National Oceanic and Atmospheric Administration
U.S. Department of Commerce

The Office of Coast Survey (OCS) is the Nation's only official chartmaker. As the oldest United States scientific organization, dating from 1807, this office has a long history. Today it promotes safe navigation by managing the National Oceanic and Atmospheric Administration's (NOAA) nautical chart and oceanographic data collection and information programs.

There are four components of OCS:
The Coast Survey Development Laboratory develops new and efficient techniques to accomplish Coast Survey missions and to produce new and improved products and services for the maritime community and other coastal users.

The Marine Chart Division acquires marine navigational data to construct and maintain nautical charts, Coast Pilots, and related marine products for the United States.

The Hydrographic Surveys Division directs programs for ship and shore-based hydrographic survey units and conducts general hydrographic survey operations.

The Navigational Services Division is the focal point for Coast Survey customer service activities, concentrating predominately on charting issues, fast-response hydrographic surveys, and Coast Pilot updates.

## EXECUTIVE SUMMARY

The National Ocean Service (NOS) of the National Oceanic and Atmospheric Administration (NOAA) has developed a three-dimensional hydrodynamic ocean model-based Cook Inlet Operational Forecast System (CIOFS) for Cook Inlet region of Alaska. The primary purpose of this model is to provide navigational mariners with water surface elevation (water level) and current forecast guidance, but in addition, it also generates temperature and salinity predictions which could be used to support oil spill, marine environment, ecological and ecosystem forecasting in the region.

CIOFS is based on Rutgers University's Regional Ocean Modeling System (ROMS) numerical ocean model. The model domain covers all of Cook Inlet and the waters leading to Cook Inlet around the Kodiak Archipelago, including Shelikof Strait to the south, and Stevenson Entrance, Kennedy Entrance and Chugach Passage to the southeast.

Three numerical simulations have been performed based on the availability of observed data sets. One tidal only simulation and two hindcast simulations were conducted. Ten tidal constituents ( $\mathrm{K}_{1}$, $\mathrm{O}_{1}, \mathrm{P}_{1}, \mathrm{Q}_{1}, \mathrm{M}_{2}, \mathrm{~S}_{2}, \mathrm{~N}_{2}, \mathrm{~K}_{2}, \mathrm{M}_{4}$, and $\mathrm{M}_{6}$ ) are used to force the tides and tidal currents in the CIOFS. Of two hindcast simulations, the first hindcast simulation (Hindcast 1) was from 1/1/2012 to $9 / 15 / 2012$, which coincided with summer 2012 current meter deployments in Cook Inlet. The second hindcast simulation (Hindcast 2) lasted two years from $8 / 15 / 2013$ to $9 / 15 / 2015$. The skill assessments based on these simulations and corresponding observations were performed. The water level prediction performed very well for both hindcasts. Central Frequency (CF) was more than $95 \%$ from all water level stations. The major finding of the water level skill assessment is that the RMSE increased towards the upper Cook Inlet (Anchorage) where it is shallow, muddy, and tidal range can be 8-9 meters high.

For temperature skill assessment, the CF was usually more than $98 \%$, with the exception of Anchorage where CF was $88.3 \%$ in Hindcast 2. In the upper Cook Inlet (Anchorage), the model temperature, especially during the summer, usually had a warm bias. With gradual improvement of weather models, the surface forcing bias should be able to be reduced along with improvement of the hydrodynamic model results.

For current skill assessment, the current direction was simulated well. At 8 out of 9 current observation locations, CF of current direction was above $90 \%$. At one station near south Fire Island, CF of current direction was $87.0 \%$. For current speed, 6 out of 9 stations had a CF value above $90 \%$. Three current stations had a CF of current speed less than $90 \%$. These three stations are Southwest of Pt. Pogishi, Point Possession, and North Fire Island. The corresponding CF values were $74.3 \%, 86.4 \%$, and $65.2 \%$ respectively.

In summary, the CIOFS development and performance verification have been completed. NOS has implemented the hindcast setup in the NOS standard HPC-COMF environment. CIOFS has undergone pre-operational test runs on the National Centers for Environmental Prediction (NCEP) high-performance computer systems. The system has been in full operation since July, 2019.

## 1. INTRODUCTION

The Cook Inlet region of Alaska (Figure 1) is heavily trafficked by shipping and contains the major ports of Homer, Nikiski and Anchorage. Ships enter Cook Inlet via the Shelikof Strait to the South and the Gulf of Alaska (Stevenson Entrance, Kennedy Entrance and Chugach Passage) to the Southeast and travel upwards towards these ports. NOAA's National Ocean Service (NOS) has developed a hydrodynamic ocean model-based Operational Forecast System (OFS) for this geographic region to provide guidance to marine navigators. This report describes the development, calibration and skill assessment of such a hydrodynamic model,named Cook Inlet Operational Forecast System (CIOFS). The primary purpose of CIOFS is to provide navigational mariners with water surface elevation (water level) and current predictions, but in addition, it also generates temperature and salinity predictions which could be used to support ecological and ecosystem forecasting in the region.

CIOFS is based on Rutgers University's Regional Ocean Modeling System (ROMS) numerical ocean model (Haidvogel et al., 2000; Shchepetkin and McWilliams, 2003, 2005; Warner et al., 2005). ROMS is a split-explicit model which computes on structured, orthogonal curvilinear grids in the horizontal and on terrain-following coordinates in the vertical. Additional details on the attributes of the model can be found on myroms.org (Shchepetkin and McWilliams, 2003, 2005; Warner et al., 2005) and the particular features of the model key to CIOFS will be elaborated further here. As CIOFS was partly designed as an inundation model with flooding and drying over the tidal cycle, the ROMS wetting-drying algorithm was employed and both bathymetry and topography are present in the model. ROMS has three options for specifying the bottom stress quadratic, logarithmic and linear formulations. The logarithmic formulation generated the most accurate water level predictions (online communication in ROMS forum, myroms.org/forum/) and hence it was employed. A special algorithmic option in ROMS was employed to prevent the abrupt reversal of the sign of the bottom stress during the drying cycle, without which computations in wetting-drying cycles would be rendered numerically unstable (online communication in ROMS forum, myroms.org/forum/). ROMS has a suite of eddy-viscosity models which characterize vertical mixing in the water column and after testing several of these options, the Mellor-Yamada level-2.5 turbulence closure scheme (Mellor and Yamada, 1982) was found to be as effective as any of the others which is attributed to the well mixed nature of the water column due to the strong actions of the tides; furthermore, this algebraic model is computationally cheaper than using a General Length Scale (GLS) (Umlauf and Burchard, 2003) model which is inherently expensive as a result of having to solve additional partial differential equations for the turbulence variables (Warner et al., 2005). At the ocean surface, ROMS allows the wind stresses and the net heat flux to be specified in two ways: directly, using known fields, or indirectly, using the TOGA-COARE Bulk Flux formulation (Fairall et al., 1996; Fairall et al., 2003) which needs the wind velocity components, air temperature, relative humidity, air pressure, net shortwave radiation flux and downward longwave radiation flux. In CIOFS, the latter approach was adopted as sufficiently accurate surface stress and heat fluxes were not available and the model surface forcing was augmented by imposing atmospheric pressure onto sea surface to account for the effects of the air pressure on the water surface elevations. It is known in upper Cook Inlet that there is massive sediment transport and deposition especially during the spring time, and during the winter months, broken ice is present throughout Cook Inlet. However, in the current version of CIOFS, due to the
lack of reliable sediment and ice forecast capabilities in ROMS, sediment and ice dynamics are not included in the model. Due to computational time limits on supercomputing platforms, long simulations often need to be broken up into smaller segments; this was also the case with CIOFS, and the ROMS perfect restart algorithms were employed to carry out the full simulations in a seamless and continuous fashion.

