of an incidentally caught species approaches its overfishing limit.

Under the current in-season management system, a species is either open, or on bycatch or prohibited status at any given point in time. When a species is open, vessels are allowed to target and retain it with no restrictions on the amount harvested. Once a particular species TAC or prohibited species bycatch allowance specified for a fishery has been reached, NOAA Fisheries closes the directed fishery for that species. Vessel operators are then limited in the amount of the species closed to directed fishing that they may retain. If the harvest of a given species goes beyond the TAC and approaches the ABC, NOAA Fisheries will prohibit retention of that species for the remainder of the year.

NOAA Fisheries uses information from a variety of sources to determine how much groundfish and prohibited species are caught in the groundfish fisheries. This information is used to determine when to close a directed fishery so that the groundfish or PSC limit will not be exceeded. In general, data submitted by both observers and by at-sea and shoreside processors are used to accrue catch against a quota. The non-CDQ fisheries generally are managed through the blend, which combines information from observers on vessels and information submitted by processors in a weekly production report to determine the best estimate of catch for each processor and week. In some cases, NOAA Fisheries requires more timely submission of catch data. For example, AFA shoreside processors are required to submit pollock landings data daily through the electronic shoreside logbook. For fisheries with small quotas or those rapidly approaching a catch limit, in-season managers also rely on daily catch data and anecdotal information from the industry to decide when closures should occur.

Any increase in the number of quota categories that must be monitored and closed on time increases the complexity of the fisheries management system. The difficulty of accurately determining when a quota will be reached and when to close a fishery increases as the number of quota categories increases and the amount of quota available in each category decreases.

Complexity of Area Boundaries

Enforcement of regulations that close specific areas to vessel activity is the responsibility of the USCG and NOAA Fisheries Enforcement. Enforcement of closed area regulations is more difficult and time consuming as the complexity of the area boundaries increase. Large, rectangular areas, such as NOAA Fisheries 3-digit reporting areas in the BSAI and GOA (e.g., 518, 541, 620, see Figures 1.2-2 and 1.2-3) are less complex to monitor from aircraft, vessels, or through VMS (see NMFS 2001b [Steller sea lion SEIS Section 4.11.3] for a more detailed description of a VMS) than are concentric circles around a point, particularly if these circular closures overlap each other. Complex area closures are more difficult to monitor and enforce than simple area closures for a number of reasons. It is more difficult to accurately communicate complex area boundaries to those being regulated and to agency personnel, as is apparent from the numerous revisions that have been made to tables, maps, and regulations as the complexity of the Steller sea lion area closures has increased in recent years. In addition, although computer and satellite technology is sophisticated enough to accurately determine the location of a vessel relative to almost any area boundary, the sheer number of closed areas and the complex, irregular boundaries require enforcement personnel to check vessel positions and activities relative to closed area boundaries more frequently, which could reduce the number of vessels or areas that can be monitored during a flight or vessel cruise.

Increasing Number and Complexity of Directed Fishing Closures

Increasing the number of directed fishing closures and the complexity of the boundaries of the closed areas complicates enforcement. The catch accounting system developed by NOAA Fisheries, and described in detail in Appendix B, was designed to collect the best available data to estimate total catch (retained and discarded) from all vessels fishing for groundfish. The catch accounting system was not designed to determine which directed fishery a vessel is participating in for areas smaller than a federal reporting area, or whether the vessel was complying with maximum retainable amounts in that smaller area.

When an area is closed to directed fishing by vessels using a particular gear type, fishing can continue in the area by vessels using other gear types or by vessels directed fishing for species other than the closed species. To determine whether a vessel is fishing legally in an area, the composition of retained catch *from that area at any time during a fishing trip* must be assessed to determine whether any applicable maximum retainable amounts have been exceeded. Making this determination while a vessel is at sea is difficult for catcher processors and nearly impossible for catcher vessels.

For catcher processors, the report of processed product in the daily catch and production logbook is assessed to check compliance with maximum retainable amounts. However, to accurately check compliance with maximum retainable amounts, catch from areas with different directed fishing status must be recorded separately in the logbook. For example, assume that directed fishing is closed in a sub-area of a larger NOAA Fisheries management area, but is open elsewhere in the management area. This means that catch of the closed species up to the maximum retainable amount could be retained inside the closed area, but all catch of the species could be retained outside the closed area. If a vessel caught fish both inside and outside the closed area in a particular day, it is not possible to assess whether they complied with maximum retainable bycatch amounts inside the closed area unless they kept records of catch made inside the closed area separate from catch made outside the closed area. Current logbook formats require catcher processors to report catch by a variety of factors that relate to different directed fishing closures and maximum retainable amounts (day, gear, management program), reporting area (3-digit area codes), and two special areas for managing crab bycatch. However, catcher processors are not required to report catch separately in their logbooks, for example, inside and outside Steller sea lion critical habitat or specific Steller sea lion management areas where different directed fishing closures could occur for pollock, Pacific cod, Atka mackerel. The format of the catcher processor and mothership logbooks need to be revised to keep up with area-specific directed fishing closures.

It is nearly impossible to check compliance with maximum retainable amounts for catcher vessels at-sea. The weight of each species onboard a catcher vessel cannot be reliably determined until the catch is removed from the vessel, sorted by species, and weighed. If a catcher vessel delivers catch from areas with different directed fishing closures, it is impossible to verify at the time of delivery how much catch came from each area that the vessel fished. If accurate accounting of the location of catch and compliance with maximum retainable amounts by unobserved catcher vessels is required, the following options should be considered: 1) require offload of catch from specific areas before continuing to fish in areas with different directed fishing closures (different maximum retainable amounts); 2) apply the most restrictive maximum retainable amounts to the entire catch at the time of delivery (even though the vessel may have caught some fish in areas with less restrictive maximum retainable amounts); 3) use a VMS to determine if the vessel fished inside special management areas at any time during the trip and, if so, apply the most restrictive maximum retainable amounts to the entire delivery, or 4) require observers to monitor catch for vessels fishing in areas with different directed fishing closures. VMS on unobserved vessels is of limited value in determining what directed fishery a vessel was in, what proportion of the catch came from closed areas, or whether the vessel complied with maximum retainable amounts. VMS provides location data, but it does not provide data about total catch or catch composition.

5.2.3 Basis for Comparing the Effects of the Alternative

The alternatives provide policy goals and objectives for fishery management that will be implemented by measures that fall within the range provided in the analytical framework (see Section 4.2). Most of these management measures are already used in some form under the current regime, including catch limits to control the amount of a species harvested in the commercial fisheries; prohibition of commercial fisheries in certain areas or during certain times of the year; regulations that limit or define the type of fishing gear that may be used or the manner in which the fishing gear may be used; and rights-based fishing systems. Table 5.2-1 summarizes how the specific management measures change over the alternatives.

Six categories of management measures will be used to assess the significance of the alternatives in their effect on management and enforcement complexity (relative to the baseline condition described in Section 4.4). The six management measure categories are as follows:

- Managing harvest within specified catch limits (TAC & PSC).
- Monitoring and enforcing compliance with area closures (including seasonal, gear, directed fishery).
- Monitoring and enforcing compliance with bycatch (discard) reduction standards.
- Managing and enforcing gear modifications requirements and gear restrictions.

- Management complexity due to rights-based management programs.
- Managing observer programs and data collection.

5.2.4 Alternative 1

Alternative 1 continues the management of the groundfish fisheries based upon the present risk-averse policy. The guideline for implementing this policy is the current (2002) BSAI and GOA FMPs as amended, and the 2002 regulatory environment. Management measures that were approved by NPFMC through the June 2002 meeting are also assumed to be incorporated in this implementing guideline.

The Alternative 1 management measures differ from the baseline only with respect to those measures that were only approved but not yet fully implemented at the 2002 cut-off date. These include full retention for demersal shelf rockfish (DSR) in southeast Outside for the hook-and-line and jig fisheries, and the seabird avoidance measures approved by NPFMC in December 2001 but not yet implemented.

Monitoring and Enforcing Compliance with Bycatch (Discard) Reduction Standards

The DSR retention management measures applies only to fixed gear fisheries in the southeast Outside District of the eastern GOA. The implementation of the retention standard will be managed by the State of Alaska, and is thus unlikely to cause a significant increase in management complexity to NOAA Fisheries managers.

Managing and Enforcing Gear Modifications Requirements and Gear Restrictions

The seabird avoidance measures approved by NPFMC in 2001 require staff time for writing regulations and preparing training material to educate fishers as to the nature of the additional measures. The additional seabird avoidance measures were initiated at the request of the longline industry, to reduce the risk of a premature closure of the fishery due to short-tailed albatross interaction. Proven incentives for industry to adopt the avoidance measures should allow enforcement within existing enforcement activities.

Summary

As compared to the baseline suite of management and enforcement measures, Alternative 1 may result in some additional time to monitor and enforce DSR retention and the use of seabird avoidance methods. However, because of their localized effects, it seems unlikely that these efforts will result in an overall increase in the complexity of management and enforcement.

5.2.5 Alternative 2

Alternative 2 represents a more aggressive harvest strategy that would be implemented based upon the assumption that the present policy is overly conservative and that higher harvests can be taken without overfishing the target groundfish stocks. Alternative 2 would be implemented through management measures that fall within the range of two example FMP bookends (see Section 4.2). Both bookends 1) increase the BSAI harvest by redefining the cap on optimum yield; 2) repeal bycatch and incidental catch restrictions, with the exception of PSC limits; and 3) repeal the 2001 gear modifications for hook-and-line gear intended to decrease interactions with seabirds.

FMP 2.1 also contains additional changes to existing management measures, including eliminating PSC limits, repealing all closure areas and gear restrictions save those required to avoid jeopardy or adverse modification under the ESA, repealing the Improved Retention/Improved Utilization (IR/IU) standard, eliminating all non-AFA rights-based management, repealing the Observer Program, and rescinding monitoring through VMS devices.

Managing Harvest Within Specified Catch Limits (TAC & PSC)

Although both Alternative 2 bookends would result in an increase in the BSAI groundfish quota, they differ in the way they redefine the optimum yield cap. FMP 2.1 defines the optimum yield cap as the sum the OFLs of the managed species or species complexes, and sets the ABC level equal to OFL. This removes the buffer between ABC and OFL that exists under the current system. FMP 2.2 sets the optimum yield cap equal to the sum of ABCs, which still would result in a substantial decrease in the buffer between ABC and OFL in the BSAI. (For background information about TAC, ABC, OFL and optimum yield, see the TAC-setting Process paper in Appendix F-1.)

The current management system provides a buffer between TAC/ABC and OFL for many species, as NOAA Fisheries is required to take management action to prevent further catch of that species if the catch of any species reaches its OFL. This may mean closing other directed fisheries in which that species might be taken as incidental catch. Fishery managers try to limit the catch of a particular species in directed fisheries and as incidental catch to less than the TAC. However, if TAC is exceeded by small amounts, the OFL generally is not reached due to the buffer. Under Alternative 2, the consequences of reaching the catch limit may be the same as the consequences of reaching OFL. Therefore, NOAA Fisheries managers would need to be more conservative in their management of the directed fisheries and incidental catch to ensure that a TAC was not exceeded. Alternative 2 likely would lead to earlier fishery closures to protect certain species from reaching OFL. It is also likely that more directed fisheries would be curtailed because an incidentally-caught species had reached OFL than occurs under the existing management system.

Repealing the Observer Program except for AFA monitoring requirements, and lifting bycatch and incidental catch restrictions under FMP 2.1, would increase the need to manage conservatively. The data used to monitor catch limits would be less reliable, and directed species quotas would need to take into account the level of incidental catch that would likely be taken in other fisheries. As above, this would potentially result in earlier fishery closures. FMP 2.1 also eliminates all PSC limits, however, which would decrease management complexity by removing an entire category of catch limits that currently need to be monitored by NOAA Fisheries.

