ABSTRACT

Since 1984 NOAA's National Status and Trends Program has analyzed samples of surface sediment collected at about 200 coastal and estuarine sites throughout the United States. The chemical contaminants measured are chlorinated pesticides, polychlorinated biphenyls(PCBs), polyaromatic hydrocarbons (PAHs), and twelve trace elements. Sediment characteristics such as grain size, which affect contaminant concentrations, have also been quantified. With few exceptions, the higher levels of contamination have been found among the175 sites where the sediment is muddy rather than sandy. Most of the highest concentrations for any particular contaminant have been at the 20 sites near Boston, New York, San Diego, Los Angeles, or Seattle. Despite being sandy, sediments at two Long Island Sound sites showed high levels of polyaromatic hydrocarbons. Except for some sites near the Florida cities of Jacksonville, Tampa, Panama City, and Ft. Walton Beach, levels of contamination at sites in the Gulf of Mexico and in the southeastern United States were relatively low.

INTRODUCTION

Decisions on the use and allocation of resources in the nation's coastal and estuarine regions require reliable and continuous information on the status and trends of environmental quality in those areas. Beginning in 1984 the National Oceanic and Atmospheric Administration (NOAA) undertook the task of providing this information through its National Status and Trends (NS&T) Program for Marine Environmental Quality. The program's objectives include defining the geographic distribution of contaminant concentrations in tissues of marine organisms and in sediments, and documenting biological responses to contamination. Samples have been collected since 1984 at about fifty Benthic Surveillance sites and since 1986 at about 150 Mussel Watch sites. Sediment samples are collected at all sites. At Benthic Surveillance sites, benthic fishes are collected and their livers excised and stored for subsequent chemical analysis. At Mussel Watch sites bivalve molluscs are collected for analysis. The first NS&T report (NOAA, 1987a), based on data from analyses of sediments and fish livers collected in 1984, was issued in January 1987. The second report (NOAA, 1987b) was issued in December of 1987 and was a summary of tissue contaminant data for fish collected in 1984 and 1985 and bivalves collected in 1986.

This report includes an analysis of Benthic Surveillance sediment data for 1984 and 1985 samples, and of Mussel Watch sediment data from 1986 and 1987. All data from all years have been combined in this report. Differences, if they exist, between years at a given site have been ignored in order to focus on the geographical distribution of chemical contamination.

Information from the NS&T Program will provide a basis for setting priorities for management action and for documenting changes that may occur because of such actions. One objective of the program is to quantify general, depositional areas of contamination and not to define "hot spots". Sites are selected deliberately away from major point sources of contamination. Management action taken on any individual point source will probably not be seen in the NS&T data unless that source exerts a dominant influence on environmental quality over a relatively large area. On the other hand, the NS&T program will identify the combined influence of many point and non-point sources of contamination to an area.

SITE LOCATIONS

The sites sampled by the Benthic Surveillance Project in 1984 and 1985 and by the Mussel Watch Project in 1986 and 1987 are located on the series of maps that comprise Appendix A. Each site carries the name of its general location. Because there is often more than one in a general area, the Mussel Watch sites also have a more specific designation. All sites are assigned a code -- four letters for Mussel Watch and three for Benthic Surveillance. The codes used throughout this report are intended to remain constant from year to year as the NS&T Program evolves.

FIELD AND ANALYTICAL METHODS

Sediment was collected at three stations within each site, a station being anywhere within 500 m of a site center. For the Mussel Watch Project, if only sand could be found at the bivalve site, the center of a sediment site could be as much as 2 km from that bivalve site. For Benthic Surveillance sampling in the Northeast, stations were up to about 5 km apart, so in effect a site was up to 100 times larger than that for other NS&T sites.

In the Benthic Surveillance Project, sediment samples were obtained with a specially constructed box corer or a standard Smith-MacIntryre bottom grab. In the Mussel Watch Project, the samples were obtained with the box corer or with a Kynar-coated Van Veen grab sampler. Three grabs or cores were obtained at each of the three stations at a site. Composite samples were made from surface sediment in those three grabs or cores. Three separate composites were made per station, one for organic chemical analysis, one for inorganic analysis, and one for other sediment characteristics such as grain-size and total organic carbon. Sediment analyses for a site consisted of organic analyses of three composites (one from each station), inorganic analyses of three separate composites, and grain-size and other measurements on a third set of three composites.

In the Benthic Surveillance Project, subsamples for organic analyses were composites of surface skims from the top 3 cm of each grab or core. A small corer was used to subsample the top 3 cm of each box core or grab sample for trace metal and other analyses. In the Mussel Watch Project, the subsamples for all composite were surface skims from the top 1 cm of each box core or grab.

Samples for analyses of organic components were stored in Teflon jars or glass jars with lids lined with aluminum foil. Those to be used for analyses of major and trace elements were stored in Teflon jars or ziplock bags. A more detailed presentation of the sampling protocols is included in Shigenaka and Lauenstein (1988).

The chemical properties measured in NS&T sediment samples are listed in Table 1. The methods used for analysis of organic chemicals in sediments collected in the Benthic Surveillance Project are described in a technical report prepared by NOAA's National Analytical Facility (MacLeod et al., 1985). For elemental analysis sediments were digested in concentrated hydroflouric acid. The grain size distribution among sediment particles was measured and used in this report to account for differences among levels of contamination that are due to differing capacities for sediments to accumulate contaminants. Total organic carbon was also measured and might have been used, instead of grain size, to "normalize"

Table 1. Chemicals measured in the National Status and Trends Program.