The model domain was defined to include the whole of Cook Inlet (lower, middle and upper Cook Inlet) and also the adjacent waters of Kodiak Archipelago (Kodiak Shelikof Strait and western Gulf of Alaska) due to the ship traffic passing through it. This ensured that the ports of Homer, Nikiski and Anchorage were contained in the computational domain. Ship traffic enters Cook Inlet via the entrances from the Gulf of Alaska (Stevenson Entrance, Kennedy Entrance and Chugach Passage) too and hence a segment of the Gulf of Alaska was included. In upper Cook Inlet, both the Knik and Turnagain Arms were present so as to incorporate the shipping routes and the shallow tidal mudflats. Another reason for including the full Cook Inlet estuary including the tidal flood-drying regions (e.g. mudflats, etc.) and some topography was to ensure that the full volume of the domain was accounted for so as to ensure the hydrodynamic balance of fluid flow in shallow regions.

CIOFS was developed in two stages. In the first stage, the computational domain was truncated at the boundary between Cook Inlet and the Gulf of Alaska and at the entrance to Shelikof Strait from the open ocean (Lanerolle et al., 2012). The model consisted of a parent grid covering the full domain and two higher resolution nests - one for the Kachemak Bay region and the other for the upper Cook Inlet region both of which are significant for navigation (ports of Homer and Anchorage are encompassed in these nests). First the parent grid was run and using the predictions from that as boundary conditions, the nested grids were forced and run. Hence, the nesting was one-way only. Simulations with this setup showed that the discrepancies of the model predictions relative to observations in the water levels grew significantly when moving up the domain (towards Anchorage) and were "locked" and could not be diminished (or controlled) with the prescription of various bottom stress formulations or coefficient strengths. Furthermore, a single simulation involved running three separate computational domains which was triple the effort. Additionally, the model predictions from the nests were not a significant improvement over those from the parent grid. These shortcomings motivated the designing of a single grid for CIOFS which had similar grid resolutions as the nested grids in Kachemak Bay and upper Cook Inlet. In addition, the open boundary was extended farther out (beyond the outside of Kodiak Island) and the topography was extended up to 15 m elevation above Mean Sea Level (MSL), thus allowing the action of tidal flooding-drying to occur unimpeded and in a natural way. The extension of the open boundary and the topography enabled the water level model discrepancies to be controlled more effectively and generate significantly improved water level predictions. The single grid configuration also resulted in a simpler CIOFS set-up where only a single domain was necessary to be run as opposed to three separate domains as in the nested configuration. In this CIOFS technical report only the second stage development is represented. For first stage nested grid one-way coupling approach, the results can be referred to the Oceans ' 12 tidal kinetic energy paper (Lanerolle et al., 2012).

Three simulations were conducted using the single grid CIOFS configuration: a tidal simulation to evaluate the accuracy of the water level and current predictions and to calibrate the tides to achieve the most accurate model predictions; an 8 -month summer 2012 synoptic hindcast simulation to
evaluate the model predicted water levels, currents, temperature and salinity against field survey observations; and a multi-year (25-month) synoptic hindcast simulation covering the August 2013 - September 2015 time period again to evaluate these model predicted variables and also examine the response of the model to the springtime river discharges, summertime tidal mudflat heating, and wintertime oceanic and atmospheric conditions (due to the lack of an ice module, etc.).

This report is organized as follows. Section 2 will provide information about model configuration, development and calibration of CIOFS. Section 3 gives details of the three simulations conducted; model results and skill assessment of the single grid CIOFS configuration against observed data will be discussed. In Section 4, a summary, set of conclusions and recommendations will be stated.

Figure 1. Cook Inlet Operational Forecast System (CIOFS) domain. The blue curve is the CIOFS open water boundary. There are three main long term water level stations (red triangles) in the domain: from north to south, Anchorage, Nikiski, and Seldovia. Black dashed line is the MHW shoreline, black solid line is 50 foot depth contour, and green patch is tidal flat between MLLW and MHW.

## 2. CIOFS MODEL CONFIGURATION

In this Section the CIOFS model development will be described by elaborating on its various components.

### 2.1 Model Domains and Curvilinear Mesh Grids

The model domain is shown in Figure 1. The domain covers the full Cook Inlet region (lower, middle and upper Cook Inlet) and extends to the north of Anchorage, AK. It also includes Knik Arm, Turnagain Arm in the upper Cook Inlet, Kachemak Bay in the middle Cook Inlet, the Shelikof Strait, Stevenson Entrance, Kennedy Entrance and Chugach Passage to the south which is important navigationally.

The model grid was of a structured, orthogonal quadrilateral type. The model grid was extended into the topography up to the 15 m contour above mean sea level. The adjustment was to ensure that the full flooding-drying zone was incorporated in the model so as to ensure that the true volume of the hydrodynamic basin would be accounted for. The single, high resolution grid was generated in seven individual pieces and pasted together (and orthogonalized) using Delft3D grid generator (Deltares, 2014). It is shown in Figure 2.

Figure 2. The single high resolution CIOFS grid and the individual grid segments. 1. Knik Arm, 2. Turnagain Arm, 3. Susitna River delta, 4. Tuxedni Bay (River), 5. Kamishak Bay, 6. Kachemak Bay, 7. Cook Inlet main stem, Shelikof Strait, Kodiak Archipelago, and entrances from Gulf of Alaska to Cook Inlet.

Figure 3. Cross-axial grid resolution and along-axial grid resolution of CIOFS curvilinear mesh grid.

Figure 3 shows the model grid resolutions in the cross-axial and the along-axial directions. It shows the refinement that has been added to the regions within Cook Inlet and in particular Kachemak Bay and upper Cook Inlet. The grid had $744 \times 1024$ grid points in the horizontal and 30 vertical terrain-following sigma grid levels were specified. The maximum horizontal spatial resolution is around 8000-9000 meters along the open boundary, and the minimum resolution is about 50 meters around upper Cook Inlet.