Monitoring and Enforcing Compliance with Area Closures (Including Seasonal, Gear, Directed Fishery)

Although FMP 2.2 does not change the existing area closures, FMP 2.1 eliminates all closure areas except those that are required to avoid jeopardy or adverse modification to Steller sea lions. The repeal of bycatch restrictions, including PSC limits, under this bookend also means that those areas that are triggered closures after a certain catch limit is reached will also no longer be implemented. As a result, FMP 2.1 would result in a substantial relaxation of management and enforcement complexity.

On the other hand, the elimination of VMS in the directed pollock, Pacific cod and Atka mackerel fisheries under FMP 2.1 would create difficulties for the effective enforcement of the Steller sea lion closure required under ESA. Traditional methods to monitor compliance with Steller sea lion area closures, including periodic USCG overflights and USCG cutter operations, do not fully meet the NOAA Fisheries' need to monitor fishing activities in and around Steller sea lion rookeries, haulouts, and areas designated as critical habitat because of their complexity and their irregular boundaries. Reverting to these methods would require a substantial increase in effort.

Monitoring and Enforcing Compliance with Bycatch (Discard) Reduction Standards

FMP 2.1 repeals the current IR/IU requirements for pollock and Pacific cod and does not implement the DSR retention program. This would reduce operational regulations on the fishing industry, reduce recordkeeping and reporting requirements, and reduce the staff resources needed to monitor compliance.

Managing and Enforcing Gear Modifications Requirements and Gear Restrictions

The 2001 seabird avoidance measures that are repealed under this alternative are not currently implemented in the 2002 baseline, therefore there is no change to management or enforcement complexity.

Management Complexity Due to Rights-Based Management Programs

Alternative 2 maintains the statutorily mandated rights-based management programs authorized under AFA, for the BSAI pollock fishery and the CDQ program. The absence of any objectives to eliminate excess capacity and the race-for-fish leads to the repeal of all other rationalization programs under FMP 2.1, and the cessation of work on further rationalization of the groundfish fisheries. This would eliminate the IFQ program for sablefish, and associated community quota purchase programs, and the License Limitation Program (LLP). The elimination of the LLP is likely to increase management complexity to some degree, due to the likely increase in the number of vessels participating in the fishery. The repeal of the IFQ program, on the other hand, would likely result in a decrease in management complexity, as its implementation since 1995 has had the opposite effect.

Managing Observer Programs and Data Collection

Repealing the Observer Program, except for AFA monitoring requirements, under FMP 2.1 would result in foregone data about the amount and location of catch, and species composition of the haul. Non-AFA pollock monitoring accounts for approximately 80 percent of groundfish observer days annually (Appendix F-10). Observers also record information on interactions with marine mammals and ESA-listed seabirds. The observer data is used to groundtruth industry reporting, and the lack of such data would require NOAA Fisheries to assume a certain degree of under-reporting and consequently manage the fisheries more conservatively to avoid overfishing. The agency currently contributes about $3,000 per year to manage the Observer Program, with the remainder of the costs paid by industry, and some of these costs would be saved by repealing the non-AFA portion of the program (Appendix F-10).

FMP 2.1 also repeals the use of at-sea scales, which would result in less accurate data and consequently would decrease the ability of fishery managers to accurately manage TAC in order not to exceed OFLs.

Summary

Alternative 2 will require more conservative management, particularly in the BSAI, due to the redefinition of optimum yield that reduces the buffer between TAC and OFL and the repeal of bycatch restrictions. The repeal of bycatch restrictions would allow some budget and staff to be redirected to other management and enforcement priorities, resulting in a conditionally significant beneficial rating. The FMP 2.1 end of the range, however, repeals several existing management measures that would significantly alleviate management complexity, particularly the IFQ program, the Observer Program, PSC limits, IR/IU, and closure areas. An FMP 2.1 illustration of Alternative 2 would be significantly beneficial in terms of reducing management complexity. Basing the assessment of Alternative 2 as a whole on the assumption that the alternative would be implemented somewhere in the middle of the range, and that should any one of the FMP 2.1 measures be implemented it would represent a substantial reduction in management complexity.

5.2.6 Alternative 3

Alternative 3 would seek to accelerate the existing precautionary management measures through community or rights-based management, ecosystem-based management principles and, where appropriate and practicable, increased habitat protection and additional bycatch constraints. This policy recognizes the need to balance many competing uses of marine resources and different social and economic goals for fishery management. Alternative 3 would be implemented through management measures that fall within the range of two FMP bookends (see Section 4.2). Both bookends 1) initiate new research and re-examine existing management practices; 2) implement rationalization for the groundfish fisheries; 3) break out new species for TAC setting; and 4) improve monitoring data.

The bookends do differ in their implementation, however. FMP 3.1 eliminates the existing vessel incentive program. FMP 3.2 incorporates additional quota specification adjustments, and develops an expanded system of closure areas. Bycatch incentive programs are instituted, the Observer Program coverage is increased, and mandatory VMS is extended to vessels greater than 125 ft length overall (LOA).

Managing Harvest Within Specified Catch Limits (TAC & PSC)

Alternative 3 would increase the number of individual TAC limits managed by NOAA Fisheries by breaking out species from species complexes for TAC setting. Additionally, PSC limits are established in the GOA for salmon, herring and crab. Increasing the number of individual catch limits increases the need for accurate, complete, and timely catch data from fishermen in order to manage the commercial fisheries within catch limits. NOAA Fisheries is responsible for monitoring commercial fishing activity by all vessel types, to estimate the amount of each species caught, and to know the date and location of the catch. NOAA Fisheries uses this information to limit or prohibit commercial fishing so that the catch limits are not exceeded. Obtaining the data necessary to manage current catch limits, as well as additional catch limits recommended under this alternative is particularly difficult for unobserved vessels or for vessels that do not have the capability to transmit observer data to NOAA Fisheries. Reassessment of agency priorities or additional staff resources may be necessary for data collection, research, and analysis to establish catch limits based on new criteria.

FMP 3.2 implements further adjustments to the TAC-setting process by incorporating uncertainty corrections into the quota assessments. This measure would increase the buffer between TAC and OFL to allow for uncertainty, and would thus provide more leeway for fishery managers for in-season actions.

The development of the uncertainty correction in FMP 3.2, and the establishment of new PSC limits in the GOA and the reduction of existing limits in the BSAI and GOA under Alternative 3, also necessitate allocation of staff resources to prepare the analysis to support the revised quotas.

Monitoring and Enforcing Compliance with Area Closures (Including Seasonal, Gear, Directed Fishery)

Alternative 3 prioritizes the development of an marine protected area (MPA) system, that may or may not encompass existing closure areas. This effort is likely to require staff analytical support as well as additional research efforts to situate the closure areas. Although FMP 3.1 makes no actual changes to the closure system currently in place in the BSAI and GOA, FMP 3.2 designs series of comprehensive closures.

In FMP 3.2, the existing Steller sea lion protection measures are left intact. Additionally, two other kinds of closures are implemented, namely no-take marine reserves and no bottom contact MPAs. Depending on the complexity of the areas, the closure of areas or times all fishing can be effectively enforced using aerial or at-sea surveillance by the USCG, a VMS tracking system, or information supplied by observers on the vessels. No bottom contact MPAs, however, present more of an enforcement challenge. Effective monitoring and enforcement requires the ability to assess whether the gear is coming into contact with the bottom, which would require technology not currently used on the groundfish boats.

The no-take marine reserve and no bottom contact MPA closures do, however, supplant the existing mix of closure areas that are often specific to certain directed fisheries. Such closures require assessment of the catch onboard the vessel to determine whether the vessel is complying with catch composition requirements associated with particular directed fisheries, and are consequently complex to monitor and enforce.

Additional agency resources would also be needed under Alternative 3 for data collection, research, and analysis to identify critical or essential habitat areas to be protected by the closures.

Monitoring and Enforcing Compliance with Bycatch (Discard) Reduction Standards

FMP 3.1 eliminates the vessel incentive program, which would, in a minor way, reduce operational regulations on the fishing industry, reduce recordkeeping and reporting requirements, and reduce the staff resources needed to analyze and revise regulations and to monitor compliance.

Under FMP 3.2, the reductions in bycatch limits would be achieved by industry as a result of increased flexibility inherent in the rationalization of the fisheries (see Section 4.7.9). NOAA Fisheries management and enforcement experience with rationalization and rights-based management programs, including bycatch management under these programs, has been that they result in increased complexity. The impacts on complexity of rights-based management programs is discussed further in that section below.

Managing and Enforcing Gear Modifications Requirements and Gear Restrictions

As discussed under Alternative 1, the seabird avoidance measures approved by NPFMC in 2001 and implemented under Alternative 3 require staff time for writing and regulations, and preparing training material to educate fishers as to the nature of the additional measures. Additional seabird protection measures would also be researched under this alternative, in cooperation with USFWS.

The gear restrictions implemented under FMP 3.2 would be designed to allow vessel compliance with the no bottom contact MPA requirements discussed in the time and area closure subsection above.

Management Complexity Due to Rights-Based Management Programs

Rationalization is one of the distinguishing features of Alternative 3. Both bookends develop a rationalization program, although FMP 3.1 takes a more gradual fishery-by-fishery approach and FMP 3.2 proceeds with comprehensive rationalization. Both bookends incorporate community protection concerns in their implementation of rationalization programs.

NOAA Fisheries (NMFS 2001a, Section 4.1.5.2) contains a lengthy discussion about many of the management issues related to the rights-based fishing systems currently in existence in the Alaska Region, including the IFQ and CDQ programs and fishing cooperatives established under the AFA. Each program was implemented together with existing traditional management measures, such as overall catch limits, limits on seasons or areas, gear restrictions, and Observer Programs. However, they also required implementation of additional administrative and catch monitoring regulations to manage and enforce programs based on the assignment of fishing rights to individuals or groups. In some cases, such as the IFQ and CDQ programs, NOAA Fisheries no longer manages the catch limits through closures of directed fishing by a group of vessels once a catch limit is reached. Instead, catch limits are assigned to individuals or groups, who are required to provide accurate and timely reports of catch and to stop fishing once a catch limit is reached.

Rights-based systems present some potential difficulties and some advantages for fisheries managers. Because they are likely to change the practices of harvesters (e.g., less emphasis on maximizing catch rates) they are likely to lead to discontinuities in fishery-dependent data. Commercial catch per unit effort is likely to change independent of stock sizes, and the relative catch rates of different species or cohorts may also change. Any stock assessment models that rely on fishery-dependent data may require recalibration. However, rights-based systems also have the potential to provide new useful information to managers. The prices of quota shares or use rights, if transferable, should indicate the net value of the fishery and changes in prices can be useful indicators of the economic impact of regulatory changes. Prices of transferable individual quotas on catch and bycatch (including prohibited species) also provide information on the relative value of allocations to different fisheries and sectors.

Experience with the IFQ and CDQ programs and pollock cooperatives suggests that expansion of rights-based systems to other fisheries is likely to result in substantial increases in the costs of monitoring, enforcement, and administration. Cost recovery fees will at least partly offset management costs that would otherwise be publicly funded. To implement rights-based fishing systems, additional agency resources would be required to develop the process through which fishing rights are assigned; to adjudicate appeals about the assignment of fishing rights to individuals or groups; to administer the annual assignment of catch amounts and transfers of fishing rights; to monitor catch of individual or group quotas; and to penalize people violating regulations.

Managing Observer Programs and Data Collection

Alternative 3 introduces a variety of research and analytical objectives that impact management primarily through the need for additional resources for data collection, research and analysis. Increasing data collection requirements for observers requires assessment of the priority of these data relative to other demands on the observers' time.

The objective to improve data quality applies to both observer and industry data. Changes to the data collected by the Observer Program require assessment of the impact of adding more duties for the observer. Increasing the breadth and precision of industry logbook data would require management and enforcement staff resources for program development and maintenance.