DDT and its metabolites[a]

o,p'-DDD
p,p'-DDD
o,p'-DDE
p,p'-DDE
o,p'-DDT
p,p'-DDT

Chorinated Pesticides Other Than DDT[b]

Aldrin
Alpha-Chlordane
Trans-Nonachlor
Dieldrin
Heptachlor
Heptachlor epoxide
Hexachlorobenzene
Lindane (gamma-BHC)
Mirex

Polyaromatic Hydrocarbons[d]

2-ring
Biphenyl
Naphthalene
1-Methylnaphthalene
2-Methylnaphthalene
2,6-Dimethylnaphthalene
Acenaphthalene

3-ring
Flourene
Phenanthrene
1-Methylphenanthrene
Anthracene

4-ring
Flouranthene
Pyrene
Benz(a)anthracene

5-ring
Chrysene
Benzo(a)pyrene
Benzo(e)pyrene
Perylene
Dibenz(a,h)anthracene

Major Elements

Al	Aluminum
Fe	Iron
Mn	Manganese
Si	Silicon

Trace Elements

Sb	Antimony
As	Arsenic
Cd	Cadmium
Cr	Chromium
Cu	Copper
Pb	Lead
Hg	Mercury
Ni	Nickel
Se	Selenium
Ag	Silver
Sn	Tin
Zn	Zinc

Polychlorinated Biphenyls[c]

Dichlorobiphenyls
Trichlorobiphenyls
Tetrachlorobiphenyls
Pentachlorobiphenyls
Hexachlorobiphenyls
Heptachlorobiphenyls
Octachlorobiphenyls
Nonachlorobiphenyls

Other Parameters

Total organic carbon
Grain size
Coprostanol
Clostridium perfringens spores

[a] Combined and reported in this paper as total DDT (tDDT). The dominant compounds were generally p,p'DDE and p,p' DDD

[b] Combined and reported in this paper as total chlorinated pesticides other than DDT (tChlP). Generally this fraction was dominated by dieldrin and the chlordanes.

[c] Combined and reported in this paper as total polychlorinated biphenyls (tPCB).

[d] Combined and reported in this paper as total polyaromatic hydrocarbons (tPAH). In 70% of the samples, more than 75% of the tPAH was comprised of 4-and 5-ring compounds

sediments for their ability to accumulate organic contaminants. In this report, however, total organic carbon is treated as a contaminant. The major elements, Al, Fe, Mn, and Si, were included in the analytical scheme and might have served as normalizing factors but have not been used in this report. In addition, the sediments were analyzed for their concentrations of *Clostridium perfringens* spores (only in the Benthic Surveillance Project) and coprostanol, both of which can serve as indicators of the level of contamination with sewage. Battelle(1987) and Texas A&M (1988) both provide details of analytical methods employed in the Mussel Watch Project .

Quality assurance (QA) protocols are an integral part of the NS&T Program. QA efforts are designed to produce nationally uniform analytical results of known and accepted quality, thereby ensuring comparability among data sets. Attainment of this goal involves five major activities:

Development and use of standardized field sampling procedures and analytical protocols;
Conduct of interlaboratory comparisons of analytical methods;
Conduct of periodic quality assurance workshops;
Development of Standard Reference Materials (SRMs) and Interim Reference Materials (IRMs) for marine sediments and tissues; and
Development and use of a standardized data base for QA data and information.

NORMALIZING CONCENTRATIONS

Sediments are used in the NS&T program as integrators of contaminant loadings to individual sites. Bivalves and fish are also used for this purpose and have the advantage of being substrates whose contaminant concentrations can change relatively quickly in response to changes in their surroundings. Contaminant levels in sediments will not quickly reflect changes in contaminant discharges. However, for determining spatial distributions on a national scale they have the distinct advantage over bivalves and fish in that concentration differences among sites are not influenced by differences in species.

Nevertheless, contaminants are associated with particle surfaces and differences in contaminant concentrations among sites can be generated simply by differences in particle sizes of sediments. To compensate for this sediment data have been normalized by dividing the raw concentration in a composite by the fraction by weight of sediment particles in the composite (from the same station) which are less than 64μ in diameter (i.e., the fine-grained or silt and clay fraction). This is equivalent to assuming that no contaminants are associated with sand-sized particles and that the only effect of sand in a sample is to dilute its level of contamination.

To some extent contaminants can be associated with sand-sized particles and this method of normalizing can yield misleading results for sediments that are primarily sand. When such sediments contain detectable levels of contamination, that level, when normalized, will appear to be very high because it will have been divided by a low number. The opposite will occur when sandy sediment has contaminant levels that are below detection. Normalizing such values still leaves them below detection, which in this report are treated as zero. Such zeroes, due primarily to the diluting effect of sand, would be misleading in the context of other samples from a site which were not so sandy. To avoid concluding that a sediment composite has an unusually high or low level of contamination when, in fact, it is simply a sandy sample, no contaminant data were used if they were derived from sediments containing less than 20% fine-grained material. Therefore, at most, the normalizing procedure could increase a raw concentration by a factor of five.