### 2.2 Bathymetry and Topography

Due to flooding and drying (i.e. wetting and drying), the model domains require both bathymetry and topography. As CIOFS is not built to simulate tsunamis, the topography is truncated at a 15 m elevation above mean sea level.

The bathymetry-topography needs to be seamless without any discontinuities. It is generated by interpolation from a Digital Elevation Model (DEM) built by combining (i) bathymetric sounding data, (ii) shoreline data and (iii) land topography data in a seamless fashion. One of the challenges in developing the DEM is to account for the different vertical datums associated with (i), (ii) and (iii) in a consistent manner.

The bathymetric soundings used were from NOAA/National Ocean Service (NOS) surveys of the Shelikof Strait - Cook Inlet region covering the 1907-2004 and 2008-2009 time periods. The soundings have been quality controlled and the data files in Bathymetry Attributed Grid (BAG) format where first converted to ASCII format before being used. The native vertical datum of the bathymetry was Mean Lower Low Water (MLLW). Soundings were interpolated to the CIOFS model grids in a supersession sequence beginning with the year 2009 and ending with 1907. The
interpolation covered the wet-point grid delineated by the MLLW shoreline. The interpolation method was an inverse-square algorithm with the radius of influence being determined by the encompassing grid size.

The above interpolated bathymetry, MLLW and Mean High Water (MHW) shorelines are used to fill the area between MLLW and MHW with bathymetric values by adopting a MLLW reference frame where the MLLW shoreline is assumed to have a bathymetric value of zero as illustrated in Figure 4. The filling is carried out using a bilinear interpolation algorithm.

Figure 4. MHW (blue) and MLLW (red) shorelines for upper and middle Cook Inlet.
The topography above the MHW shoreline is filled by interpolating gridded/digitized land topography from the US Geological Survey (USGS) and from a DEM of Kachemak Bay produced by NOAA/National Centers for Environmental Information (NCEI). The USGS digitized data has spatial resolutions of $1 / 9 ", 1 / 3 ", 1$ " and 2 " and the NCEI DEM was of a $1 / 3$ " spatial resolution. When interpolating the topography, the finest resolution was employed first and thereafter, progressively coarser resolutions were used. The topography was assumed to be on a MHW vertical datum and the interpolation was carried out using the same algorithm as for the bathymetry (for consistency).

The bathymetric soundings are on a MLLW datum, the two shorelines are on a MLLW and a MHW datum and the topography is on a MHW datum. When carrying out the numerical interpolations, the interpolating fields must all be on the same datum. Furthermore, the final
bathymetry-topography needs to be on a Mean Sea Level (MSL) datum as the NOS OFSs are run on this datum and hence, the CIOFS model grid's bathymetry-topography also needs to be on a MSL datum. The vertical datum transformational fields (to go from one datum to another) were formed by interpolating the discrete values derived and published by NOS/Center for Operational Oceanographic Products and Services (CO-OPS) to cover the full Shelikof Strait - Cook Inlet domain. In addition to interpolation, some extrapolation was also required and this process in turn required the specification of extended pseudo-points of data. The interpolated bathymetrytopography was clipped at 15 m above MSL.

Figure 5 shows the bathymetry-topography on the single grid with zoom-ins for Cook Inlet, upper Cook Inlet and Kachemak Bay. The plots show the deep, narrow channels present in both upper Cook Inlet and Kachemak Bay and also the bathymetry-topography interface.

### 2.3 Tidal Forcing at Open Boundary

In ROMS, tides are forced by predicted tidal water level and predicted tidal currents at the open boundary, which consists of 10 tidal harmonic constituents, namely $\mathrm{K}_{1}, \mathrm{O}_{1}, \mathrm{P}_{1}, \mathrm{Q}_{1}, \mathrm{M}_{2}, \mathrm{~S}_{2}, \mathrm{~N}_{2}, \mathrm{~K}_{2}$, $\mathrm{M}_{4}$, and $\mathrm{M}_{6}$. The individual tidal constituents are interpolated from an Advanced Circulation (ADCIRC) tidal model-generated tidal database for that region (Spargo et al., 2003).

### 2.4 River Input

Figure 6 shows the catchment area of Cook Inlet. The total drainage area is about $50,000 \mathrm{~km}^{2}$. It can be divided into 4 major subdomains: Kenai Peninsula, Anchorage/Matanuska Area, Susitna Area, and West Cook Inlet Area (Table 1). The Susitna Area is the major drainage area with more than $50 \%$ of Cook Inlet catchment area.

Table 1. Cook Inlet 4 drainage areas.

The temperature of the river influx that flows into the Cook Inlet was assigned the ambient water temperature at the location where the river discharge data was available.

### 2.5 Initial Condition

There are two sets of data used for the temperature and salinity initial condition when hindcast run is first initialized and needs to be spun up (cold start). One is to use the World Ocean Atlas for the temperature and salinity field (applied to both hindcast runs), and another alternative is to use Global Real-Time Ocean Forecast System (G-RTOFS) to initialize the temperature and salinity field. In the tides only simulation, the temperature and salinity are set to a constant without surface boundary fluxes. The initial condition for velocity was set to zero, and water level was set to model zero as well. In a cold start, the model always had some spin up period (for days, months and even years dependent on the variables and physical dimension of the model) to eliminate the impact of the initial condition on the model results.

### 2.6 Open Boundary Condition

In the tidal only simulation, the temperature and salinity at open boundary are set to a constant (the same value as the initial condition). The open boundary was forced by the prescribed tidal water level and tidal currents without non-tidal water level and velocity. For Hindcast 1, the open boundary condition was provided by G-RTOFS for non-tidal water level and velocity in addition to the prescribed tidal water level and tidal currents, and temperature, and salinity open boundary condition was provided by World Ocean Atlas. For Hindcast 2, the open boundary condition was provided by G-RTOFS for temperature, salinity, non-tidal water level and velocity in addition to the prescribed tidal water level and tidal currents.

### 2.7 Model Sea Surface Condition, Heat and Water Exchange

In the tides only run, there is no heat and water exchange on the sea surface. For the hindcast runs, the exchange is formulated using the bulk flux formulation (Fairall et al., 1996; Fairall et al., 2003). All meteorological parameters are provided using the North American Mesoscale (NAM) (DiMego, 2012) 6 kilometer resolution Alaska nest hourly products.