The expansion of observer coverage to 100 percent on all vessels over 60 ft LOA may be difficult to implement in the first year or two due to the changes that the requirement creates in the numbers of observers required and the timing of when observers are required, either competing with existing fisheries that need observers or requiring observers at a time of year when they had not been required before. An increase in observer deployments could require additional resources in the Observer Program, NOAA Fisheries Enforcement, and NOAA General Counsel to ensure their ability to manage and support a larger program, depending on the scope of the increase.

Finally, recommendations to expand the use of VMS to all groundfish vessels over 125 ft LOA, together with observer data or vessel logbook data, to increase the precision of catch location data would require management and enforcement staff resources for program development and maintenance.

Summary

Alternative 3 contains a number of changes for management and enforcement. Rationalization of the fisheries, and the increased emphasis on improving data and research efforts, as well as the potential for redesigning the existing closure system, would tend to create a considerably more complex management and enforcement scenario than exists in the baseline case, resulting in additional need for staff and budget resources.

5.2.7 Alternative 4

Alternative 4 represents an extremely precautionary approach to managing fisheries under scientific uncertainty. It shifts the burden of proof to the users of the resource and NPFMC/NOAA Fisheries to demonstrate that the intended use would not have a detrimental effect on the environment. This policy assumes that fishing does produce adverse impacts on the environment, but due to a lack of information and uncertainty, we know little about these impacts. The initial restrictive and precautionary conservation and management measures would be modified (strengthened or relaxed) when additional, reliable scientific information becomes available. Alternative 4 would be implemented through management measures that fall within the range of two FMP bookends (see Section 4.2). Both bookends require more data collection, research and monitoring due to shifting the burden of proof.

The bookends differ substantially in their method of implementation. FMP 4.1 adapts the existing fishery management environment to comply with the Alternative 4 policy, by imposing harvest, bycatch and other conservation constraints on the groundfish fisheries. The implementing management measures include adjustment of the quota specification process, establishment of closure areas and gear restrictions, establishment of additional PSC limits and bycatch limits for non-target species, protection measures for seabirds, effort-based regulations, expanded observer coverage and mandatory VMS and motion-compensated scales. FMP 4.2 implements a more extreme management regime, by suspending all fishing in federal waters off Alaska until such time as individual directed fisheries can be shown to have no adverse impact on the environment.

Managing Harvest Within Specified Catch Limits (TAC & PSC)

The adjustments to the TAC-setting process specified under FMP 4.1 generate a variety of management impacts. Managing TAC on smaller spatial scales, and breaking out species from their species complexes where possible, increases the number of individual catch limits to monitor and enforce. The level of attention required by inseason management staff would increase substantially not simply by expansion of the number of inseason actions but also by increased attention to management of data and monitoring and interacting with the fleet. This requires accurate and timely catch data from industry, and analytical agency support to manage the quantity of data. Additionally, reducing the TACs under this bookend would also require staff resources to prepare the analysis to support revised quotas.

Additionally, PSC limits are established in the GOA, and catch limits will be developed for non-target species. Again, this would increase management and enforcement complexity by increasing the number of catch limits that would have to be monitored and managed. Placing a priority on catch limits for non-target species likely would result in closure of directed fisheries for target species due to bycatch of non-target species before the target species catch limit was fully harvested. In addition, because most non-target species currently are discarded at sea, this alternative would rely more heavily on data collected by observers for estimating catch and would increase the need to extrapolate data from observed vessels to estimate at-sea discards by unobserved vessels. Additional agency resources also may be needed for stock assessment (data collection, research, and analysis) to establish catch limits for species that currently are not assessed and do not have catch limits.

The accuracy of the data available to assess and monitor catch limits would be improved, however, through the expansion of the Observer Program and the requirement for motion-compensated scales to weigh all catches at-sea or at shore-based processing plants.

Monitoring and Enforcing Compliance with Area Closures (Including Seasonal, Gear, Directed Fishery)

The implementation of closure areas under this FMP should reduce management complexity by reducing the variation in the types of closures. All closure areas under this bookend are either no-take reserves (closed to all commercial fishing) or no-trawl MPAs. Also, all fishing effort, and trawl effort in particular, is substantially reduced under Alternative 4. Staff resources would be required to prepare the analysis to support the design of closure areas. However, closures to all fishing, or to vessels using fishing gear that can be easily identified, can be effectively enforced using aerial or at-sea surveillance by the USCG, or information supplied by observers on the vessels.

Additionally, monitoring and enforcement would also be assisted by the requirement that all groundfish vessels carry VMS. Management measures such as comprehensive closure areas require VMS for effective monitoring and management. While VMS alone is not sufficient to effectively implement the closure areas, VMS is an essential component of monitoring and management. The benefits of a VMS system are significantly increased by extending the VMS requirement to all groundfish vessels. The baseline case of having vessels turning the units on and off because they are required to operate them only in particular areas or while targeting a particular species of groundfish reduces the effectiveness of the system and increases agency operational costs and complexity. Removing this complexity under this alternative would be beneficial.

Monitoring and Enforcing Compliance with Bycatch (Discard) Reduction Standards

FMP 4.1 expands the IR/IU program to apply to all target species. Other elements of Alternative 4 would significantly decrease the size of the fleet due to a reduction in catch limits and extensive closure areas. The monitoring and enforcement of this program expansion would increase management complexity, but the impact would not be substantial due to the reduction in the fleet.

Managing and Enforcing Gear Modifications Requirements and Gear Restrictions

The introduction of effort-based regulations such as trip limits, vessel size or horsepower limits, gear size limits, or area registration, increases management and enforcement complexity.

Trip limits are a maximum amount of fish that can be caught on a fishing trip or the maximum amount that can be onboard a vessel at any time while fishing in an area. They currently exist in two Alaska fisheries managed by NOAA Fisheries: the 6,000 pound trip limit in the area 4E halibut CDQ fishery and the 300,000 lb trip limit for pollock in the GOA. Trip limits for catcher vessels do not present any new or difficult in-season management or enforcement issues. A specific trip limit would be established for a fishery and catcher vessel deliveries would be monitored to determine whether participating vessels had exceeded the trip limit. However, determining the appropriate amount of the trip limit to accomplish specific objectives of slowing the pace of fisheries is complicated, particularly in fisheries without quota allocations among different gear types and vessel categories, all of whom fish at the same time during some parts of the year. In addition, it is not clear how trip limits would be adapted for catcher processors, because catcher processors fish for a much longer time in a trip. Sometimes a "trip" can be an entire season.

Imposing additional limits, whether trip, vessel, horsepower or gear size, increase the need for data collection, research and analysis to identify and evaluate appropriate actions, and require additional resources to monitor and enforce.

Area registration would require a vessel owner to register with NOAA Fisheries each season before they participate in directed fisheries. They may be restrictions on the number of areas or species that may be registered per season. NOAA Fisheries would be required to establish registration forms, accept registration forms from fishermen, acknowledge receipt of registration (something fishermen have onboard vessel to show compliance with registration requirements), and provide a database of registration information to fishermen and enforcement officers (which might link up with VMS).

The primary management and enforcement issues associated with seabird protection measures are providing the staff resources necessary to conduct the research to identify and evaluate appropriate gear modifications and the difficulty of enforcing restrictions on gear and fishing operations on unobserved vessels. In addition, the recommendation to develop protection measures (which could include elements such as bycatch limits or a bycatch monitoring program) would require possible changes in observer duties, and increases in management and observer program staff involvement in the seabird protection program.

Managing Observer Programs and Data Collection

FMP 4.1 expands observer coverage to 100 percent on all vessels over 60 ft LOA. The bookend also proposes to require 30 percent observer coverage on groundfish vessels less than 60 ft LOA. An observer onboard a vessel can help NOAA Fisheries improve estimates of the amount and location of catch, and the target species. However, observers on catcher vessels are limited in the information they can collect about total catch weight and species composition due to the fishing operations (sorted or unsorted catch) and tools available for weighing and sampling catch. To date, Council and NOAA Fisheries have not required observers on vessels less than 60 ft LOA due to concerns about safety, cost, and accommodations for the observers. However, the 60 ft LOA cut-off between observed and unobserved vessels is an arbitrary length established because of the decision to base observer coverage requirements on vessel categories by length. Observer data from vessels less than 60 ft LOA would contribute greatly to information about catch and at-sea discards by this vessel class.

Substantial increases in observer coverage requirements may be difficult to implement in the first year or two due to the changes that the requirement creates in the numbers of observers required and the timing of when observers are required—either competing with existing fisheries that need observers or requiring observers at a time of year when they hadn't been required before. An increase in observer deployments could require additional resources in the Observer Program, NOAA Fisheries Enforcement, and NOAA General Counsel to ensure their ability to manage and support a larger program, depending on the scope of the increase. For instance, timely debriefing of returning observers directly affects observer availability.

The requirement for motion-compensated scales and mandatory VMS on all vessels would require additional resources for equipment certification, and also would require additional staff effort to monitor and analyze the VMS data. The cost of the VMS units has to date been reimbursed by NOAA Fisheries, for up to $2,000. Should the Agency continue with this policy, additional funding would be required to support the extension of VMS to all vessels.

FMP bookend 4.2 would also require a considerable staff and budget commitment in order to develop the criteria and the standards of proof to assess each of the directed fisheries. While the suspension of the commercial fisheries would free up staff, the complexity of designing a new commercial fishing regulatory environment that can be proven to have no adverse effect on the environment would be immense and would presumably require many specialists. Additional data collection and research would likely be required to bolster the fishery assessments, assuming that a higher standard of proof would be necessary to authorize the resumption of fishing. However, all data collection and research would need to be conducted with experimental permits as there would be no data collected in conjunction with commercial fishing, and the data would be obtained at considerably greater additional expense to the agency. The suspension of fishing would likely take a minimum of two years, to develop the criteria and assess directed fisheries. Currently, those fisheries that are under rights-based management, such as BSAI pollock and the sablefish IFQ program, contribute to their management costs through a cost-recovery program. Although a comparable staff load would likely be required to craft the restructured management regime, no management costs would be recovered during the suspension of fishing.

Summary

The management and enforcement complexity under Alternative 4, as represented within the bookend range of FMP 4.1 and FMP 4.2, would be significantly greater than the baseline. The shifting of the burden of proof would implement new types of management measures and expand on the use of existing budget, staff and analytical needs beyond the capability of the existing management and enforcement structure.

5.2.8 The Preferred Alternative

The Preferred Alternative (PA) represents a combination management approach, incorporating forward looking conservation measures that address differing levels of uncertainty. The alternative would be implemented through management measures that fall within the range of two FMP bookends (see Section 4.2 for more detail). Both bookends 1) initiate new research and re-examine existing management practices; 2) implement rationalization for the groundfish fisheries; 3) establish PSC limits for all prohibited species in the GOA; 4) evaluate seabird avoidance measures for the trawl and longline fisheries; and 5) improve monitoring data.

Additional management measures are specific to PA.2. The bookend, however, also implements additional changes to groundfish management. PA.2 adjusts quota specification, develops an expanded system of closure areas, and institutes other bycatch incentive programs while eliminating the existing Vessel Incentive Program (VIP).

Managing Harvest Within Specified Catch Limits (Total Allowable Catch and Prohibited Species Catch)

The PA would increase the number of individual limits managed by NOAA Fisheries by establishing PSC limits in the GOA for salmon, herring and crab. Additionally, in PA.2, species are broken out for TAC-setting. Increasing the number of individual catch limits increases the need for accurate, complete, and timely catch data from fishermen in order to manage the commercial fisheries within catch limits. NOAA Fisheries is responsible for monitoring commercial fishing activity by all vessel types, to estimate the amount of each species caught, and to know the date and location of the catch. NOAA Fisheries uses this information to limit or prohibit commercial fishing so that the catch limits are not exceeded. Obtaining the data necessary to manage current catch limits, as well as additional catch limits recommended under this alternative is particularly difficult for unobserved vessels or for vessels that do not have the capability to transmit observer data to NOAA Fisheries. Reassessment of agency priorities or additional staff resources may be necessary for data collection, research, and analysis to establish catch limits based on new criteria.

