## INTRODUCTION

Over the past several years ichthyoplankton surveys have been made in the eastern Bering Sea by the Northwest and Alaska Fisheries Center (NWAFC) for a variety of purposes (Waldron and Favorite, 1977; Waldron and Vinter, 1978; Waldron, 1978). The main objective in these studies was to assess walleye pollock (Theragra chalcogramma) eggs and larvae to determine spawning times and locations and to identify areas of high walleye pollock larval abundances. During the 1979 trawl and hydroacoustic survey of the adult walleye pollock population in the eastern Bering Sea, ichthyoplankton samples were taken to measure growth rates of field-caught larval walleye pollock by enumerating daily growth increments of the otolith. These results have been presented elsewhere (Walline, 198ø). This report describes the distribution and abundance of the ichthyoplankton caught on the 1979 trawl and hydroacoustic survey of the eastern Bering Sea. Besides those surveys by the NWAFC previously mentioned, only a few investigations of the Bering Sea ichthyoplankton have been made. The reports of Kashkina (1970) and Maeda and Hirakawa (1977) include much of the Japanese data from cruises made by the Faculty of Fisheries, Hokkaido University, and Musienko (1963) reports on ichthyoplankton collected by the Bering Sea Expedition of 1958-1959.

These reports and the results from 41 other ichthyoplankton cruises in the eastern Bering Sea by U.S. r Russian, and Japanese biologists are summarized by Waldron (1979). He emphasizes the difficulty in comparing these data because the surveys were
conducted during different seasons using different nets and types of tows. Although the present survey was limited in time and area, the gear and methods used were identical to those of Waldron and Favorite (1977) and Waldron and Vinter (1978). These are the surveys to which the results can most easily be compared. It provides preliminary indications of spawning times and locations for some of the other commercially important species in the eastern Bering Sea.

## METHODS

Ichthyoplankton was collected from the Bering Sea on a cruise of the NOAA research vessel Miller Freeman from l June to 23 July 1979. The main objective of the cruise was to carry out a trawl and hydroacoustic survey of the adult walleye pollock population in the eastern Bering Sea, so the cruise track was intended to cover the entire shelf area between depths of $90-$ 460 m once. This allowed samples of ichthyoplankton to be taken from widely separated areas of the eastern Bering Sea (Fig. 1 , Table l), but allowed only limited time series observations at single locations. The cruise was divided into three legs: I (1 Jun-7 Jun), II (16 Jun-2 Jul), and III (8 Jul-23 Jul). Ichthyoplankton sampling was the primary mission on Leg I. The dates listed demarcate only the periods during which ichthyoplankton sampling occurred.

Plankton was collected using the procedures described by the National Marine Fisheries Service Resources Monitoring Assessment and Prediction (MARMAP) Field Group. The slight modifications
employed are described in Waldron and Vinter (1978).
Surface samples were collected using a modified Sameoto neuston sampler with a mouth opening of 30 x 50 cm and a net mesh of $5 \emptyset 5$ um towed for 10 min at $2-3$ knots. Plankton from deeper layers was collected with paired 0.6 m open bongo nets, one with 505 um mesh and the other with 333 um mesh. Double oblique tows were made from the surface to slightly more than 200 m depth, or to within $5-10 \mathrm{~m}$ of bottom in shallower water. Both of these tows and at least one CTD (Conductivity, Temperature, Depth) cast for salinity, temperature, and depth were made at nearly every station. On Leg I two stations were occupied for 48-h each. At the first, 8 bongo and 8 neuston tows were made, and at the second, 8 neuston and 15 bongo tows were made.

Both nets were equipped with calibrated mechanical flowmeters with digital readout. The data from the flowmeters was used to standardize the catches using procedures adapted from Kramer et al. (1972). For each haul a standard haul factor (SHFA) was calculated to convert catch to catch per $10 \mathrm{~m}^{2}$ surface area and another (SHFB) to convert catch to catch per $10 \emptyset 0 \mathrm{~m}^{3}$ (Table 1).