THE DATA BASE

There are 212 sites throughout the coastal United States at which sediment was collected in 1984 or 1985 (Benthic Surveillance) or 1986 or 1987 (Mussel Watch). For 176 of those sites, contaminant data exist for at least one sufficiently fine-grained composite sample. Most sites were occupied in two years and most yielded fine-grained sediment in composites from all three stations in both

years, so for most sites there are six replicate sets of analytical results.

Chemicals in Table 1 considered as "contaminants" are all the trace elements whose naturally occurring concentrations can be elevated because of human activity: antimony, arsenic, cadmium, chromium, copper, lead, mercury, nickel, selenium, silver, tin, and zinc. Polyaromatic hydrocarbons are also naturally-occurring substances whose concentrations have been increased by human activities. In that same sense total organic carbon is considered a contaminant. Lastly, the chlorinated organic chemicals whose actual existence is due to humans are included among the contaminants.

The organic chemical data have been aggregated for this report. The concentrations of 18 individual polyaromatic hydrocarbons have been combined to create a single analytical result in terms of total polyaromatic hydrocarbons (tPAH). It should be noted, however, that more than 75% of the tPAH found in 70% of the samples consisted of 4-and 5-ring rather than 2- and 3-ring compounds. Individual PCB data have been combined into a tPCB value. Individual data on DDT and its metabolite compounds have been combined to a total value called tDDT, which is dominated by the metabolites p,p' DDE and p,p' DDD. While chlordanes and dieldrin generally prevail, all the non-DDT chlorinated pesticide data have been combined into a single value, tChlP.

Summary statistics (mean, coefficient of variation, and number of samples) for normalized contaminant concentrations in fine-grained sediment in the NS&T data base are listed in Appendix B. Although they will not be used for comparisons among sites, non-normalized data for the sand-sized sediments are listed in Appendix C.

DATA DELETIONS

In this summary we are emphasizing mean concentrations of contaminants. Occasionally one value for a contaminant concentration at a site is very much higher than all the other values. Whenever a mean is dominated by one value that is more than ten times greater than the next highest (of at least three) values that high value has been deliberately ignored. This has resulted in ignoring one Sn value, one Hg value, seven tDDT values, three tChlP values, three tPCB values, and one tPAH value. Appendix B contains a table listing those deliberately ignored values and shows the difference their exclusion has meant to the mean and variance used for that site. Four of those 16 deletions caused the site to not be considered among the most contaminated sites for that contaminant.

RESOLUTION OF THE DATA

Because this summary emphasizes means and rankings among them, it is important to recognize variability in the data and the limits that imposes on comparing concentrations. Table 2 lists ratios of low to high concentrations for each contaminant, and an estimate of how large the ratio must be between concentrations at any two sites to be 90% confident that the two sites really differ in their concentration for that contaminant.

Low to high ratios have been diminished to some extent by not including the four highest and four lowest values. It is, still, evident that the tChlP, tDDT, tPCB, tPAH, mercury, silver and tin span large concentration ranges and strongly indicate human influence. On the other hand, the sedimentary concentrations of arsenic, zinc, TOC, selenium, nickel, lead and chromium vary by less than a factor of 20 over the national network and are therefore not so greatly indicative of human activities. One contaminant, selenium, shows a very narrow range and so high a variability that almost all the sites must be considered equivalent in terms of their selenium concentration. For that reason, selenium concentrations are not used when, in the following section, the most contaminated sites are specified. A special consideration with regard to selenium is its apparent absence in sediments at Mussel Watch sites in California. The laboratory making those analyses reported detection limits of 6.0 and 0.6 ppm in 1986 and 1987, respectively. Only one sample yielded a quantifiable concentration. That concentration, 8.3 ppm at site SFEM in San Francisco Bay, was the highest concentration in the entire data base.

Table 2. Resolution in sediment data

Chemical	Number of sites with detectable conc.	Concentration range as the ratio of the 5th heighest to 5th lowest[a]	Number of sites with more than 2 detectable conc. values[b]	Overall coefficient of variation(%)[c]	Ratio required to establish a significant difference[d]
tChlP	161	160	140	75	11
tDDT	164	1500	142	66	9.8
tPCB	159	290	142	58	3.0
tPAH	167	470	156	58	4.7
TOC	141	16	160	34	1.6
Sb	139	26	123	45	4.0
As	175	7.6	160	31	1.8
Cd	175	32	160	30	1.5
Cr	169	16	153	27	2.4
Cu	175	22	160	23	1.3
Pb	174	17	160	24	1.3
Hg	136	88	151	45	2.9
Ni	175	13	159	22	1.3
Se	148	12	128	69	15
Ag	140	94	158	37	2.0
Sn	121	61	137	51	3.6
Zn	175	10	160	21	1.4

[a]The highest and lowest concentrations were not used to avoid having the ratio skewed by extremely high or low values.

[b]Number of sites at which there were at least three reported concentrations, two of which were above detection. The calculations required for the last two columns used only data that met these criteria.

[c]The average coefficient of variation among those sites (individual c.v.'s are in Appendix B).