PA.2 implements further adjustments to the TAC-setting process by incorporating uncertainty corrections into the quota assessments. This measure would increase the buffer between TAC and OFL to allow for uncertainty, and would thus provide more leeway for fishery managers for inseason actions.

The development of the uncertainty correction in PA.2, and the establishment of new PSC limits in the GOA and the reduction of existing limits in the BSAI and GOA under the PA, also necessitate allocation of staff resources to prepare the analysis to support the revised quotas.

Monitoring and Enforcing Compliance with Area Closures (Including Seasonal, Gear, Directed Fishery)

The PA prioritizes the development of an MPA system, that may or may not encompass existing closure areas. This effort is likely to require staff analytical support as well as additional research efforts to review the efficacy of existing area restrictions as well as to situate new closure areas. Although PA.1 makes no actual changes to the closure system currently in place in the BSAI and GOA, PA.2 designs a series of comprehensive closures.

In PA.2, the existing Steller sea lion protection measures are left intact. Additionally, two other kinds of closures are implemented, namely no-take marine reserves and no bottom contact MPAs. Depending on the complexity of the areas, the closure of areas or times to all fishing can be effectively enforced using aerial or at-sea surveillance by the USCG, a VMS tracking system, or information supplied by observers on the vessels. No bottom contact MPAs, however, present more of an enforcement challenge. Effective monitoring and enforcement requires the ability to assess whether the gear is coming into contact with the bottom, which would require technology not currently used on the groundfish boats.

The no-take marine reserve and no bottom contact MPA closures do, however, supplant the existing mix of closure areas that are often specific to certain directed fisheries. Such closures require assessment of the catch onboard the vessel to determine whether the vessel is complying with catch composition requirements associated with particular directed fisheries, and are consequently complex to monitor and enforce.

Additional agency resources would also be needed under the PA for data collection, research, and analysis to identify critical or essential habitat areas to be protected by the closures.

Monitoring and Enforcing Compliance with Bycatch (Discard) Reduction Standards

PA.1 eliminates the vessel incentive program which, while reducing operational regulations on the fishing industry, recordkeeping and reporting requirements, and the staff resources needed to analyze and revise regulations and to monitor compliance, would not ultimately impact the ability of the agency to monitor/enforce compliance with bycatch reduction standards.

Under PA.2, the reductions in bycatch would be achieved by the industry as a result of increased flexibility inherent in the rationalization of the fisheries (see Section 4.9.9 for further detail). NOAA Fisheries' management and enforcement experience with rationalization and rights-based management programs, including bycatch management under these programs, has increased management complexity. The impacts of the increase in complexity of monitoring and enforcement inherent in rights-based management programs is discussed further in that section below.

Managing and Enforcing Gear Modifications Requirements and Gear Restrictions

The seabird avoidance measures implemented for trawl fisheries under PA.2 would require staff time for writing and regulations, and preparing training material to educate fishers as to the nature of the additional measures.

Gear restrictions may also need to be implemented under PA.2, that would be designed to allow vessel compliance with the no bottom contact MPA requirements discussed in the time and area closure subsection above.

Management Complexity Due to Rights-based Management Programs

As with Alternative 3, rationalization is one of the distinguishing features of the PA. Both bookends develop a rationalization program, although PA.1 takes a more gradual fishery-by-fishery approach and PA.2 proceeds with comprehensive rationalization. Both bookends incorporate community protection concerns in their implementation of rationalization programs.

The Overcapacity qualitative analysis paper (Appendix F-8) contains a lengthy discussion about many of the management issues related to the rights-based fishing systems currently in existence in the Alaska region, including the IFQ and CDQ programs and fishing cooperatives established under the AFA. Each program was implemented together with existing traditional management measures, such as overall catch limits, limits on seasons or areas, gear restrictions, and observer programs. However, they also required implementation of additional administrative and catch monitoring regulations to manage and enforce programs based on the assignment of fishing rights to individuals or groups. In some cases, such as the IFQ and CDQ programs, NOAA Fisheries no longer manages the catch limits through closures of directed fishing by a group of vessels once a catch limit is reached. Instead, catch limits are assigned to individuals or groups, who are required to provide accurate and timely reports of catch and to stop fishing once a catch limit is reached.

Rights-based systems present some potential difficulties and some advantages for fisheries managers. As rights-based management systems are likely to change the practices of harvesters (e.g., less emphasis on maximizing catch rates), they are likely to lead to discontinuities in fishery-dependent data. Commercial catch per unit effort is likely to change independent of stock sizes, and the relative catch rates of different species or cohorts may also change. Any stock assessment models that rely on fishery-dependent data may require recalibration. However, rights-based systems also have the potential to provide new useful information to managers. The prices of quota shares or use rights, if transferable, should indicate the net value of the fishery and changes in prices can be useful indicators of the economic impact of regulatory changes. Prices of transferable individual quotas on catch and bycatch (including prohibited species) also provide information on the relative value of allocations to different fisheries and sectors.

Experience with the IFQ and CDQ programs and pollock cooperatives suggests that expansion of rights-based systems to other fisheries is likely to result in substantial increases in the costs of monitoring, enforcement, and administration. Cost recovery fees will at least partly offset management costs that would otherwise be publicly funded. To implement rights-based fishing systems, additional agency resources would be required to develop the process through which fishing rights are assigned; to adjudicate appeals about the assignment of fishing rights to individuals or groups; to administer the annual assignment of catch amounts and transfers of fishing rights; to monitor catch of individual or group quotas; and to penalize people violating regulations.

Managing Observer Programs and Data Collection

The PA introduces a variety of research and analytical objectives that impact management primarily through the need for additional resources for data collection, research and analysis. Increasing data collection requirements for observers requires assessment of the priority of these data relative to other demands on the observers' time.

The objective to improve data quality applies to both observer and industry data. Changes to the data collected by the observer program require assessment of the impact of adding more duties for the observer. Increasing the breadth and precision of industry logbook data would require management and enforcement staff resources for program development and maintenance. An increase in observer deployments could require additional resources in the Observer Program, NOAA Fisheries Enforcement, and NOAA General Counsel to ensure their ability to manage and support a larger program, depending on the scope of the increase. For instance, timely debriefing of returning observers directly affects observer availability.

Finally, recommended changes to observer data or vessel logbook data, to increase the precision of catch location data, would require management and enforcement staff resources for program development and maintenance.

Summary

The PA contains a number of changes for management and enforcement. Rationalization of the fisheries, and the increased emphasis on improving data and research efforts, as well as the potential for redesigning the existing closure system, would tend to create a considerably more complex management and enforcement scenario than exists in the baseline case, resulting in additional need for staff and budget resources.

5.2.9 Comparison of the Alternatives

The significance of each alternative is determined relative to the baseline, in terms of the alternative's effect on the complexity of management and enforcement in terms of budget, staff, data, and analysis needs. The ratings are included in Table 5.2-2.

CHAPTER 6

List of Preparers

This page intentionally left blank

Chapter 6 List of Preparers

6.1 Programmatic Supplemental Environmental Impact Statement Steering Committee

Laurie Allen, Director, Protected Resources Division, NOAA Fisheries Headquarters.

Dr. James Balsiger, Regional Administrator, Alaska Regional Office, NOAA Fisheries

Ronald Berg, Deputy Regional Administrator, Alaska Regional Office, NOAA Fisheries.

Nancy Briscoe, Senior Counselor for Environmental Compliance, The Office of General Counsel Fisheries, NOAA Fisheries.

James Coe, Deputy Director, Science & Research, Alaska Fisheries Science Center, NOAA Fisheries.

Steve Davis, Fishery Biologist, Alaska Regional Office, NOAA Fisheries.

Tony DeGange, Special Assistance for Ecosystems, U.S. Fish and Wildlife Service, Anchorage, Alaska.

Dr. Doug DeMaster, Director, Science & Research, Alaska Fisheries Science Center, NOAA Fisheries.

Kevin Duffy, Acting Commissioner, Alaska Department of Fish and Game, Anchorage, Alaska.

Tamra Faris, Fisheries Biologist, Alaska Regional Office, NOAA Fisheries.

Earl Krygier, Extended Jurisdiction Coordinator, Alaska Department of Fish and Game, Anchorage, Alaska.

Lisa Lindeman, Alaska Regional Counsel, Office of the Alaska Regional Counsel, Juneau, Alaska, NOAA Fisheries.

Dr. Richard Marasco, Director, Resources Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries.

Joseph McCabe, Paralegal Specialist, Office of the Alaska General Counsel, Juneau, Alaska, NOAA Fisheries.

Chris Oliver, Executive Director, North Pacific Fishery Management Council.

Lauren Smoker, Attorney-Advisor, Office of the Alaska General Counsel, Juneau, Alaska, NOAA Fisheries.

6.2 Project Team List

Project Leaders

Steve Davis, Programmatic SEIS Project Manager. Fishery Biologist, Alaska Regional Office, NOAA Fisheries. Provided overall project management and leadership of the Alaska Groundfish Programmatic SEIS Project Team. Led scoping meetings, prepared the SEIS outline, and drafted sections in all chapters of the document. Directed and coordinated agency and contract analysts located in Anchorage, Juneau, and Seattle. 20 years of fishery management experience in Alaska. Has drafted or led the preparation of more than 30 National Environmental Policy Act Environmental Impact Statements and Environmental Assessments. Served on the National Research Council's Bering Sea Ecosystem Committee. Has published a substantial body of work in the field of fisheries management and bycatch. Served on the staff of the North Pacific Fishery Management Council (Senior Biologist and Deputy Executive Director), and its Gulf of Alaska Groundfish Plan Team. *B.S. in Biology, University of Puget Sound; M.S. in Fisheries Science, College of Fisheries, University of Washington.*

Dr. Anne Babcock Hollowed, Supervisory Fisheries Biologist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Provided leadership and direction to analysts tasked with model development and analysis of alternatives. Assisted in the preparation of the evaluation of biological impacts of alternatives on walleye pollock, reviewed the gear restrictions and allocation and Total Allowable Catch-setting quality analysis papers and assisted in the preparation of other sections. She has 22 years experience as a fisheries biologist and has worked on North Pacific fisheries issues for the last 19 years. *M.S. in Biological Oceanography, Old Dominion University; Ph.D. in Fisheries, University of Washington.*

Contributors

Kerim Aydin, Fisheries Biologist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Aided in preparation of ecosystem effects of alternatives. Three years experience with NOAA Fisheries, *Ph.D. (2000) from the School of Aquatic and Fisheries Sciences, University of Washington, Seattle*.