## 3. MODEL TESTS AND SKILL ASSESSMENT

In the development of CIOFS, three numerical tests were performed under different scenarios:

1) Tides only simulation. Test the tide forcing boundary inputs and the response of the model to the tidal forcing.
2) Hindcast 1 model simulation from $1 / 1 / 2012$ to $9 / 15 / 2012$. Test the model performance during the testing time period, especially the currents using the observed currents data.
3) Hindcast 2 model simulation from $8 / 15 / 2013$ to $9 / 15 / 2015$. Test the model performance under multiple year simulation.

### 3.1 NOS Standards for Skill Assessment

Skill assessment is a key component of OFSs development. It provides unified measures to ensure the quality and performance of OFSs against certain criteria for output state variables, e.g. water level, current, temperature and salinity. The skill assessment will follow NOS Standards for Evaluating Operational Nowcast and Forecast Hydrodynamic Model Systems (Hess et al., 2003). The skill assessment will be conducted using the skill assessment software package developed by Zhang et al. (2010).

The main measure of the skill assessment is the central frequency $\mathrm{CF}(\mathrm{X})$, which is the fraction (percentage) of errors that lie within the limits $\pm \mathrm{X}$, where X is the acceptable error magnitude. Table 3 provides the default acceptable error magnitude ( $\mathrm{X}_{0}$ ) for water level, current direction, current speed, temperature and salinity. In an area where there is high water level and current diurnal/semidiurnal variability, the acceptable error magnitude X should be an adjustable parameter that is proportional to the diurnal range of the variable being assessed. That is $\mathrm{X}=$ $\max \left(\mathrm{X}_{0}, 10 \%\right.$ range $)$, where $\mathrm{X}_{0}$ is the default acceptable error magnitude. For velocity, the speed range is the diurnal range of the observed current velocity projected into the Principle Current Direction (PCD).

Beside Central Frequency $\mathrm{CF}(\mathrm{X})$, the NOS standard skill assessment software also computes some major additional statistical parameters: Root Mean Square Error (RMSE), Positive Outlier Frequency (POF), and Negative Outlier Frequency (NOF). The NOS standard criteria are greater than $90 \%$ for CF and less than $1 \%$ for NOF and POF. More detailed definitions of the above parameters can be found in Hess et al. (2003).

For Hindcast 1 simulation, in additional to current skill assessment, we performed harmonic analysis for both observed and modeled currents, and made comparison of tidal constituent amplitudes and epochs for tidal currents in PCD and cross PCD. PCD and values of R (ratio of variance of cross PCD current and variance of PCD current) are also calculated from harmonic analysis of currents. Standard and implementation of harmonic analysis of current for model evaluation purpose can be found in Hess et al. (2003) and Zhang et al. (2010).

Table 3. Criteria for skill assessment acceptable error magnitude X , and default acceptable error magnitude $\mathrm{X}_{0}$.

| $\mathrm{X}_{0}, \mathrm{X} \backslash$ value\variable | Water <br> level | Current <br> direction | Current <br> speed | Temperature | Salinity |
| :--- | :--- | :--- | :--- | :--- | :--- |
| $\mathrm{X}_{0}$ | 15 cm | 22.5 degrees | $26 \mathrm{~cm} / \mathrm{s}$ | 3 degree <br> Celsius | 3.5 PSU |
| X | $\max \left(\mathrm{X}_{0}\right.$, <br> $10 \%$ <br> range $)$ | 22.5 degrees | $\max \left(\mathrm{X}_{0}\right.$, <br> $10 \%$ range | 3 degree <br> Celsius | 3.5 PSU |

Since our main purpose of CIOFS is to provide forecast guidance to the mariner, and also because of lack of data, we will not perform skill assessment for salinity in this report.

### 3.2 Tidal Simulation and Calibration

Tidal signal is the most dominant component of water level and current in Cook Inlet. Therefore, in order to calibrate the tides, a simulation in which the density was held constant (temperature at $15^{\circ} \mathrm{C}$ and salinity at 35 PSU ) was carried out. The calibration was done with water levels, currents, the quadratic and logarithmic bottom stress formulations, and various levels associated with them were tried together with the modulation of the tidal harmonic constituent amplitudes and phases.

The tidal calibration process showed that the best water level predictions were accomplished with the logarithmic bottom stress formulation, and the quadratic formulation was ignored. Bottom roughness coefficients ranging from 0.0075 m to 0.024 m were tried out with various open boundary conditions and with phase and amplitude adjustments to the boundary forcing tidal harmonic constituents. The best results were achieved with no modulation of tidal constituent amplitude but with a phase adjustment of 5 minutes. The optimal bottom roughness coefficient was 0.01 m . Using larger coefficients did not impact the water levels significantly, but was seen to inflict noticeable damping in the current model predictions. Unlike the nested grid configuration, here in addition to attempting to get the best water level predictions, it was also attempted to achieve the best possible current predictions from the model. The currents used for the comparison in this exercise were the Principal Current Direction (PCD) components (Preisendorfer, 1988). The metrics used to measure the model prediction accuracy were the amplitude and phase error, calculated via an autocorrelation method as described in Lanerolle et al. (2011). The outcome of the calibration exercise is summarized in Table 4.

Table 4. Water level amplitude and phase error, PCD currents amplitude and phase error. Amplitude error computed with raw time series and demeaned time series separated with slash /. Demeaning does not affect phase error.

|  | Seldovia | Nikiski | Anchorage |
| :--- | :--- | :--- | :--- |
| Water level amplitude <br> error (cm) | $15.9 / 16.4$ | $20.9 / 18.9$ | $40.6 / 32.0$ |
| Water level phase <br> error (min) | 1.0 | -2.0 | 2.0 |
| PCD current <br> amplitude error <br> $(\mathrm{cm} / \mathrm{s})$ | $3.2 / 3.2$ | $30.3 / 28.5$ | $42.8 / 36.0$ |

|  | Seldovia | Nikiski | Anchorage |
| :--- | :--- | :--- | :--- |
| PCD current phase <br> error (min) | 35.0 | 4.0 | -15.0 |

The model is seen to exhibit excellent phase accuracy in the water level predictions, and the phase errors of the currents are larger in the current predictions. The amplitude error for both water levels and currents is seen to decrease with the demeaning process as seen before. Also, the amplitude error is seen to grow when moving up Cook Inlet whereas the phase error does not show any geographical bias.
3.3 Synoptic Hindcast 1 (Summer 2012) Simulation and Skill Assessment

In the summer of 2012, NOS/CO-OPS conducted a field survey in Cook Inlet which involved the deployment of current meters. This survey resulted in high spatio-temporal resolution current measurements at 9 locations in Cook Inlet which included Kachemak Bay and lower, middle and upper Cook Inlet (Table 5). This dataset was in addition to NOS' 6-minute water level measurements at Seldovia (Kachemak Bay), Nikiski and Anchorage. This field survey provided the motivation to carry out a synoptic hindcast simulation covering the summer of 2012 to assess the accuracy and robustness of the CIOFS model set-up.