[d] Ratios between two values to detect a significant difference at the 90% level of confidence. Calculated by first converting data to its logarithmic equivalent, then deriving the overall coefficient of variation for the geometric means, then applying that overall value to each geometric mean to calculate a pooled standard error, and finally calculating a Least Significant Difference (LSD) at the 90% confidence level (Snedecor and Cochran, 1980). Strictly speaking these ratios apply only to geometric means, not the arithmetic means that are used throughout this report.

Combined with five non-detected determinations the mean for that site became 1.4 ppm with a coefficient of variation of 245%. Although the data are not so variable, tin was also an element detected in only a single sediment sample from a Mussel Watch site in California, because of a laboratory's high limit of detection.

The overall ranges for all mean concentrations, including those for selenium, are shown graphically in Appendix D. To convey the differences among the highest mean values and their difference from the lowest values, the plots include the highest 25 and lowest 10 mean concentrations.

THE MOST CONTAMINATED SITES

All 212 sites are shown in Table 3 ordered from the Northeast to the Northwest in more-or-less clockwise fashion. To portray a sense of the extent to which normalizing has altered raw data, the average percentage of fines among the sufficiently fine-grained material is also listed. (Concentrations were normalized, however, on the basis of individual station data not on the basis of mean values.) For completeness, even though the data are not being used, sites are listed at which no fine-grained material was collected. These are sites, like others, for which there are data on contaminant levels in bivalves and fish livers. The lack of fine-grained material does not necessarily mean that a site is not receiving contaminants. It means only that the sediment is too coarse to accumulate contaminants in a manner comparable with other sites.

Table 3 indicates the number of times a contaminant concentration at a site is among the upper 20 of 176 concentrations, specifies the contaminant, and lists its ranking. The upper ten percent of the concentrations are emphasized because the differences among concentrations are larger than among lower-ranked values. Also, it is biological response to contamination that is of more concern than the contamination itself, and it is at these highest levels of contamination that one would most likely find a response. Table 3 may be read as a list of the most contaminated coastal areas in the United States. Because of limitations, listed in Table 2, imposed by concentration ranges and variability, little significance should be attached to a site having only one or two high concentrations unless those concentrations are very high.

If contaminant levels in sandy sediments had been normalized in the usual fashion, many sandy composites would have ranked among the more contaminated. It was to avoid such artifacts that sediment composites containing more than 80% sand have not been used. Nevertheless there are a few instances where even non-normalized contaminant concentrations in sandy sediments (Appendix C) would rank among the 20 highest normalized concentrations. Sandy samples from two sites in the Hudson/Raritan Estuary, NY (HRUB and HRLB) had tPAH concentrations in excess of 10,000 ng/g and would have placed those sites high in the rankings if they were not already there on the basis of tPAH in their fine-grained samples. Similarly, the tDDT concentrations in the sandy samples from San Pedro Canyon, CA (SPC) and Choctawatchee Bay, FL (CBSP), the Cr concentration in a Humboldt Bay, CA (HMB) sample and the Ag concentration in the sandy sediments at a Hudson/ Raritan Estuary, NY (HRLB) site would all have placed those sites among the highly contaminated if the fine-grained samples had not done so. In three cases sites with only sandy sediments were found to have non-normalized concentrations of a contaminant that would have been among the highest 20 normalized concentrations: Sb in Elliott Bay, WA (EBFR), and Cr at both San Francisco Bay,CA (SHS) and Bodega Bay, CA (BOD). While the concentrations were not quite as high as at the 20th ranking fine-grained site, it is worth noting that tPAH was about 5000 ng/g at two sites in Long Island Sound (LICR and LIHR) at which only sand was collected.

Table 3. NS&T sites with their CODES keyed to maps in Appendix A, mean percent fines (%f) in samples with >20% fine-grained sediments, total number (T) of contaminant concentrations (normalized to fines) ranking among the highest 20 concentrations, and symbol and ranking of specific contaminants in that category , (nfgs = no fine-grained sediments collected at the site)

REPRESENTATIVENESS

It is the intention of the NS&T Program to sample sites that are representative of areas rather than only the site itself. However, that is a qualitative concept until the size of the area being "represented" is defined. The straight-line distances between adjacent Mussel Watch sites vary considerably but average 20 km within estuaries or semi-enclosed areas and almost 100 km along open stretches of coast. A test of a site's representativeness is approximate agreement in contaminant concentrations between adjacent sites. On that basis, the obvious clustering in Table 3 of sites with high contaminant levels, argues for the areas around Boston, New York, San Diego, and Los Angeles to have been representatively sampled.

Even in those cases, there are irregular observations. The highest mean tPAH concentration in the entire data base was found near Boston, MA at site, BOS. That site was one of only five among all 212 sites where more than 75% of the tPAH consisted of low molecular weight (2- and 3-ring) compounds. Without those compounds the tPAH concentration would have been 10000 ng/g, still a high value but one closer to those at the other Boston Harbor sites. On the west coast, the most anomalous of the highly contaminated sites was that off Palos Verdes, CA, PVRP. As at most west coast sites along open coasts, it was necessary to move offshore to obtain fine-grained sediment. The sampling site in this case turned out to be within 2 km of the terminus of the Los Angeles County sewage effluent discharge pipe. The reported tDDT concentration of 6800 ng/g is similar to those reported by Swartz et al. (1986) who deliberately sampled near the discharge to test effects of uniquely high contaminant levels. That site can hardly be considered representative of the coastal area, but many of the contaminants found to be highly concentrated there, tDDT, tPCB, Cd and Ag, are also at high levels at other sites near Los Angeles. When viewed from a national perspective, the coastal waters around Los Angeles can be considered contaminated for at least those chemicals. When viewed from a local perspective, it becomes important to note differences between sites that are inside and outside the breakwater that creates Los Angeles and Long Beach Harbors, and inside the breakwater contaminant levels increase towards the inner harbors.