Sally Bibb, Economist and Community Development Quota Program Coordinator, Sustainable Fisheries Division, Alaska Regional Office, NOAA Fisheries. Prepared Environmental Consequences section on Effects of the Alternatives on Enforcement and Management, contributed to Community Development Quota program descriptions. Fifteen years experience in fisheries management and research. *M.A. in Agricultural Economics, Washington State University.*

William G. Clark, Quantitative Scientist, International Pacific Halibut Commission. Assisted with various report sections dealing with Pacific halibut. Extensive experience in stock assessment and population dynamics; presently senior International Pacific Halibut Commission assessment scientist. *B.A. Economics, University of Michigan; Ph.D. Fisheries, University of Washington.*

David Clausen, Research Fisheries Biologist, Auke Bay Laboratory, Alaska Fisheries Science Center, NOAA Fisheries. Contributed to analysis of the effects of proposed fishery management alternatives on Gulf of Alaska shortraker/rougheye rockfish, other slope rockfish, and pelagic shelf rockfish. Twenty-five experience with NOAA Fisheries working on Alaskan groundfish. *B.A. in Biology, Occidental College, California.*

Catherine Coon, Fisheries Analyst/Geographic Information System specialist, North Pacific Fishery Management Council. Prepared tables on history of regulatory closure areas. Seven years experience as fisheries biologist. *M.S. in Fisheries Science, University of Alaska, Fairbanks.*

Dean Courtney, Research Fisheries Biologist, Auke Bay Laboratory, Alaska Fisheries Science Center, NOAA Fisheries. Prepared impact of alternatives sections on Gulf of Alaska Pacific ocean perch and Gulf of Alaska northern rockfish. Four years experience with the Auke Bay Laboratory working on sablefish and rockfish. *M.S. in Fisheries, University of Alaska, School of Fisheries and Ocean Science.*

Jane DiCosimo, Senior Plan Coordinator, North Pacific Fishery Management Council. Nineteen years experience as a fisheries biologist with State and Federal agencies. Assisted in preparation of Fishery Management Plan summaries and prepared sections reflecting current management regime with regard to target and non-target species. *B.A. Rutgers University; M.S. Virginia Institute of Marine Sciences, College of William and Mary.*

Elaine Dinneford, Fisheries Analyst, North Pacific Fishery Management Council. Provided catcher vessel harvest data. Over 22 years experience evaluating, maintaining, and presenting Alaska fisheries harvest data for the State of Alaska Commercial Fisheries Entry Commission and North Pacific Fishery Management Council. *B.S. in Microbiology Humboldt State College, California.*

Dr. Martin Dorn, Fisheries Research Biologist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Assisted with the writing of the section on target species impacts. Fifteen years of experience in fishery biology/population dynamics and groundfish stock assessment modeling. *M.S. in Biomathematics, Ph.D. in Fisheries, University of Washington.*

Gary Duker, Technical Publications Writer/Editor (Biological Sciences), Office of the Science and Research Director, Alaska Fisheries Science Center, NOAA Fisheries. Edited second version of the Programmatic SEIS and also assisted with layout of the second version. Ten years experience as a fisheries biologist and 16 years experience as a writer/editor for NOAA Fisheries. *B.S. in Biology, San Diego State College; M.S. in Fisheries Science, University of Washington.*

Matthew Eagleton, Fisheries Biologist, Habitat Conservation Division, Alaska Regional Field Office, NOAA Fisheries. Co-member Marine Habitat/Essential Fish Habitat. Contributed to analysis of the baseline environment in Chapter 3 and alternatives analysis in Chapter 4. Technical review and input to the Essential Fish Habitat/Marine Protected Area Qualitative Analysis Paper. Provided guidance and recommendations specific to the provisions of Essential Fish Habitat and Marine Protected Areas. Over 15 years experience with NOAA Fisheries Research Platforms and Alaska Regional Management. Former NOAA Corps Officer with specific emphasis on Alaska fisheries including fishery stock and oceanic investigations aboard the *NOAAS Miller Freeman, NOAAS John N. Cobb,* and *NOAA 1273* operating in the Bering Sea, Aleutian Islands, Gulf of Alaska, North Pacific Ocean, and Beaufort Sea, respectively. *B.S. in Biological Sciences, Montana State University; NOAA Corps Commissioned Officer, U.S. Merchant Marine Academy, Kings Point, New York.*

Diana Evans, NEPA Specialist, North Pacific Fishery Management Council. Assisted in project management and development of revised draft alternatives. Prepared Fishery Management Plan Amendment analysis, assisted with Fishery Management Plan summaries. Assisted with drafting policy analysis. Three years experience preparing environmental impact statements on pelagic and groundfish fisheries off Hawaii and Alaska. *B.A. Geography and Linguistics, University of California, Berkeley; M.S. Geography, King's College London, University of London.*

Ron Felthoven, Industry Economist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Provided comments on the impacts of each alternative on overcapacity and on the current programs implemented to reduce overcapacity. Two years as an economist with NOAA Fisheries. *M.S. and Ph.D. in Natural Resource and Environmental Economics, Department of Agricultural and Resource Economics, University of California, Davis.*

Jennifer Ferdinand, Fishery Biologist, North Pacific Groundfish Observer Program. Authored the Observer Program Qualitative Analysis paper. Worked in the Observer Program office and currently works with the Information Services task on data quality issues. Main author of the "North Pacific Groundfish Observer Manual," distributed annually. Also co-authored the Observer Program's Management Control Review in 2000. *B.S. Environmental and Forest Biology, State University of New York College of Environmental Science and Forestry, Syracuse, New York.*

Shannon Fitzgerald. Fishery Biologist, Fisheries Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Currently works as the specialist for seabird/fishery interactions at the Alaska Fisheries Science Center and was until recently the Observer Services subtask leader in the North Pacific Groundfish Observer Program. Provided reviews for the seabird and observer program components of the document. Has observer program experience in several programs off and on over the last 20 years, including the Tuna/Porpoise, High Seas Driftnet, Alaska Groundfish Joint Venture, and Alaska domestic groundfish programs. Seabird experience focusing on fishery interactions has been ongoing for the last 13 years. This includes specific work in the high seas driftnet observer program, several research cruises in the North Pacific Transition Zone, acting as the seabird specialist withing the North Pacific Groundfish Observer Program, and close collaboration with Washington Sea Grant during studies to test various seabird deterrent devices in demersal longline fisheries. Fitzgerald has also done extensive marine mammal surveys that include the Eastern Tropical Pacific, Antarctic, the North Pacific Transition Zone, and Alaskan waters. *B.S. Wildlife Biology, University of Minnesota; M.S. Wildlife Ecology, University of Wisconsin.*

Lowell Fritz, Fisheries Biologist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Assisted in the preparation of alternatives and determination of alternative impacts. Twelve years experience as a fisheries biologist with NOAA Fisheries, and 12 years experience as a marine biologist with Rutgers University, New Jersey, and College of William and Mary, Virginia. *M.S. in Marine Science, Virginia Institute of Marine Science, College of William and Mary.*

Dr. Jeff Fujioka, Mathematical Statistician, Auke Bay Laboratory, Alaska Fisheries Science Center, NOAA Fisheries. Worked on preparation of impact of alternatives section on habitat. Developed habitat impact model applied in habitat analysis. Thirty-five years experience in fisheries biology, 20 years experience in groundfish research. *Ph.D. in Fisheries, University of Washington.*

Brandee Gerke, Fishery Biologist, Protected Resources Division, Alaska Regional Office, NOAA Fisheries. Co-authored the marine mammal section of Chapter 4. Over six years experience specializing in state and federal marine resource issues in Alaska. Marine mammal and fishery project involvement includes assessment of Steller sea lion and groundfish fishery interactions, technical review of Steller sea lion research projects, analyses for evaluating proposed critical habitat for endangered Northern Right Whales, and conducting effects analyses of various federal projects on marine mammals in compliance with the Endangered Species Act, Marine Mammal Protection Act, and National Environmental Protection Act. *B.S. Fisheries Science, Oregon State University; M.S. Fisheries, University of Alaska, Fairbanks.*

Jay Ginter, Fishery Management Biologist, Sustainable Fisheries Division, Alaska Region, NOAA Fisheries. Prepared sections of the fishery management process and early (pre-1976) history of the groundfish fisheries. Twenty-three years experience working in federal fisheries management, the most recent 18 years have been in the Alaska Region. *M.S. in Marine Environmental Studies, State University of New York; additional graduate study in Marine Fisheries Management, University of Washington.*

Jim Hale, Technical Writer-Editor, Analytical Team, Alaska Regional Office, NOAA Fisheries. Edited the document for clarity and consistency. With over 15 years of technical writing experience in private and public sectors, he has given technical writing seminars to staff at Alaska Department of Fish & Game and at Alaska Department of Transportation (where he also served as a writing consultant). He has taught English literature and composition at Rutgers University, Central Washington University, and the University of Alaska Southeast; has held fellowships from the Folger Institute for Renaissance Studies in Washington, D.C., and from the U.S. Department of Higher Education; and has published essays and presented papers on topics ranging from the politics of 17^{th} century theology to subsistence fishing issues in the poetry of contemporary Alaska Natives. *B.A. in Literature, Ramapo College; M.A., M.Phil., Rutgers University.*

Dr. Jonathan Heifetz, Fishery Research Biologist, Auke Bay Laboratory, Alaska Fisheries Science Center, NOAA Fisheries. Co-author of the effects of the alternatives on essential fish habitat. Reviewed the Gulf of Alaska Pacific ocean perch and essential fish habitat sections of Chapter 3 and the marine protected areas and essential fish habitat qualitative analysis paper. Nineteen years experience as a fisheries biologist involved with stock assessment and effects of fishing gear on benthic habitat. *M.S. in Fisheries, Humboldt State University; Ph.D. in Fisheries University of Alaska, Fairbanks.*

Nick Hindman, Fisheries biologist, Sustainable Fisheries Division, Alaska Region, NOAA Fisheries. Co-authored "Descriptions of Fisheries in the Bering Sea and Aleutian Islands" in Chapter 2. Nine years experience managing commercial fisheries, six years experience conducting fisheries research. *B.S. in Fisheries, University of Idaho*.

Dr. Dan Holland, Economist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Assisted with developing the Alternative 6 model regime; preparing data for the models used to make the catch, exvessel value and product value projections for the six alternative model regimes; summarizing those projections; and describing the expected effects of the Alternative 6 model regime. Four years experience assessing fishery management issues including two years at the Alaska Fisheries Science Center. *Ph.D. in Economics, University of Rhode Island.*

Dr. James Ianelli, Fisheries Research Biologist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Developed the multispecies management model used as background for the Programmatic SEIS and assisted in the preparation of a number of subsections. Over 20 years of experience in fisheries research and contributes annually to a number of stock assessment and fishery evaluation documents. *Ph.D. University of Washington.*

Jim Ingraham, Oceanographer, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Assisted in the preparation of Chapter 3.3, Physical Oceanography of the Fisheries Management Units. Forty years of experience in physical oceanography with NOAA Fisheries in Seattle, WA. *M.S. in Oceanography, University of Washington, Seattle, Washington.*

Dr. Daniel Ito, Fisheries Research Biologist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Assisted in the coordination and preparation of alternatives and determination of alternative impacts, as well as assisted in the preparation of other sections. Over 25 years experience as a fishery biologist with NOAA Fisheries. *Ph.D. in Fisheries, University of Washington.*

Nicole Kimball, Fisheries Analyst, North Pacific Fishery Management Council. Prepared sections on effects of the current regime on marine mammals and seabirds and was a major contributor to the Fishery Management Plan amendment summaries. More than four years experience as an analyst with the North Pacific Fishery Management Council, three years as a coastal planner, and two years as an environmental scientist. *B.S. in Natural Resource Management and M.A. in Environmental Policy Tufts University.*

James Lee, Writer-Editor, Office of the Science and Research Director, Alaska Fisheries Science Center, NOAA Fisheries. Edited document and assisted with layout. Seventeen years experience in fisheries research with the Alaska Department of Fish & Game, Oregon Department of Fish & Wildlife, and NOAA Fisheries. *B.S. in Fisheries and Technical Journalism, Oregon State University.*

Steve G. Lewis, Geographic Information System Analyst and Coordinator, Analytical Team, Alaska Region, NOAA Fisheries. More than four years of experience in the Fisheries Geographic Information System field. Past projects include Essential Fish Habitat mapping and Internet applications, staff member on the Steller Sea Lion Reasonable and Prudent Alternatives Committee, developer of interactive Steller Reasonable and Prudent Alternatives closure selector, and several user-friendly applications for finding spatial closures and corresponding regulations. Analytical projects have included working within a team to develop meaningful spatial measures and providing descriptive spatial statistics for the Programmatic SEIS. Project included developing a complex Catch-In-Areas and redistribution of effort database. *B.Ed, Secondary, University of Alaska - Southeast, Juneau.*