Sorting of fish eggs and larvae from neuston and 505-bongo samples was done through a contract with Texas Instruments, Inc., Dallas, Texas. The quality of sorting by this contractor had been evaluated previously and found to be acceptable (Waldron and Vinter, 1978). No samples from the present cruise were sorted to check thoroughness of sorting.

Eggs and larvae were identified at the NWAFC using criteria
developed inhouse from numerous published and unpublished sources. Only lø of 1479 eggs and 4 of 16,292 larvae were unidentified.

Common and scientific names used are those recommended by the American Fisheries Society.

## RESULTS

Ichthyoplankton samples were taken at 114 locations covering a large part of the eastern Bering Sea (Fig. l). Several locations were sampled more than once, resulting in a total of 130 neuston samples and 126 5ø5-bongo samples. At the two diel stations (Fig. 1), replicate bongo tows were made and therefore these two locations are over-represented in the catch totals.

A total of 136 casts were made for salinity, temperature, and depth. Temperatures in the upper mixed layer, where most of the larvae were caught, ranged from about $6^{\circ} \mathrm{C}$ to just over $8^{\circ} \mathrm{C}$. Bottom temperatures were less variable, being everywhere about $3.7^{\circ} \mathrm{C}$. The complete data set is available from NWAFC (Arthur $W$. Kendall, Jr.).

A combined total of 16,292 larvae were caught, of which $83 \%$ were caught in the neuston net. Just over $90 \%$ of the 1479 eggs were also caught in the neuston net.

Eggs from two families, Gadidae and Pleuronectidae, were present in both the bongo and neuston samples. In addition 6 eggs from the family Macrouridae were present in the bongo samples. Ten eggs could not be identified.

Fish larvae from 17 families occurred in the samples. All

17 were represented in the 505 -bongo samples, but only 14 in the neuston samples. Within the bongo catches, 21 taxa were identified to species and 4 to genus only. Twenty-five of the taxa represented in the neuston catch were identified to species and 4 to genus only (Table 2).

The larval catch for the bongo net is dominated by three taxa, walleye pollock, Sebastes spp., and Bathymaster spp., which account for $79 \%$ of the total catch. Two taxa, Bathymaster spp., and Lyconectes aleutensis, make up $82 \%$ of all larvae caught in the neuston net. Eggs of two species, walleye pollock and Limanda aspera, are the most abundant eggs in both nets and make up $89 \%$ of all eggs caught.

## Distribution of eggs

Both bongo and neuston catches show maximum concentrations of walleye pollock eggs at the stations farthest inshore (Figs. 2 and 3). However, at no station were eggs nearly as abundant as during the 1976 or 1977 surveys. Comparison of the numbers caught per $1 \emptyset \mathrm{~m}^{2}$ in the neuston and bongo nets confirms previous findings that only a small percentage of walleye pollock eggs occur in the upper 0.25 m of the water column.

All of the Limanda aspera eggs were taken at two locations, the inshore diel station (V09A-V16A) and the station SllA which was the station nearest the inshore diel station.

Sampling on this cruise was not done on a random basis. On Leg I stations were chosen in an attempt to find concentrations of larval walleye pollock. The two diel stations were established on the basis of the occurrence of larval walleye pollock in preliminary bongo tows. Therefore, the numbers of walleye pollock in Table 2 may not be completely representative of their numbers in the survey area, especially since at the two diel stations multiple bongo and neuston tows were made. However, in preparing the maps of the distribution of larval walleye pollock (and other species) only the first bongo and neuston catches at a location are plotted. Nearly all samples were taken at night, except at the diel stations, so numbers plotted can be compared without considering the problem of diel variations in avoidance.