Sites around Boston, New York, San Diego, and Los Angeles tend to support one another in the sense that high contaminant levels at one are reflected at others. High contaminant levels at the ELL site near Seattle, WA, the SAWB site near Panama City, FL and the CBSP site near Ft. Walton Beach, FL may or may not be representative of their surroundings. In all three cases no fine-grained sediment was collected within 10 to 20 km. It will be necessary to do so in the future, to test whether high levels of contamination are typical of the areas.

Fifteen of the highest levels of total organic carbon (TOC), including the three extremely high values, were found between the southern tip of Florida and Terrebonne Bay in Louisiana. In general, these levels are not due to human activity but reflect the marshy nature of sites where sediments contain large amounts of decaying vegetation. All of the sites in San Francisco and San Pablo Bays are highly enriched in nickel. Nickel was also commonly found at high levels at sites north of San Francisco and into Alaska. Rather than being a manifestation of human activity, this could well be a natural condition signifying a tendency for minerals in the region to be relatively enriched in nickel.

HOT SPOTS

The low concentrations found within the NS&T network probably encompass the least contaminated sites in the coastal United States. Except for tDDT concentrations at the PVRP site, the highest concentrations do not include the most contaminated locations in the country. If "hot spots" were deliberately sought, sampled, and analyzed, it is probable that all sites, except PVRP, could be replaced on the current list of the 20 most contaminated. For example, sediments taken from Black Rock Harbor in Bridgeport, CT (Rogerson et al. 1985) show higher levels of tPAH, tPCB, Cd, Cu, Pb, and Zn than any of the NS&T sites. The tPAH, As, Hg, and Pb levels found in sediments of the Duwamish and Hylebos

Waterways in Seattle and Tacoma, WA, respectively, (Malins et al.1982) would rank above the highest NS&T values. Levels of tPCB well above those at any NS&T site have been found in sediments of New Bedford Harbor, MA (Weaver, 1984). Samples of sediment near a creosote facility on the Elizabeth River, VA have been found with higher tPAH concentrations than the highest concentration at an NS&T site (Huggett et al, 1987). The NS&T sites locations are intended to yield data that are "representative" of general areas rather than spots. The exact spatial scale that differentiates "areas" from "spots" has not been quantitatively prescribed but a "hot spot" would not qualify as "representative" when a sediment sample collected within about 10 km of it is found to be much less (ten times or more less) contaminated.

CONCLUSIONS

The NS&T Program is determining the status and trends of contamination in the coastal United States through analysis of bivalves, fish livers, and sediments. The status of contamination has now been assessed in both biological tissues (NOAA, 1987b) and in sediments with this report. Much remains to be done in comparing those two sets of data and in expanding the tissue data to begin to define temporal trends, but it is immediately evident that regardless of what is sampled, or when, the highest levels of contamination are associated with urban areas.

More important than the distribution of contamination itself is the distribution and spatial scale of locations within which marine organisms are responding to contamination. There are no reliable criteria with which to extrapolate levels of sediment contamination to the presence of biological effects and we cannot claim, *a priori*, that the areas found to be highly contaminated are necessarily places where biota have been affected. There is, however, a biological monitoring component to the NS&T Program. There is work ongoing to test whether fish in contaminated areas are suffering reproductive damage or responding to contamination in other, less consequential ways. Tests of sediment toxicity are also being done in a few areas. While such tests suffer to some extent from being artificial exposures to manipulated sediment they can serve the purpose of finding correlations between levels of contamination and biological response.

REVISIONS to APPENDIX B

Since this report was compiled, some additions and changes have been made to the organic chemical data. None affect the discussion in the report. Listed here are cases where, because of additions or changes, the reported mean normalized concentration in **fine-grained sediment** has been altered by more than 10% and by at least 3 ng/g. As in APPENDIX B, a mean concentration of "nd" denotes "not detected" and a dash (-) denotes "no data". All concentrations are in units of ng/g-dry wt.

APPENDIX B.

Summary Statistics for Contaminant Concentrations in Fine-Grained Sediments

APPENDIX B.

National Status and Trends Program

Summary Statistics for Contaminant Concentrations in Fine-Grained Sediments Collected in 1984 through 1987

All the concentrations in this appendix are normalized values. Raw concentrations from composite samples at a station (three stations per site per year) have been divided by the fraction of the total sediment in composites from that station which was fine-grained (<64 μ). Whenever that fraction was <0.2 the data were not used, but data from those sandy sediments are reported in Appendix C.

The first page in this appendix lists the values that have been considered to be outliers and have not been incorporated into the summary statistics.

Explanation of tables:

The column labeled "CODE" indicates site location more specifically than does the column labeled "SITE" and is keyed to the maps in Appendix A showing site location.