Table 5. Locations of the NOS/CO-OPS Summer 2012 current survey.

| Station | Longitude | Latitude | Name | Depth of <br> assessment <br> pkesented (m) |
| :--- | :--- | :--- | :--- | :--- |
| COI1201 | -151.40 | 59.59 | Homer Spit | 6.4 |
| COI1202 | -151.92 | 59.42 | Pt. Pogishi, SW of | 4.6 |
| COI1203 | -152.03 | 59.74 | Anchor Point, W of | 5.8 |
| COI1204 | -151.08 | 62.06 | North Forelands | 6 |
| COI1205 | -151.71 | 60.47 | Kalgin Island | 5.5 |
| COI1207 | -150.36 | 61.06 | Point Possession | 5.7 |
| COI1208 | -150.26 | 61.10 | Fire Island, South | 6.2 |
| COI1209 | -150.20 | 61.18 | Fire Island, North | 5.9 |
| COI1210 | -151.23 | 60.89 | Middle Ground Shoal | 5.2 |

As ocean models take time to spin-up from rest, it was decided to begin the synoptic hindcast simulation on January 01, 2012 and run it through September 15, 2012. This would allow at least a few months spin-up which was thought to be sufficient. Due to the unavailability of sufficiently accurate water level and current fields, it was decided to spin-up the model from rest so that the currents would develop in response to the density field. The initialization and open boundary temperature and salinity fields were generated from NOAA's World Ocean Atlas (WOA) gridded monthly climatology. The tides were ramped linearly over a 5-day period to ensure a numerically stable spin-up where the currents would grow gradually in time. The river forcing data was from the USGS data sources (both volume discharge and temperature) and the Bradley River temperatures were used for all of the rivers after finding out that the river temperatures over the Cook Inlet domain did not show a strong variation geographically. The Susitna River has two
contributions which needed to be combined - the discharge measured at the Susitna station and that measured at Sunshine station. The gauge at Sunshine has been discontinued and a historical analysis showed that the combined discharge was roughly twice the discharge from the Susitna station. Hence, the Susitna River volume discharge was estimated as being twice that measured at Susitna and this discharge level was used in the numerical simulations. River forcing too was ramped-up in time linearly over a 5-day time period.

Along the open ocean boundary, tidal forcing was provided by harmonic constituents for the water levels and the barotropic velocities which were obtained by interpolating from an ADCIRC modelgenerated tidal harmonics database (Spargo et al., 2003). The water level tidal signal was augmented by adding a sub-tidal component from the Global Real Time Ocean Forecast System (G-RTOFS) model product. The sub-tidal forcing too was linearly ramped-up in time over a 5day period. At the ocean surface, meteorological forcing was applied via wind stresses and net heat fluxes generated by the TOGA-COARE Bulk Flux algorithm contained within ROMS. The forcing data to generate the stresses and heat flux (wind speed components, air pressure, air temperature, relative humidity, net shortwave radiation flux and downward longwave radiation flux) were provided by the $6-\mathrm{km}$ resolution NAM Alaska nest model. Here too, the wind speeds were ramped-up in time linearly over a 5 -day time period. The modeling set-up did not include ice dynamics or sediment dynamics and ice formation was prevented by suppressing the meteorological cooling during the winter months. The baroclinic time step employed in ROMS was 5 seconds and the baroclinic: barotropic splitting was $30: 1$. The computation was sped up using MPI parallelization with 384 processors used with an $8 \times 48$ tiling in the $x-y$ directions.

### 3.3.1 Water Level Skill Assessment

Predicted water levels were evaluated against observations at Seldovia, Nikiski and Anchorage where NOS/CO-OPS continuously carries out observations. These three locations are shown as magenta triangles in Figure 1. The results for individual stations are summarized below in Figure 8 and Table 6 . The water level time series was demeaned before the skill assessment. The acceptable error magnitude, $X$, is calculated with the formulation, $X=\max \left(X_{0}, 10 \%\right.$ range $)$, and criteria outlined in Section 3.1.

Figure 8. (Panel clockwise from top-left) Geographic location of station, Graphic comparison between modeled and observed water level, histogram of error probability distribution, and summary of water level (demeaned) skill assessments, Hindcast 1 (4/30/2012-9/3/2012). The histogram is the probability distribution of the error or mismatch between the model and observation. Red dashed line and red solid line define the range of $\left[-\mathrm{X}_{0}, \mathrm{X}_{0}\right]$. Blue dashed line and blue solid line define the range of $[-\mathrm{X}, \mathrm{X}]$. The probability within the range $[-\mathrm{X}, \mathrm{X}]$ is the CF (central frequency). a. Anchorage. b. Nikiski. c. Seldovia.

Table 6. Summary of water level skill assessment for water level at Anchorage, Nikiski and Seldovia, Hindcast 1 (4/30/2012-9/3/2012). Results from different scenarios are also presented.

| Location |  | $\mathrm{X}_{0}: 15 \mathrm{~cm}$ | $\mathrm{X}_{0}: 15 \mathrm{~cm}$ <br> with <br> demeaning | $\mathrm{X}: 10 \%$ tidal <br> range | $\mathrm{X}: 10 \%$ tidal <br> range with <br> demeaning |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Anchorage | CF (\%) | $9 \%$ | $35 \%$ | $86 \%$ | $99 \%$ |
|  | RMSE (cm) | 56.7 | 29.6 | 56.7 | 29.6 |
| Nikiski | CF (\%) | $37 \%$ | $48 \%$ | $99 \%$ | $99 \%$ |
|  | RMSE (cm) | 26 | 21.2 | 26 | 21.2 |
| Seldovia | CF (\%) | $36 \%$ | $59 \%$ | $96 \%$ | $100 \%$ |
|  | RMSE (cm) | 25.3 | 17.9 | 25.8 | 17.9 |

Overall the model water levels perform well for these three stations. Demeaning reduced the RMSE and improved the model skill. Demeaning, a post processing for the water level prediction (can be used for current prediction as well), is to remove the model local mean sea level from model time series. The model predicted water level will be demeaned water level plus the observation local mean sea level. Ideally the mean removed from the model water level time series should be a long term average of the local model water level. For both Hindcast 1 and Hindacst 2
water level skill assessments, only the local mean water level of the skill assessment period is removed when the demeaning is performed. For Anchorage station, CF is $86 \%$ without demeaning. CF improved to $99 \%$ after demeaning.