Patricia Livingston, Fishery Research Biologist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Prepared effects of the alternatives on the ecosystem and assisted in the preparation of the ecosystem section of Chapter 3. Twenty-five years experience in trophic ecology and ecosystem modeling of North Pacific ecosystems. Program leader of Resource Ecology and Ecosystem Modeling Program. *M.S. in Quantitative Fisheries Management, and MPA in Natural Resource Administration, University of Washington.*

Dr. Thomas R. Loughlin, Wildlife Biologist, National Marine Mammal Laboratory, Alaska Fisheries Science Center, NOAA Fisheries. Helped prepare marine mammal section and reviewer for impact sections. Twenty-five years as a marine biologist. *M.A. in Biology, Humboldt State University; Ph.D. UCLA.*

Sandra Lowe, Research Fisheries Biologist, Resource Ecology and Fisheries Management, Alaska Fisheries Science Center, NOAA Fisheries. Assisted in the preparation of the impacts of the alternatives on target groundfish species. Conducted review of the Atka mackerel section of Chapter 3. Twenty years experience as a fisheries biologist working on stock assessments of North Pacific groundfish. Member of the North Pacific Fishery Management Council's Gulf of Alaska Plan Team since 1987, and has chaired the Plan Team since 1991. *M.S. in Fisheries, University of Washington.*

Dr. Robert McConnaughey, Fisheries Biologist, Resource Assessment and Conservation Engineering Division, Alaska Fisheries Science Center, NOAA Fisheries. Member of Habitat Working Group. Also contributed to sections on fishing gear effects, benthic invertebrates, Habitat Areas of Particular Concern and Bering Sea substrates. *B.S. in Zoology and M.S. in Marine and Estuarine Environmental Sciences, University of Maryland; Ph. D. in Fisheries Science, University of Washington.*

Jon McCracken, Economist, North Pacific Fishery Management Council. Assisted in preparation of Fishery Management Plan summaries. Four years experience as a Council analyst, 12 years as an economist. *B.A. Economics, University of Northern Colorado; M.S. Resource Economics, University of Alaska, Fairbanks.*

Mark W. Nelson, Fisheries Biologist, Stock Assessment Scientist, Pacific States Marine Fisheries Commission. Wrote the forage species section of Chapter 4 and reviewed the forage species section of Chapter 3 in the current document. 5 years experience working on the trophic interactions of groundfish species in Alaskan waters and on the West Coast. Currently on staff at Pacific States Marine Fisheries Commission developing a stock assessment for the forage species category. *B.S. Fisheries Biology, and currently working on a M.S. Fisheries Biology, University of Washington, Seattle, Washington.*

Victoria O'Connell, Fisheries Biologist, Groundfish Project, Southeast Region, Alaska Department of Fish and Game. Prepared impact of alternatives section on demersal shelf rockfish. Twenty years of experience as a fishery biologist related to research and management of commercial marine fisheries. *B.S. University of Washington, School of Fisheries.*

Dr. Clarence Pautzke, Executive Director, North Pacific Research Board (starting January 1, 2002), and ex-Executive Director of the North Pacific Fishery Management Council (1988-2001). Advising the U.S. Secretary of Commerce on management of fisheries in the federal 3 to 200 mile Exclusive Economic Zone off Alaska since 1988. Prepared the Evolution of Fishery Management Plans. Eight years experience as the Council's Deputy Director from 1980 to 1988, and Assistant to the Executive Director of the Pacific States Marine Fisheries Commission in Portland, Oregon, from 1978 to 1980. *Ph. D. in Oceanography, University of Washington, Seattle.*

Kim Rivera, Wildlife Biologist, Protected Resources Division, Alaska Regional Office, NOAA Fisheries. Contributed to the Environmental Consequences section on seabirds, contributed material to Affected Environment sections about Endangered Species Act Considerations for seabirds, and coordinated review by US Fish and Wildlife Service of some seabird sections. Nine years experience with NOAA Fisheries. *M.S. in Zoology, Colorado State University.*

Dr. Craig S. Rose, Research Fisheries Biologist, Resource Assessment and Conservation Engineering Division, Alaska Fisheries Science Center, NOAA Fisheries. Participated in preparing summary of research on effects on fishing on seabed communities and analysis of effects on essential fish habitat. Twenty-five years experience as a fisheries biologist, and team leader of the Alaska Fisheries Science Center fishing gear research program for 15 years. *M.S. and Ph.D. in Fisheries Biology, University of Washington.*

Susan Salveson, Assistant Administrator, Sustainable Fisheries Division, Alaska Region, NOAA Fisheries. Prepared Description of Fisheries in the Bering Sea/Aleutian Island and Gulf of Alaska. Twenty years experience as a fisheries biologist. *M.S. in Fisheries Biology, University of Alaska, Southeast.*

Jennifer Sepez, Anthropolgist, Economics and Social Science Research Program, Alaska Fisheries Science Center, NOAA Fisheries. Reviewed and commented on sections on Subsistence, Environmental Justice Existing Conditions, Community Development Quota Program, and Historical Overview. Also reviewed Alaska Natives Qualitative Analysis Paper. *M.A Cultural Anthropology, and Ph. D. Environmental Anthropology, University of Washington.*

Maria Shawback, Graphic Artist/Secretary, North Pacific Fishery Management Council. Formatted and finalized the Programmatic SEIS Fishery Management Plan Amendment summaries document for publication and coordinated the graphics and layout throughout. Eight years experience working with computer graphics, websites, and providing administrative support, the last year with the North Pacific Fishery Management Council. *BFA in Commercial Art, Utah State University, Logan, Utah.*

Kim Shelden, Marine Biologist, National Marine Mammal Laboratory, Alaska Fisheries Science Center, NOAA Fisheries. Review of Section 3.8 (cetaceans). Thirteen years evaluating abundance and distribution of marine mammals in Alaska, Washington, and California waters. *B.S. Environmental Science/Marine Studies, Rutgers University; M.M.A. Marine Policy/Conservation Biology, University of Washington.*

Dr. Michael Sigler, Mathematical Statistician, Auke Bay Laboratory, Alaska Fisheries Science Center, NOAA Fisheries. Prepared impacts of the alternatives on sablefish in Alaska. Nineteen years experience with stock assessment and population dynamics. *B.S. and M.S. Cornell University; Ph.D. University of Washington.*

Dr. Paul Spencer, Research Fisheries Biologist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Contributed to the effects of the alternatives on essential fish habitat section, and prepared the impact of the alternatives section on Bering Sea/Aleutian Island Pacific ocean perch, other red rockfish, flathead sole and other flatfish. Conducted reviews of the Bering Sea/Aleutian Islands Pacific ocean perch and other rockfish sections of Chapter 3. Seventeen years experience in fisheries biology/population dynamics and stock assessment modeling. *Ph.D. in Oceanography, University of Rhode Island.*

Dr. Diana L. Stram, Plan Coordinator/Oceanographer, North Pacific Fishery Management Council. Served as an analyst and dedicated project coordinator between NOAA Fisheries and contractor. Provided assistance to the Project Manager throughout document development and preparation. Assisted in the development of programmatic alternatives for the revised draft, drafted sections of the revised document and assisted in the review and synthesis of comments on the previous draft and preparation of the comment analysis report. Eight years experience in oceanographic research and coastal resource management, two years experience in Alaskan fisheries-related Environmental Impact Statements/Environmental Assessments. *B.A. Geology, Colgate University; Ph.D. Oceanography, University of Rhode Island.*

Dr. Joe Terry, Economist, Economic and Social Sciences Research Program Leader, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Assisted with developing the Alternative 3 model regime; preparing exvessel price data used in the catch optimization models, preparing the catch distribution data that were used to apportion catch optimization model output by processing sector and vessel category, preparing product value per unit of retained catch data used to estimate product value by processing sector, and reviewing several sections. Twenty-six years of experience assessing effects on fisheries off Alaska. *Ph.D. in Economics, University of California, Santa Barbara.*

Dr. Grant Thompson, Fisheries Research Biologist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Prepared the evaluation of biological impacts of alternatives on Pacific cod as a target species. Conducted reviews of the Pacific cod section of Chapter 3 and the Total Allowable Catch-setting and spatial and temporal management qualitative analysis papers. Twenty-two years experience in fisheries research. Currently a stock assessment analyst and is responsible for contribution to two stock assessment and fishery evaluation documents for the North Pacific Fishery Management Council. *M.S., Ph.D. Oregon State University.*

Benjamin J. Turnock, Fishery Biologist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Prepared the Arrowtooth flounder and other flatfish in the Gulf of Alaska sections. Twenty years experience as a fishery biologist working on stock assessment of marine fish, population dynamics modeling and population estimation methods of fish and marine mammals. *Working on a Ph.D. in Fisheries Science at the University of Washington.*

Tom Wilderbuer, Fishery Biologist, Resource Ecology and Fisheries Management Division, Alaska Fisheries Science Center, NOAA Fisheries. Prepared impact analyses sections on Bering Sea and Gulf of Alaska flatfish species. Twenty-two years experience as a fishery biologist working on stock assessment of flatfish populations off Alaska. *M.S. degree in Fisheries, University of Washington.*

David Witherell, Deputy Director, North Pacific Fishery Management Council. Prepared discussion of ecosystem-based management and history of habitat protection measures. Eighteen years of experience as a fisheries biologist. *M.S. in Fisheries Biology, University of Massachusetts, Amherst.*

6.3 Consultant Team List

Project Leaders

Jon Isaacs, Associate Planner, Director of Business Development, URS Anchorage. Consultant team project manager. Assisted with Environmental Impact Statement scoping and issue identification; lead for National Environmental Policy Act process oversight; contributor to cumulative effects analysis. Twenty-eight years of Alaska experience, primarily in National Environmental Policy Act compliance, coastal management and community planning. Participated in preparation of 16 Environmental Impact Statements and numerous Environmental Assessments. *B.A. Environmental Studies, University of California, Santa Barbara; Graduate Studies Planning and Economics, University of Alaska, Anchorage.*

Anne Maki, Consultant Team Deputy Project Manager, URS Anchorage. Responsible for project team coordination and oversight. Co-task leader for ecosystem and resource issues for the consultant team. Contributor to the development of cumulative impact analysis, socioeconomic sections of Chapter 3, socioeconomic cumulative effects in Chapter 4, and the Alaska Native Issues qualitative analysis paper. Over three years of experience preparing National Environmental Policy Act documents. Ms. Maki has a broad technical background including water quality assessment and ecological risk assessment. *B.S. Environmental Science and Communications, Indiana University, Bloomington, Indiana; M.S. Environmental Science - Water Quality, University of North Texas, Denton, Texas.*

Task Leaders

Sue Ban, Project Biologist, URS Anchorage. Co-task leader for cumulative impact analysis for the consultant team. Coordinated historical review and development of cumulative impact analysis approach; assimilated impact analyses from environmental consequences narratives, co-author of the target fish and the essential fish habitat sections of Chapter 3. She was also the primary author for the marine protected areas and essential fish habitat qualitative paper. Prepared comment analyses, response to comments, the Comment Analysis Report for the first Draft Programmatic SEIS. Eighteen years of experience in Environmental Impact Statements/Environmental Assessments and ecological risk assessments under National Environmental Policy Act. *B.S. Biology, Pennsylvania State University; M.S. Biological Oceanography, Florida Institute of Technology.*

Marcus Hartley, Senior Economist, Northern Economics, Inc. Serves as the Socioeconomics task leader for the project consultants. Coordinated preparation of the sector and regional profiles. Twelve years of direct experience as a fisheries economist in Alaska, four years as Senior Economist for the North Pacific Fishery Management Council, and three years as senior economist with Northern Economics. Has prepared more than 15 Environmental Impact Statements/Environmental Assessments on fisheries in Alaska. *B.A. History, Lewis and Clark College; M.S. Agriculture and Resource Economics, Oregon State University.*