The next nine columns are three values for each of three analytes: the mean concentration, the coefficient of variation (c.v.%, standard deviation divided by mean), and the number (n) of composites whose normalized concentrations are part of the mean.

A mean is listed as "nd" when the contaminant was not detected in any of the samples for the site. When at least one analysis yielded a quantifiable signal the "nd's" have been treated as zeros when calculating the summary statistics. When no analyses was made for a contaminant, its mean is listed as a triple dash (---). A single dash (-) appears for a c.v% whenever n ≤1 and for n whenever n=0.

DATA DELETIONS

This report emphasizes mean concentrations of contaminants and, occasionally one value for a contaminant concentration at a site is very much higher than all the other values. Whenever a mean is dominated by one value that is more than ten times greater than the next highest (of at least three) values that high value has been deliberately ignored. This table lists those deliberately ignored values and shows the difference their exclusion has made in the summary statistics for that site.

		Outlying	Unmodified summary			Summary as used

APPENDIX C.

Summary Statistics for Contaminant Concentrations in Sandy Sediments

APPENDIX C.

National Status and Trends Program

Summary Statistics for Contaminant Concentrations in Sandy Sediments Collected in 1984 through 1987

Unlike the data for fine-grained sediments (%fine >20%),where contaminant concentrations were normalized for the fraction of fine-grained sediment in the sample, these data for sandy sediments (%fine ≤20%) have been derived directly from the raw concentration data.

Explanation of tables:

The column labeled "CODE" indicates site location more specifically than does the column labeled "SITE" and is keyed to the maps in Appendix A showing site location.

The next nine columns are three values for each of three analytes: the mean concentration, the coefficient of variation (c.v.%, standard deviation divided by mean), and the number (n) of composites whose normalized concentrations are part of the mean.

A mean is listed as "nd" when the contaminant was not detected in any of the samples for the site. When at least one analysis yielded a quantifiable signal the "nd's" have been treated as zeros when calculating the summary statistics. When no analyses was made for a contaminant, its mean is listed as a triple dash (---). A single dash (-) appears for a c.v% whenever n ≤1 and for n whenever n=0.

Sites appear in both this and in Appendix B, for fine-grained sediments, whenever individual composites from stations at a site fall into separate categories.

Sediments at these five sites were too coarse to even be collected by a grab sampler or box-corer:

BHBI	Boston Harbor MA , Brewster Islands
SCFP	Santa Cruz CA, Fraser Point
SSSS	San Simeon Point CA, San Simeon Point
PAPA	Point Arena CA, Point Arena
PDSC	Point Delgada CA, Shelter Cove

Percentages of fine-grained material ,% dry-wt., (**fine**) and concentrations, %dry-wt., of total organic carbon (**TOC**) and polyaromatic hydrocarbons, ng/g dry-wt., (**tPAH**) in sandy sediments from NS&T Sites from **Maine** through **Mississippi.**

APPENDIX D.

Plots of Ranked Contaminant Concentrations

APPENDIX D.