### 3.3.2 Current Skill Assessment

The modeled currents were compared against the NOS/CO-OPS Summer 2012 survey data which were taken by current meters at 9 locations (Table 5) in Cook Inlet. Figure 9 shows that the current meters are distributed well throughout Cook Inlet and hence provide a good picture of the nature of currents within Cook Inlet. Model current skill is assessed against the observation for the 2 month long observation period from around $6 / 14 / 2012$ to $8 / 14 / 2012$. Subsurface currents from both model and observation between 4 and 30 meters below the sea surface at roughly 2 meters interval are used for skill assessment. The modeled current will be extracted from the model corresponding to the depth of the observed current. Some observations are not available at some depths or rejected due to poor data quality. Due to the fact that the observed currents are very much uniformly distributed in the vertical along the water column between 4 and 30 meters below the surface, only skill assessment results from 5-6 meter below sea surface will be presented in this report. Two skill assessments are performed for the currents. Firstly, we perform the harmonic analysis to the velocity along the principal current direction (PCD) and across the PCD. A comparison is made from the harmonic analysis results. Then we made a statistical analysis and skill assessment to the raw current direction and speed data.

Figure 9. The distribution of the nine current stations (red crosses, COI1201, COI1202, COI1203, COI1204, COI1205, COI1207, COI1208, COI1209, COI1210) during NOS/CO-OPS summer 2012 months long field campaign in Cook Inlet.

### 3.3.2.1 Comparison of Currents Harmonic Constants

The standard procedure (Hess et al., 2003) of harmonic analysis of a tidal current time series, either observed or modeled, requires firstly to calculate Principal Current Direction (PCD, usually the flood and ebb currents direction). Then the velocity vectors are projected into both PCD direction and cross PCD. Lastly harmonic analysis is performed to the projected time series for both PCD and cross PCD. Two additional parameters, diurnal range of the principal currents and R (ratio of variance of cross PCD current and variance of PCD current), are computed from projected current velocity time series. The diurnal range provide a good estimate of the amplitude of the tidal current. It is used for computation of the current speed skill assessment acceptable error magnitude $\mathrm{X}=$ $\max \left(\mathrm{X}_{0}, 10 \%\right.$ range). Another parameter calculated is R , ratio of variance of cross PCD current and variance of PCD current, which is the indication of the flow pattern $(0<=\mathrm{R}<=1, \mathrm{R}=0$ means a unidirection current, and $\mathrm{R}=1$ is rotary current). A basic requirement for current is that the difference between observed and modeled PCD should be within 30 degrees. For all nine stations (Table 7), the RMSE of the modeled PCD is only 2.05 degree, with maximum difference less than 5 degree. Ratio R for both observed and modeled current are less than 0.25 , which means currents in Cook Inlet are very much unidirection currents.

Table 7. Principal Current Direction (PCD), R of observed and modeled currents, diurnal range of observed current, PCD difference between observed and modeled currents from all 9 current stations at skill assessment depth (around 5-6 meters below sea surface).

| Station | Depth <br> $(\mathrm{m})$ | Observed <br> PCD <br> (degree) | Observed <br> R | Observed <br> PCD <br> velocity <br> diurnal <br> range <br> (m/s) | Modeled <br> PCD <br> (degree) | Modeled R | observed PCD <br> difference <br> (degree) |

Harmonic analysis is performed to the current time series for both PCD and cross PCD. The detailed results from harmonic analysis are posted in Appendix A. In general, $\mathrm{M}_{2}$ tidal current dominates the tidal current energy. If we estimate the kinetic energy in term of square of the current
speed, a rough calculation shows that $\mathrm{M}_{2}$ and $\mathrm{S}_{2}$ tides consist of $75 \%$ and $18 \%$ of total tidal momentum energy respectively. Overall the model preforms very well in terms of the amplitude and phase of major tidal current constituents. Table 8 give the $\mathrm{M}_{2}$ tidal constituents amplitude and phase results. The RMSE for $\mathrm{M}_{2}$ current amplitude is only $17 \mathrm{~cm} / \mathrm{s}$. The $\mathrm{M}_{2}$ current phase RMSE is about 5.13 degree, which can be translate to an RMSE of 10.5 minutes.

The tidal current is usually very much uniform throughout the water column except close to the bottom where bottom friction has a large impact. There is no significant difference in terms of PCD, R, diurnal range, amplitude and phase for a few major tidal constituents over top 30 meter water column below the sea surface.

Table 8. Comparison of observed and modeled PCD M ${ }_{2}$ current tidal constituent amplitudes ( $\mathrm{m} / \mathrm{s}$ ), phase/epochs (degree), and their difference. All current stations.

### 3.3.2.2 Current Skill Assessment

Besides the harmonic analysis of tidal currents, we preformed skill assessment for currents direction and speed from raw current data (Figures 10-27).

Station: CMIST COI1201 6.4 m , Homer Spit, bin 28
Observed data time period from: / $6 / 14 / 2012$ to / 8/14/2012with gaps of 0.00 days
Data gap is filled by SVD method

Figure 10. Current direction (degree), station COI1201, Hindcast 1 (6/14/2012-8/14/2012). Note (apply to all current direction figure caption): (panel clockwise from top-left) 1) geographic location of current station, 2) graphic comparison between modeled and observed current direction, 3) histogram of error probability distribution, and 4) summary of current direction skill assessment. The histogram is the probability distribution of the error or mismatch between the model and observation. Red dashed line and red solid line define the range $[-\mathrm{X}, \mathrm{X}]$. Yellow dashed line represents evenly distributed probability when speed less than $1 / 2$ knot (the current direction is computed only for current speeds above $1 / 2$ knot) over the range $[-\mathrm{X}, \mathrm{X}]$. The probability within the range $[-X, X]$ is the CF (central frequency).

| COI1202 | -151.92 | 59.42 | $98.2 \%$ | $72.3 \%$ | $74.3 \%$ |
| COI1203 | -152.03 | 59.74 | $99.3 \%$ | $90.7 \%$ | $96.5 \%$ |
| COI1204 | -151.08 | 62.06 | $96.7 \%$ | $78.0 \%$ | $98.5 \%$ |
| COI1205 | -151.71 | 60.47 | $97.2 \%$ | $71.7 \%$ | $94.9 \%$ |
| COI1207 | -150.36 | 61.06 | $92.9 \%$ | $66.0 \%$ | $86.4 \%$ |
| COI1208 | -150.26 | 61.10 | $87.0 \%$ | $81.0 \%$ | $93.4 \%$ |
| COI1209 | -150.20 | 61.18 | $95.2 \%$ | $44.9 \%$ | $65.2 \%$ |
| COI1210 | -151.23 | 60.89 | $92.7 \%$ | $81.8 \%$ | $98.2 \%$ |

Overall, the model predicted the current direction very well (Table 9); all current stations have a central frequency of $>90 \%$, except station COI1208. That particular station COI1208, where CF is $87.0 \%$, is very close to southern tip of Fire Island which is located near the entrances of the Knik Arm and Turnagain Arm. This area is characterized by the vast muddy tidal flat off the shipping channel. That mud flat is relatively difficult to survey and to model as well. Also, mud flats are very much subject to sedimentation morphology. Subtle changes of the flat and the water channel will change the flow pattern greatly during flood and ebb.