The highest concentrations of larval walleye pollock encountered during this survey occurred at stations near the center of Bristol Bay (Fig. 4) as might have been expected. However, it was unexpected to find walleye pollock larvae occurring at deep-water stations occupied on a transect to Adak and at stations far to the north of the Pribilof Islands. The numbers are lower than those encountered during the 1976 and 1977 surveys and the larvae are larger. The size varied greatly between stations, even those as close as the two diel stations, indicating a complex spawning pattern (walline, 1980).

The second most abundant taxon of larvae in the bongo samples was Bathymaster spp. It occurred nearly everywhere in
the survey area except at some of the stations farthest inshore and at some of the deep-water stations in the center of the Bering Sea (Fig. 5).

Sebastes spp. is the only other taxon of which more than løø specimens were taken in the 505 -bongo nets. It occurred over the whole area except at the most inshore stations (Fig. 6). It occurred in somewhat greater numbers at the Bristol Bay stations.

Only a few pleuronectid larvae were caught. Flatfish larvae of species caught in spring surveys would probably be large enough to easily avoid the bongo net or would have become demersal by the time of year this survey was made (Table 3). However, 41 specimens of Hippoglossoides elassodon were caught while none were caught in the 1976 and 1977 surveys.

## Distribution of larvae: Neuston

The only taxa to occur in significant numbers in both the bongo and neuston nets was Bathymaster spp. This was the most abundant taxon in the neuston samples, with as many as 1,865 $\left(5 \emptyset / 1 \emptyset \mathrm{~m}^{2}\right)$ in a single sample (S42A). It was present over the entire survey area (Fig. 7).

The second most abundant species was Lyconectes aleutensis. This species occurred only at stations on the shelf (Fig. 8). None were caught near Adak or in the central Bering Sea.

The distributions of Hexagrammos decagrammus and Anoplopoma fimbria are similar in that both occur at many stations in low numbers (Figs. 9 and 10 ).

Ammodytes hexapterus occurred at 21 locations with most at
the inner stations in Bristol Bay (Fig. ll).
Finally, the areal distribution of the two cottids, Hemilepidotus hemilepidotus and Hemilepidotus jordani are similar but the former occurs at more stations and is more abundant (Figs. 12 and 13).

## DISCUSSION

There are several obvious differences in the results of this summer survey compared with the surveys made earlier in the year during 1976 and 1977. The lengths of many of the larvae occurring in both seasons has increased by the summer (Table 3). An exception to this trend are the hexagrammids which seem to have the same length frequency distributions in the early spring as in the summer.

The abundance of various species of ichthyoplankton also undergoes changes. Walleye pollock eggs and larvae are both less abundant. By June the peak spawning of pollock has passed. Flatfish larvae seem generally less abundant in summer, but this could result from increased avoidance by the larger larvae, especially those of species such as Lepidopsetta bilineata, and Atheresthes stomias whose spawning periods have passed by summer. Some species are more abundant in summer. The widespread occurrence of Bathymaster spp. larvae during this survey is the most striking example. Among taxa of possible commercial importance, larvae of Anoplopoma fimbria, Sebastes spp. and eggs of Limanda aspera were more abundant during this summer survey. The Limanda aspera eggs were taken in hauls in Bristol Bay in

June and indicate the initiation of spawning. Because these stations were occupied only at the start of the survey, the peak of spawning activity for this species was not delineated.

The composition of the summer ichthyoplankton is different from that encountered in spring. Some larvae occurred in this survey which were never encountered during the previous surveys. A few Pleuronectes quadrituberculatus larvae were caught but no eggs were taken. The low numbers caught ( 7 total) imply that the center of distribution was not located, but the results tend to confirm the spawning dates of May to mid-June found by Musienko (197Ø) and Waldron and Favorite (1977). Hippoglossoides elassodon larvae, which did not occur in the 1976-1977 surveys, were the most abundant flatfish larvae on this survey and were present at 12 stations. The number of eggs was much lower than in earlier surveys, indicating that the spawning season was nearly completed.