Joyce Payne, Biologist and Certified Entomologist, URS Anchorage. Assisted consultant team in the historical review of cumulative impacts issues. Coordinated efforts on Chapter 3 and developed the past effects criteria for analysis; co-authored Chapter 3 sections general approach and methods and Fishery Management Plan analysis; and documentation of response to comments. Ms. Payne has a broad background of technical experience in bioassessments, fauna and flora surveys, environmental sampling, data management, educational material development, and implementation of National Pollutant Discharge Elimination System compliance programs. *B.S. Agricultural Biology, and M.S. Agricultural Biology, Entomology Option, New Mexico State University.*

Donald M. Schug, Socioeconomic Analyst, Northern Economics, Inc. Co-task leader with Marcus Hartley for economic issues for the consultant team. Co-authored the harvesting and processing sector profiles, market channels and benefits to U.S. consumers, and non-market goods and services sections of Chapter 3 and the overcapacity, gear restrictions and allocations (with Richard Tremaine), and data and reporting requirements qualitative analysis papers. Professional experience includes a wide range of fisheries-related research and applied work in the United States and abroad. He has worked extensively in the Pacific islands and was staff economist of the Western Pacific Fishery Management Council. *B.S. Biology, Eckerd College; M.S. Oceanography, University of South Florida; M.S. Agricultural and Resource Economics, and Ph.D. Geography, University of Hawaii.*

Contributors

Patrick Burden, President and Principal Economist of Northern Economics, Inc., Anchorage. Contributor and senior reviewer for socioeconomic evaluation and assessment for the consultant team. Twenty-five years of economic consulting experience, including significant involvement in analyzing impacts of groundfish and crab management regulations on communities and infrastructure development projects throughout Alaska. *B.S Business Administration, and M.S. Economic Geography, Portland State University; Graduate work toward Ph.D. with emphasis on regional economics and modeling, University of Washington.*

Kimberli Busse, Staff Biologist, URS Anchorage. Assisted in public comment analysis, documentation, and Access database entry for the 2001 Draft Programmatic SEIS Comment Analysis Report. Co-authored revisions of various “other” and “non-specified” species sections, and assisted in revisions of marine mammals and seabirds sections for the 2003 Draft Programmatic SEIS. Over 5 years of experience specializing in technical writing and biological studies. *B.S. Biology, Loyola Marymount University, Los Angeles, California.*

Dr. Joseph Colonell, Principal Engineer and Oceanographer, URS Anchorage. Co-authored physical oceanography section of Chapter 3. Over 35 years of experience conducting and managing physical oceanographic studies, environmental baseline investigations, and marine engineering. His physical oceanographic work includes research on deep-water exchange processes between Gulf of Alaska and fjords and inlets along southeast and southcentral Alaska coast; baseline investigations and assessments of environmental impacts of resource development activities along coasts of Gulf of Alaska, and Bering, Chukchi and Beaufort Seas; and development of engineering design criteria for offshore platforms, subsea pipelines, and wastewater outfalls in virtually all Alaska coastal waters, several locations on U.S. Pacific and Atlantic coasts and Caribbean, Caspian, and South China Seas. *B.S. Civil Engineering, University of Colorado, Boulder; M.S. Civil Engineering and Applied Mathematics, Washington State University, Pullman; Ph.D. Civil Engineering and Applied Mathematics, Stanford University, Palo Alto, California*.

Joyce Congdon, Word Processor, URS Anchorage. Served as Senior Word Processor during the preparation of this Programmatic SEIS. Twenty-five years of keyboarding and administrative experience. Responsible for coordination and preparation of all types of written and electronic deliverables. *A.A. General Studies, University of Alaska, Anchorage.*

Dr. Michael Downs, Principal and Senior Social Scientist, EDAW, Inc. Author of the regional, Community Development Quota, subsistence, environmental, and environmental justice components of the socioeconomic analysis for the consultant team. Has performed socioeconomic assessments related to resource development and management in Alaska for the past 22 years, as well as in Hawaii, the lower 48, and the Caribbean. Thirteen years experience with North Pacific groundfish management social impact assessment as a contractor to the North Pacific Fishery Management Council. *Ph.D. Cultural Anthropology, University of California, San Diego.*

Laura L. Desmond, Marketing Coordinator, URS Anchorage. Assisted with document review and consolidation for the consultant team, and provided NOAA Fisheries support. Ms. Desmond has two years of experience writing proposals, and coordinates marketing for the Anchorage office. *B.S. Business Administration, in progress, University of Alaska.*

Dave Erikson, Senior Biologist, URS Homer. Co-authored the marine mammals, and seabirds sections of Chapter 3 and 4 and the Steller sea lion protection measures and seabird protection measures qualitative analysis papers. Over 20 years of experience specializing in biological studies. His coastal and marine ecosystem project involvement includes early baseline studies for the Outer Continental Shelf Environmental Assessment Program in Cook Inlet, Prince William Sound and the Gulf of Alaska; shoreline damage assessment studies following the *Exxon Valdez* Oil Spill; and a wide range of terrestrial and marine environmental studies in support of EISs on resource development projects in Alaska. *B.S. Wildlife Biology, and M.S. Biology, University of Nevada, Reno, Nevada.*

Dr. Robert Fechhelm, Senior Fisheries Biologist/Ecologist, LGL Alaska Research Associates, Inc. Twenty-one years of experience in Alaskan fisheries research. Co-authored qualitative review of bycatch policy alternatives under consideration by the North Pacific Fishery Management Council. Member of consultant team contributing to the Alaska Groundfish Fisheries Draft Programmatic SEIS cumulative effects section. Assisted with preparation of EISs for the U.S. Navy, U.S. Air Force, and Minerals Management Service. Principal author addressing fishery issues for an EIS of a planned offshore gas pipeline in northern Alaska/Canada. Principal author for the background section on freshwater and anadromous fisheries, and co-author of the marine, freshwater, and anadromous fish cumulative impact sections for a 30-year update Environmental Assessment/Environmental Impact Statement of the Trans-Alaskan Pipeline System. *B.S. Marine Science, Southampton College, New York; M.S. Wildlife and Fisheries Sciences, and Ph.D. Wildlife and Fisheries Sciences, Texas A&M University.*

Dr. Benny Gallaway, Senior Fisheries Ecologist and President, LGL Ecological Research Associates, Inc. Thirty years of experience dealing with fishery and environmental impact assessment issues in Alaska and the Gulf of Mexico. Co-authored qualitative review of bycatch policy alternatives and TAC alternatives under consideration by the North Pacific Fishery Management Council. Prepared a series of impact assessments for the Trans-Alaska Pipeline Liability Fund regarding the *Exxon Valdez* oil spill. Provided expert testimony before the senior review board of the U.S. Army Corp of Engineers, Washington, D.C., regarding potential environmental impacts of Arctic oil exploration and development. Author of 53 peer-reviewed publications. *Ph.D. Wildlife and Fisheries Sciences, Texas A&M University.*

Richard Kleinleder, Biologist, URS Homer. Co-authored the threatened and endangered species, marine mammal, and seabird sections of Chapter 3, the seabird protection measures and Steller sea lion protection measures qualitative analysis papers, and the seabird section of Chapter 4. Also contributed to Chapters 1 and 2 and the Appendices. Over 20 years of experience in terrestrial and marine biological studies throughout Alaska. Adjunct Faculty in ornithology at Kenai Peninsula College, Kachemak Bay Branch. Certified Ecologist with the Ecological Society of America. *B.S. Biology and Environmental Studies, Indiana University, Bloomington; M.S. Biology, University of Alaska, Fairbanks*

Earl L. Kubaskie, Jr., CADD/TI Supervisor, URS Anchorage. Assisted with report production and technical illustration. Ten years of technical experience working on National Environmental Policy Act projects.

Colleen Lavery, Environmental Planner, URS Anchorage. Co-authored/edited Historical Overview, Regional Socioeconomic Profiles, Community Development Quota Program, and Market Channels and Benefits sections of Chapter 3, the socioeconomic cumulative impact analysis section of Chapter 4, and the Alaska Native Issues paper. Ms. Lavery specializes in economic and socioeconomic analysis, as well as cumulative effects analysis and elements of subsistence, Native issues, and Environmental Justice. Other relevant experience includes preparation of the City of Seward Comprehensive Plan, North Pacific Fishery Management Council Bering Sea Aleutian Islands Crab Environmental Impact Statement, and the City of Sand Point Economic Development Strategy Plan. *B.S. Forestry and Natural Resources Management, concentration in Facilitation, California Polytechnic State University, San Luis Obispo, California.*

Kristin Marsh, Field Technician, URS Anchorage. Co-author of the target and forage fish species of Chapter 3 and assisted with the physical environment section. Conducted the cumulative effects analysis of target and forage fish. Assisted with response to comments, list of preparers and document preparation. Three years experience in wetland delineations and environmental sampling. *B.A. in Environmental Science, Biology Concentration, in progress, Alaska Pacific University.*

Kelley Nixon, Environmental Technician, URS Anchorage. Assisted in the review of technical papers, books, and other documents to identify potential sources of Traditional Knowledge for incorporation in the Environmental Impact Statement. *B.A. Sociology, Rhodes College, Memphis Tennessee.*

Becky Romano, Environmental Scientist/Toxicologist, URS Anchorage. Co-author of the prohibited species, other species, and non-specified species sections of Chapter 3. Updated comparative baseline data and authored cumulative effects sections of Chapter 4 for the non-target species. Developed tables and figures inventory. Four years of experience in regulatory toxicology, chemical compliance, and occupational risk assessment. *B.S. Animal Science, Michigan State University, E. Lansing, Michigan; Dual M.S. Animal Science and Toxicology, Oregon State University, Corvallis, Oregon.*

Robert Senner, Senior Scientist, URS Fairbanks. Responsible for developing the cumulative effects methodology and co-author of the Chapter 3 and Chapter 4 ecosystem sections. Twenty-five years of Alaskan experience as a National Environmental Policy Act specialist responsible for environmental program management, impact assessment, and preparation of National Environmental Policy Act documents. *B.S. Biology, Yale University; D.Phil. Certification Physiology, University of St. Andrews; Ph.D. Candidate, Public Policy, The University of Texas, Austin.*

Rachael G. Stavley, Environmental Technician, URS Anchorage. Coordinated document review and consolidation for the consultant team, and provided NOAA Fisheries support. Ms. Stavley has five years of experience in research and synthesis of documents and data in support of Environmental Impact Statements and Environmental Assessments. *B.S. Natural Sciences, in progress, University of Alaska.*

Ivan Vasquez, Word Processor, URS Anchorage. Served as Lead Word Processor during the preparation of the Final Programmatic SEIS. Twenty years of keyboarding and graphics experience. Responsible for coordination and preparation of all types of written and electronic deliverables.

Laura A. Young, Technical Illustrator, URS Anchorage. Ms. Young has more than 13 years experience as an environmental and engineering technician. She is responsible for performing all phases of project work including: management, work plan and scope development, data collection, data interpretation, literature reviews, CAD and Geographic Information System, and reporting. Ms. Young assisted with public hearings, graphics development, coordination of document production, and document review and consolidation for the consultant team. *B.S. Environmental Studies, in progress, University of Alaska, Anchorage.*

6.4 Individuals, Agencies, and Organizations Consulted during the Preparation of this Programmatic SEIS

Greg Balogh, U.S. Fish and Wildlife Service, Anchorage, AK.

Bill Bechtol, Alaska Department of Fish & Game, Anchorage, AK

Tony DeGange, U.S. Fish and Wildlife Service, Anchorage, AK

Todd DuBois, NOAA Fisheries Enforcement

Kevin Duffy, Alaska Department of Fish & Game, Anchorage, AK

Fritz Funk, Alaska Department of Fish & Game, Juneau, AK.