The prediction of the current speed was not as accurate as the flow direction (Table 9). Of 6 out of 9 current stations, CF was above $90 \%$. At station COI1202 (CF=74.2\%, Southwest of Pt. Pogishi) near Seldovia, the model overestimated the current. At station COI1207 (Point Possession), CF of model current was $86.4 \%$. At station COI1209 ( $\mathrm{CF}=65.2 \%$ ) near North Fire Island, histogram probability distribution shift toward negative, and the error had a negative bias. The model overestimated the current speed at COI1209 as well as at COI1202. Overall the timing of the current direction switch from the ebb to flood or flood to ebb is quite accurate from current speed plot and current direction plot (Figures 10-27), which can be further indicated by the small phase error of the dominant tidal current constituent $\mathrm{M}_{2}$ (Appendix A).

Besides the skill assessment for currents near the sea surface, we also performed skill assessment for depth along the water column from 4-30 depth range in 2 meters interval. The velocity distribution along water column from 4-30 meter is quite uniform without much variation. The maximum velocity slightly decreases from near sea surface to 30 meters depth. The central frequency for both current direction and speed is very close to 5-6 meter depth results. In other words, 5-6 meter skill assessment has a very good representation of the water column in term of model current skill. We did not present the results at all depth except 5-6 meter depth in this report due to the redundancy.

### 3.3.3 Temperature Skill Assessment

There are continuous sea surface temperature measurements at the three CO-OPS stations of Anchorage, Nikiski, and Seldovia. Model skill is assessed for the period from 5/1/2012 to 9/3/2012 (Figure 28).

Figure 28. (Panel clockwise from top-left) Geographic location of stations, Graphic comparison between modeled and observed water temperature, and summary of sea surface temperature skill assessments, Hindcast 1 (5/1/2012-9/3/2012). a. Anchorage. b. Nikiski. c. Seldovia.

Table 10. Model temperature skill assessment at Anchorage, Nikiski, and Seldovia, Hindcast 1 (5/1/2012-9/3/2012).

| Location | CF (\%) | RMSE (degree) |
| :--- | :--- | :--- |
| Anchorage | $98 \%$ | 2.24 |
| Nikiski | $100 \%$ | 0.85 |
| Seldovia | $100 \%$ | 0.88 |

The RMSE for both Nikiski and Seldovia was less than 1 degree Celsius, and their CF was $100 \%$ (Table 10). In the upper Cook Inlet, Anchorage station, the RMSE was 2.24 degree Celsius, much higher than Nikiski and Seldovia (Table 10), and CF was $98 \%$. The figure shows an almost constant error (or bias) in the Anchorage. Another item about the sea surface temperature results is that the model daily variation of temperature is higher than the observed sea surface temperature.

The Summer 2012 synoptic hindcast simulation only tested the CIOFS configuration for a single season. Therefore, in order to examine the performance of CIOFS over the four seasons and its behavior during the extreme conditions over the winter when the ice suppression algorithm will be active, a longer, multi-seasonal simulation was designed. Furthermore, as the fully operational set-up will be using G-RTOFS products for open ocean boundary forcing (temperature, salinity and sub-tidal water levels) it was decided to use this product for this second synoptic hindcast too. It was hoped that the simulation will contain at least two spring, summer, fall and winter seasons to ensure robustness and reliability. Furthermore, successful recovery of the model from the winter season's cooling effects needed to be tested.

A model simulation covering August 15, 2013 - September 15, 2015 was therefore planned and executed. The two main differences between this simulation and the summer 2012 simulation were: (i) the initial conditions were from the re-run (with convergent initial conditions) of the summer 2012 simulation assuming that August 2012 and August 2013 were similar and (ii) the use of G-RTOFS products for open boundary conditions as opposed to using climatological temperature and salinity fields. Initial attempts at running the simulation with a 5 second baroclinic timestep failed in numerical instabilities and so a reduction of the time step by $50 \%$ was performed to ensure the completion of the full 25 -month simulation without any numerical instabilities. Hence, this is the recommended time step for the fully operational setup also. The horizontal current CFL numbers are plotted as histograms (Figure 29) and their small numbers attest to the numerical stability associated with using 2.5 s as the baroclinic timestep. The vertical current CFL number has less meaning in these simulations due to the wetting-drying taking place.

Figure 29. The CFL number distributions associated with the horizontal model currents.
We conducted skill assessment using the water level and temperature station data from CO-OPS tidal gauges. No salinity skill assessment was performed since there are no salinity data available at these stations.

### 3.4.1 Water Level Skill Assessment

Hindcast 2 water level skill assessment results were very similar to the Hindcast 1 skill assessment (Figure 30; Table 11). After demeaning the water level time series, the RMSE for Anchorage, Nikiski, and Seldovia was 29.5, 25.7 and 22.3 centimeters respectively. The RMSE had a trend of increase from lower Cook Inlet upstream towards upper Cook Inlet. Even with an increase of RMSE towards Anchorage, the CF was relatively high, all above $97 \%$. That is consistent with the fact that the tidal range increased from the lower Cook Inlet upstream towards upper Cook Inlet, and the acceptable error magnitude X would increase as well. If we use the default acceptable error magnitude $X_{0}$, the skill deteriorates towards upper Cook Inlet (Table 11).

### 3.4.2 Temperature Skill Assessment

The sea surface temperature skill assessment was performed at three CO-OPS stations from $1 / 1 / 2014$ to $7 / 28 / 2015$, a period lasting about one and half years (Figure 31). While two stations have a CF of $100 \%$, the temperature CF for Anchorage was $88.3 \%$, and RMSE was $1.9^{\circ} \mathrm{C}$ (Table 12). There was a large discrepancy between the model temperature and observed temperature during the summer. The temperature bias in Anchorage area could be caused by a variety of factors, for example, net short-wave radiation, sensible and latent heat exchange, etc. From previous modeling experiences in high latitude, the summer differences in SST are often associated with the net short-wave radiation which dominated the sea surface heat flux budget. Since sea surface temperature is a tracer in a hydrodynamic model that would follow closely to the ambient air temperature, it is also very possible that the cause of the SST discrepancy is the biased forcing air temperature in Anchorage area. The temperature skill in the winter time was much better, with all stations $100 \%$ of the time within 3 degrees of the observed sea surface temperature. The summer temperature is something to follow closely in the operational setting.

Figure 31. (Panel clockwise from top-left) Geographic location of stations, Graphic comparison between modeled and observed water temperature, and summary of sea surface temperature skill assessments, Hindcast 2 (1/1/2014-7/28/2015). a. Anchorage. b. Nikiski. c. Seldovia.