National Status and Trends Program

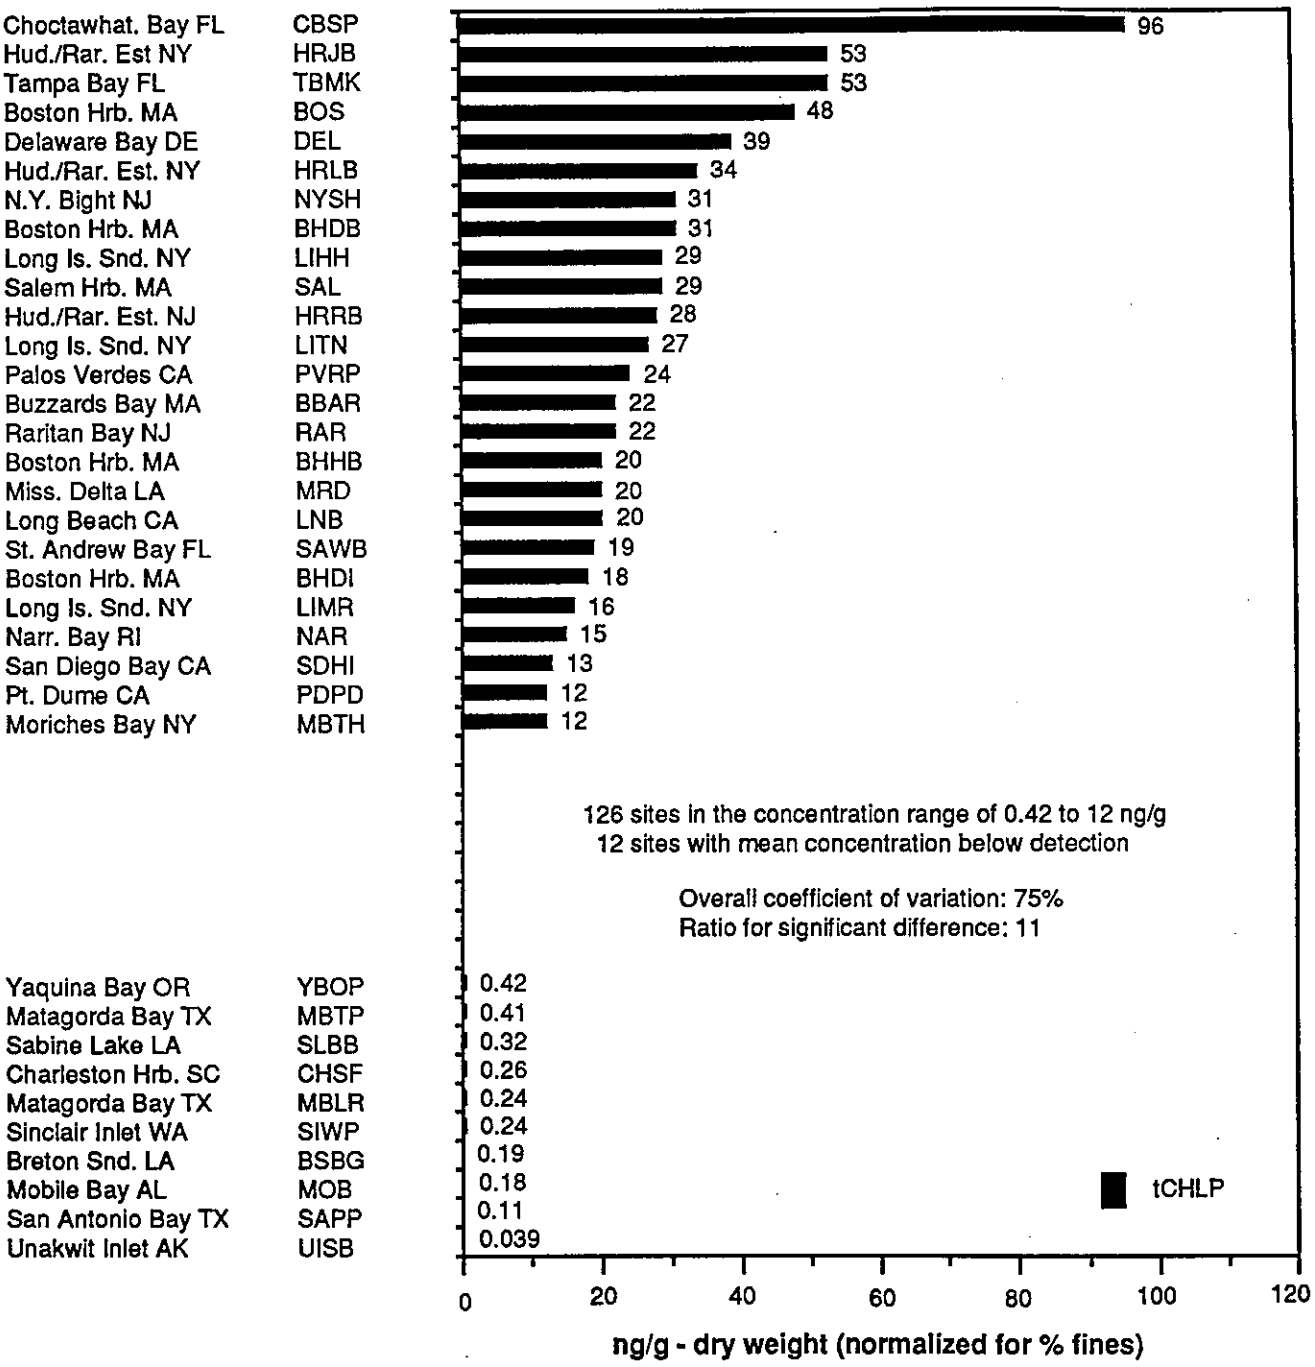
Plots of Ranked Contaminant Concentrations Observed in Sediments Collected in 1984,5,6,and 7 [a,b]