Some species occurring in earlier surveys were not found during this summer survey. Larvae of the smelt Mallotus villosus did not occur, but only two stations were occupied in the area near Unimak Pass where they were found during the 1977 survey. No Pholidae larvae were caught in 1979 and the species of larval Cottidae and Stichaeidae differed from those of the spring surveys.

Finally, the distribution of some of the species has changed by the summer. An example is the distribution of walleye pollock eggs. As Waldron and Favorite (1977) point out, the center of abundance for walleye pollock eggs differs for all surveys taken
so far, but comparison of the distribution of eggs depicted in Figure 2 with the distribution shown in earlier surveys shows that walleye pollock eggs are restricted to an area much farther inshore in summer. This confirms suggestions made by Serobaba (1968) that walleye pollock spawning proceeds from the shelf break onshore as the season progresses and the water warms. Since these surveys were not made during a single year, environmental conditions were not constant. A warming trend from 1976-1979 made the 1979 the warmest of the years being compared in this discussion. This would tend to accentuate differences observed as the season would be more advanced for a given date in 1979 as compared to 1976 or 1977. To overcome this shortcoming and those discussed earlier would require a more regular and systematic sampling program such as that outlined by Waldron (1979). However, even the massive program of $8, \varnothing \varnothing \varnothing-1 \varnothing, \varnothing \varnothing \varnothing$ samples he describes would not address problems of annual variations in the composition and abundance of the.
ichthyoplankton. In the present survey, for example, more bathymasterid larvae were caught than in all 43 surveys reviewed by Waldron (1979) combined. This is not likely to be the result of previous surveys having been mistimed with respect to maximum abundances of bathymasterid larvae since $55 \%$ of sampling effort in these surveys took place in the same months as this 1979 survey. To develop an understanding of why such events occur requires sampling intensively on smaller scales and attempting to relate changes in ichthyoplankton abundance to changes in the physical and biological environment. This work has barely begun in the eastern Bering Sea.

Table 1. (cont.)

1/ No bongo or neuston hauls made at Stns. $86,112,116$.

2/ Position is at time of first bongo haul at a station, except where bongo haul not made.

3/ Time is for first bongo haul at a station, except where bongo haul not made.
4/ Standard haul factor $A$ converts observed catch to catch per $10 \mathrm{~m}^{2}$. Standard haul factor $B$ converts observed catch to catch per $1000 \mathrm{~m}^{3}$.

Table 2. Ichthyoplankton, eastern Bering Sea, 1 June-23 July 1979. Catch by taxa,

| Taxa | 505 Bonqo |  |  |  |  | Neution net |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\begin{aligned} & \mathrm{obn}_{1} \\ & \mathrm{No}, \underline{1 /} \end{aligned}$ | $\begin{gathered} \text { Mean } \mathrm{Ng} \cdot / \\ 10 \mathrm{~m} \end{gathered}$ | $\square^{2 /}$ | $\begin{aligned} & \text { No. }+ \text { 3/ } \\ & \text { Same. } \end{aligned}$ | $\begin{aligned} & 4+ \\ & \text { same. } 4 \\ & \hline \end{aligned}$ | Obs. tio. | $\begin{gathered} \hline \text { Mean } \mathrm{Ng} \cdot \mathrm{l} \\ 10 \mathrm{~m} \\ \hline \end{gathered}$ |  | $\begin{aligned} & \text { No. + } \\ & \text { Samp. } \end{aligned}$ | $\begin{aligned} & 1+ \\ & \text { samp. } \end{aligned}$ |

1/ Obs. no. = Observed number. This is the actual number caught in the nets.
2/ = Porcentage of the total number caught in the net.
3/ No. + Samp. = Number of positive samples. This is the number of samples which contain specimens for a taxa.
4/ + Sarip. = Fercentage of poritive samples. Total amples for bongo were 118 and for neuston 130 .

Table 3. Mean and range of standard lengths in mm of some fish larvae caught in recent years during surveys of the eastern Bering Sea. The ' $N$ ' in the column for net means data is from neuston samples, the ' $B$ ' means the data is from bongo samples.