Table 12. Model temperature skill assessment at Anchorage, Nikiski, and Seldovia, Hindcast 2 (1/1/2014-7/28/2015).

| Locationไcriteria | Entire period |  | Winter (December, January, <br> February) only |  |
| :--- | :--- | :--- | :--- | :--- |
|  | CF (\%) | RMSE (degree) | CF (\%) | RMSE <br> (degree) |
| Anchorage | $88.3 \%$ | 1.90 | $100 \%$ | 0.88 |
| Nikiski | $100 \%$ | 0.69 | $100 \%$ | 0.45 |
| Seldovia | $99.9 \%$ | 0.95 | $100 \%$ | 1.16 |

There are no current measurements data available during the 2013-2015 synoptic hindcast simulation time period. Therefore, a visual comparison of the currents from this hindcast with those from the summer 2012 hindcast was carried out. It was found that they were very similar in nature thereby confirming that the two simulations were similar in nature and the use of different open boundary data sources (G-RTOFS versus monthly climatology) or a $50 \%$ reduction in the baroclinic time step does not adversely affect the quality of the model predictions.

One of the main aims of this second synoptic hindcast was to examine what happens to the model predictions during the winter months and the effectiveness of the ice suppression algorithm in ROMS. An inspection of the temperature and salinity fields during the winter months showed no abnormal values over most of the grid points with isolated locations having abnormally low/high temperature and salinity values from time to time. These locations occurred on topography (that
experience wetting-drying periodically) during drying period with no continuous wet-point connection to the open water. There were no abnormal temperature or salinity values over the locations where bathymetry was present (relative to an MSL datum and where the water surface elevation was zero).

## 4. CONCLUSION AND FUTURE WORK

The Cook Inlet Operational Forecast System (CIOFS) has been developed using the state-of-art hydrodynamic ocean model ROMS. The model covers the entire Cook Inlet and waters leading to Cook Inlet around the Kodiak Archipelago (including Shelikof Strait, Stevenson Entrance, Kennedy Entrance and Chugach Passage). The major purpose of CIOFS is to provide water level and current guidance to the mariner in and out of the ports in the Cook Inlet. CIOFS also provides a platform for future particle tracking, water quality and ecosystem modelling work in the Cook Inlet region.

The observed data used for the model validation and skill assessment include 1) observed water level and surface water temperature from long-term CO-OPS stations in Seldovia, Nikiski, and Anchorage, and 2) two month-long current observations deployed in the summer of 2012.

Three numerical simulations have been performed based on availability of observed data sets. One tidal only simulation and two hindcast simulations were conducted. Of the two hindcast simulations, the first hindcast simulated from $1 / 1 / 2012$ to $9 / 15 / 2012$, which coincided with summer 2012 current meter deployments in Cook Inlet. The second hindcast simulation lasted two years from $8 / 15 / 2013$ to $9 / 15 / 2015$. The skill assessments based on the observations were performed. The water level prediction performed very well for both hindcasts. Central Frequency (CF) was more than $95 \%$ from all water level stations. The major finding of the water level skill assessment is that the RMSE was higher in the upper Cook Inlet (Anchorage) where it is shallow, muddy, and the tidal range can be 8-9 meters high.

At two stations in the lower and middle Cook Inlet, Soldovia and Nikiski, for temperature skill assessment, the CF was always more than $99.9 \%$, mostly approaching $100 \%$. In the upper Cook Inlet (Anchorage), the model temperature, especially during the summer, usually had a warm bias. Since the sea surface temperature field usually is a very passive state variable, sea surface temperature bias is most likely due to bias of the meteorological temperature field. With gradual improvement of weather models, the surface forcing bias should be able to be reduced along with the hydrodynamic model results. The CF of temperature skill assessment at Anchorage are 98\% for Hindacast 1 (assessment period: 5/1/2012-9/3/2012) and $88.3 \%$ for Hindcast 2 (assessment period: 1/1/2014-7/28/2015) respectively.

For current skill assessment, the current direction was simulated well. At 8 out of 9 current observation locations, CF of current direction was above $90 \%$. One station near South Fire Island had a low CF value (87.0). For current magnitude, 7 out of 9 stations had a CF value above $85 \%$. One of the low CF value stations was near the north coast of Fire Island, and another station was near Seldovia. Both stations overpredicted current speed.

Cook Inlet has qualities that make it challenging to develop an OFS, for example: extreme diurnal/semidiurnal high water level change, extensive mudflats in the upper Cook Inlet region, lack of accurate bathymetry data in the upper Cook Inlet region, and lack of observation data for all the state variables. Overall, CIOFS fulfilled its original task to provide water level and currents guidance, as well as temperature.

There are a few issues that may point to a direction to improve the performance of CIOFS. The first item is to improve the tides and tidal currents of CIOFS. There are regular occurrences of tidal bores in the Turnagain Arm of upper Cook Inlet. Since tidal bores produce a discontinuity like a shock wave, simulation of tidal bores would be impossible using conventional hydrodynamic ocean models. How to cope with a nonlinearity like a tidal bore to improve the water level and current prediction in upper Cook Inlet would be a key for future improvement.

In Cook Inlet, there are vast areas of tidal mud flats which are dried out during low water and submerged during high water. Tidal flats are difficult to survey and the bottom topography is under constant change especially when there are strong currents and large sediment discharges from the river. Better bathymetry survey data, and even a coupled sediment transport and morphological model would be useful.

One of the most significant developments relevant to OFSs recently is the development of the National Water Model (NWM), which would provide a nation-wide forecast of the over-land ground runoff from rivers. The Alaska part of the NWM is expected to be implemented in the next couple of years. Once the NWM for Alaska is available, CIOFS should have a much more accurate and more complete river input file that should also include forecast information.

Another issue of CIOFS is that currently the river input in the model is in a fixed location that will never be dried out during low water. An improvement of the hydrodynamic model would be to allow the river injection in the model be far more upstream at higher elevation, which would be a better representation of reality. Considering that the CIOFS mesh grid is up to 15 meters above MSL, a more realistic dynamic interaction between water from inland and coastal/estuarine water will further improve the model.

Data availability greatly hindered the development of CIOFS. Because of this, we did not try to validate the salinity output. In the future, salinity would be one variable to be validate against.

The last item regarding improvements in the model is the ice in Cook Inlet. Although Cook Inlet is free of ice most times of the year, there is ice in Cook Inlet during the winter, especially in the upper Cook Inlet. Surely, ice will have some impact on navigation in the Cook Inlet. Ice should be the priority in the future development/refinement of CIOFS.

## ACKNOWLEDGEMENTS

The authors would like to thank Dr. Christopher Paternostro and his group's work for the tidal current observation field campaign in Cook Inlet in 2012, and for providing the data from the survey.