A.J. Gharrett, University of Alaska Fairbanks

Robin Harrison, NOAA Fisheries, Alaska Fisheries Science Center

James Hoff, NOAA Fisheries, Alaska Fisheries Science Center

Dave Irons, U.S. Fish and Wildlife Service, Anchorage, AK.

Alan Kinsolving, NOAA Fisheries, Alaska Regional Office.

Earl Krygier, Alaska Department of Fish & Game, Anchorage, AK

Kathy Kuletz, U.S. Fish and Wildlife Service, Anchorage, AK

Robert Lauth, NOAA Fisheries, Alaska Fisheries Science Center

Tori O'Connell, Alaska Department of Fish and Game, Anchorage, AK

Jay Orr, NOAA Fisheries, Alaska Fisheries Science Center

Mei-Sun Yang, NOAA Fisheries, Alaska Fisheries Science Center

Peter Yodzis, University of Guelph, Ontario, Canada

Harold Zenger, NOAA Fisheries, Alaska Fisheries Science Center

Management Tools	Section 2.5 (description)
Marine Mammal Protection Act	Section 2.2.2 (description) Section 4.11.1.1(federal statutory requirements)
Marine Mammals	Section 3.8 (background) Section 4.1.1.4 (significance of potential consequences) Section 4.1.3.4 (direct and indirect analysis) Sections 4.5.8, 4.6.8, 4.7.8, 4.8.8, 4.9.8 (bookend impacts) Sections 4.10.2.5, 4.10.3.5, 4.10.4.5, 4.10.5.5, 4.10.6.6 (policy impacts) Appendix F-4 (description and qualitative analysis)

Issues:	Sections:
Marine Protected Areas (MPAs)	Appendix F-3 (description and qualitative analysis) Sections 4.5.6, 4.6.6, 4.7.6, 4.8.6, 4.9.6 (bookend impacts) Sections 4.10.4.6, 4.10.5.6, 4.10.6.7 (policy impacts)
Market Channels	Section 3.9.7 (background) Sections 4.5.9.6, 4.6.9.6, 4.7.9.6, 4.8.9.6, 4.9.9.6 (bookend impacts)
Methodology	Section 4.1 (description)
Minke Whale	Section 3.8.14 (background) Sections 4.5.8.8, 4.6.8.8, 4.7.8.8, 4.8.8.8, 4.9.8.8 (bookend impacts)
Magnuson-Stevens Fishery Conservation and Management Act	Section 2.2 (description) Section 4.11.1 (policy impacts)
Murrelets	Section 3.7.17 (background) Sections 4.5.7.5, 4.5.7.6, 4.6.7.5, 4.6.7.6, 4.7.7.5, 4.7.7.6, 4.8.7.5, 4.8.7.6, 4.9.7.5, 4.9.7.6 (bookend impacts) Appendix F-6 (description and qualitative analysis)
Murres	Section 3.7.15 (background) Sections 4.5.7.6, 4.6.7.6, 4.7.7.6, 4.8.7.6, 4.9.7.6 (bookend impacts) Appendix F-6
National Environmental Policy Act Compliance and Public Process	Section 1.4 (description) Section 1.5 (description)
National Research Council	Section 5.1 (description)
Non-Market Goods and Services	Section 3.9.8 (background) Sections 4.5.9.7, 4.6.9.7, 4.7.9.7, 4.8.9.7, 4.9.9.7 (bookend impacts)
Non-Specified Species	Section 3.5.5 (background) Sections 4.5.5, 4.6.5, 4.7.5, 4.8.5, 4.9.5 (bookend impacts)
North Pacific Fishery Management Council	Section 2.1 (description) Section 2.4 (description) Section 5.1.1.2
North Pacific Research Board	Section 5.1.1.3 (description)
Northeast Pacific Ocean	Section 3.3.1 (background)

Issues:	Sections:
Northern Elephant Seal	Section 3.8.9 (background) Sections 4.5.8.5, 4.6.8.5, 4.7.8.5, 4.8.8.5, 4.9.8.5 (bookend impacts)
Northern Fulmars	Section 3.7.5 (background) Sections 4.5.7.4, 4.6.7.4, 4.7.7.4, 4.8.7.4, 4.9.7.4 (bookend impacts) Appendix F-6
Northern Fur Seal	Section 3.8.2 (background) Sections 4.5.8.3, 4.6.8.3, 4.7.8.3, 4.8.8.3, 4.9.8.3 (bookend impacts)
Northern Right Whale	Section 3.8.17 (background) Sections 4.5.8.8, 4.6.8.8, 4.7.8.8, 4.8.8.8, 4.9.8.8 (bookend impacts)
Notice of Availability	Section 1.6 (description) Appendix K
Notice of Intent	Appendix K
Observer Program	Appendix F-10 (description and qualitative analysis) Sections 4.10.2.9, 4.10.3.9, 4.10.4.9, 4.10.5.9, 4.10.6.10 (policy impacts)
Octopus	Section 3.5.3.5 (background) Sections 4.5.3, 4.6.3, 4.7.3, 4.8.3, 4.9.3 (bookend impacts)
Offal	Section 3.10.2 (background)
Overcapacity	Sections 4.5.9, 4.6.9, 4.7.9, 4.8.9, 4.9.9 (bookend impacts) Appendix F-8 (description and qualitative analysis)
Pacific Cod	Sections 3.5.1.2, 3.5.1.14 (background) Sections 4.5.1.2, 4.6.1.2, 4.7.1.2, 4.8.1.2, 4.9.1.2 (bookend impacts)
Pacific Halibut	Section 3.5.2.1 (background) Sections 4.5.2.1, 4.6.2.1, 4.7.2.1, 4.8.2.1, 4.9.2.1 (bookend impacts)
Pacific Herring	Section 3.5.2.3 (background) Sections 4.5.2.3, 4.6.2.3, 4.7.2.3, 4.8.2.3, 4.9.2.3 (bookend impacts)
Pacific Northwest Salmon	Section 3.4.2 (background)

Issues:	Sections:
Prohibited Species	Section 3.5.2 (background) Section 4.1.1.1 (significance of potential consequences) Section 4.1.3.1 (direct and indirect analysis) Sections 4.5.2, 4.6.2, 4.7.2, 4.8.2, 4.9.2 (bookend impacts) (policy impacts)
Puffins	Section 3.7.19 (background) Sections 4.5.7.6, 4.6.7.6, 4.7.7.6, 4.8.7.6, 4.9.7.6 (bookend impacts) Appendix F-6 (description and qualitative analysis)
Purpose and Need	Section 1.1 (description) Section 1.3 (background)
Qualitative Analysis Papers	Section 4.3 (description) Appendix F (qualitative analyses)
Red-Legged Kittiwakes	Appendix F-6 (description and qualitative analysis)
Regime Shift	Section 3.10.1.5 (description and background) Sections 4.5.10, 4.6.10, 4.7.10, 4.8.10, 4.9.10 (bookend impacts)
Regional Profiles	Section 3.9.3 (background) Sections 4.5.9.2, 4.6.9.2, 4.7.9.2, 4.8.9.2, 4.9.9.2 (bookend impacts)
Research	Section 5.1 (description of priorities, ongoing research, and research needs)
Rex Sole	Section 3.5.1.21 (background) Sections 4.5.1.10, 4.6.1.10, 4.7.1.10, 4.8.1.10, 4.9.1.10 (bookend impacts)
Ribbon Seal	Section 3.8.8 (background) Sections 4.5.8.5, 4.6.8.5, 4.7.8.5, 4.9.8.5, 4.9.8.5 (bookend impacts)
Ringed Seal	Section 3.8.7 (background) Sections 4.5.8.5, 4.6.8.5, 4.7.8.5, 4.9.8.5, 4.9.8.5 (bookend impacts)
Rock Sole	Section 3.5.1.6 (background) Sections 4.5.1.6, 4.6.1.6, 4.7.1.6, 4.8.1.6, 4.9.1.6 (bookend impacts)
Rockfish	Section 3.5.1.12, 3.5.1.23, 3.5.1.24 (background) Sections 4.5.1.12, 4.5.1.13, 4.6.1.12, 4.6.1.13, 4.7.1.12, 4.7.1.13, 4.8.1.12, 4.8.1.13, 4.9.1.12, 4.9.1.13 (bookend impacts)

Issues:	Sections:
Skates	Section 3.5.3.4 (background) Sections 4.5.3, 4.6.3, 4.7.3, 4.8.3, 4.9.3 (bookend impacts)
Sources of Data	Section 2.5.2 (background)
Spatial/Temporal Management of Total Allowable Catch	Appendix F-2 (qualitative analysis)
Spectacled Eider	Section 3.7.9 (background) Sections 4.5.7.8, 4.6.7.8, 4.7.7.8, 4.8.7.8, 4.9.7.8 (bookend impacts) Appendix F-6 (description and qualitative analysis)
Sperm Whale	Section 3.8.19 (background) Sections 4.5.8.7, 4.6.8.7, 4.7.8.7, 4.8.8.7, 4.9.8.7 (bookend impacts)
Spotted Seal	Section 3.8.5 (background) Sections 4.5.8.5, 4.6.8.5, 4.7.8.5, 4.8.8.5, 4.9.8.5 (bookend impacts)
Squid	Section 3.5.3.1 (background) Section 4.5.3, 4.6.3, 4.7.3, 4.8.3, 4.9.3 (bookend impacts)
Statutory Requirements	Section 2.2.2 (background) Section 4.11.1.1 (policy impacts)
Steller Sea Lion	Section 3.8.1 (background) Sections 4.5.8.1, 4.6.8.1, 4.7.8.1, 4.8.8.1, 4.9.8.1 (bookend impacts) Appendix F-4 (descriptions and qualitative analysis)
Steller's Eider	Section 3.7.10 (background) Sections 4.5.7.8, 4.6.7.8, 4.7.7.8, 4.8.7.8, 4.9.7.8 (bookend impacts) Appendix F-6 (description and qualitative analysis)
Storm-Petrels	Section 3.7.7 (background) Sections 4.5.7.7, 4.6.7.7, 4.7.7.7, 4.8.7.7, 4.9.7.7 (bookend impacts) Appendix F-6 (description and qualitative analysis)
Structure of the Alternatives/SEIS	Section 1.7 (document organization) Section 2.6 (alternatives) Section 4.2.1 (analytical framework/ bookends)

Issues:	Sections:
Subsistence	Section 3.9.5 (background) Sections 4.5.9.4, 4.6.9.4, 4.7.9.4, 4.8.9.4, 4.9.9.4 (bookend impacts) Appendix F-9 (description and qualitative analysis)
Total Allowable Catch (TAC)-Setting Process	Appendix F-1 (description and qualitative analysis) Sections 4.10.2.2, 4.10.3.2, 4.10.4.2, 4.10.5.2, 4.10.6.2 (policy impacts)
Terns	Section 3.7.14 (background) Sections 4.5.7.6, 4.6.7.6, 4.7.7.6, 4.8.7.6, 4.9.7.6 (bookend impacts) Appendix F-6 (description and qualitative analysis)
Threatened and Endangered Species	Section 3.4 (background)
Toothed Whales	Section 3.8 (background) Sections 4.5.8.6, 4.5.8.7, 4.6.8.6, 4.6.8.7, 4.7.8.6, 4.7.8.7, 4.8.8.6, 4.8.8.7, 4.9.8.6, 4.9.8.7 (bookend impacts)
Walleye Pollock	Section 3.5.1.1, 3.5.1.13 (background) Sections 4.5.1.1, 4.6.1.1, 4.7.1.1, 4.8.1.1, 4.9.1.1 (bookend impacts)
Walrus	Section 3.8.3 (background) Sections 4.5.8.5, 4.6.8.5, 4.7.8.5, 4.8.8.5, 4.9.8.5 (bookend impacts)
Yellowfin Sole	Section 3.5.1.5 (background) Sections 4.5.1.5, 4.6.1.5, 4.7.1.5, 4.8.1.5, 4.9.1.5 (bookend impacts)