Sequence of Plots by Contaminant

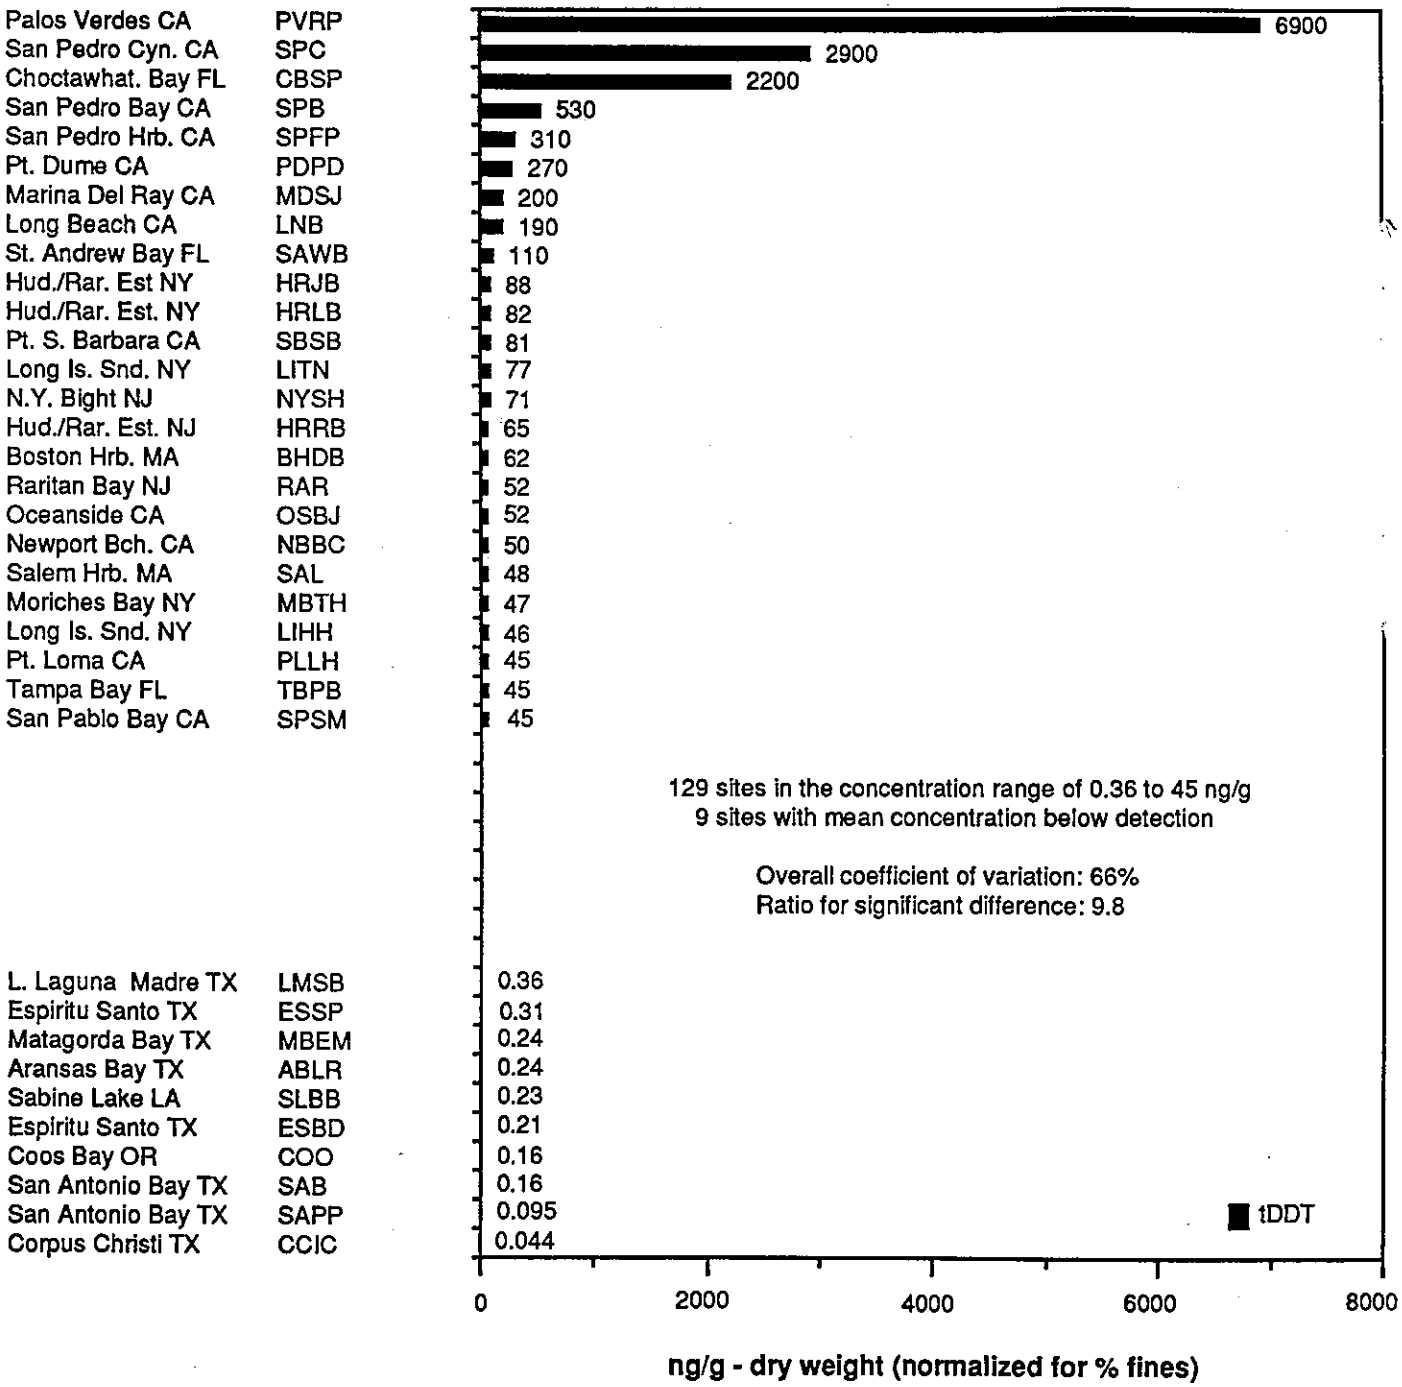
[a] Concentrations for all samples have been normalized by being divided by the fraction of fine-grained (<64μ) sediment in that sample. The rankings are of the means of the normalized values for each site. The number of fine-grained samples at each site are noted inTable 2 of the text. Sediment samples containing <20% fine-grained material have not been considered.

[b] Within each graph are the overall coefficient of variability in the mean concentrations for that contaminant and the ratio of two means that should be exceeded to, statistically, consider two means to be different (see Table 2 in text).

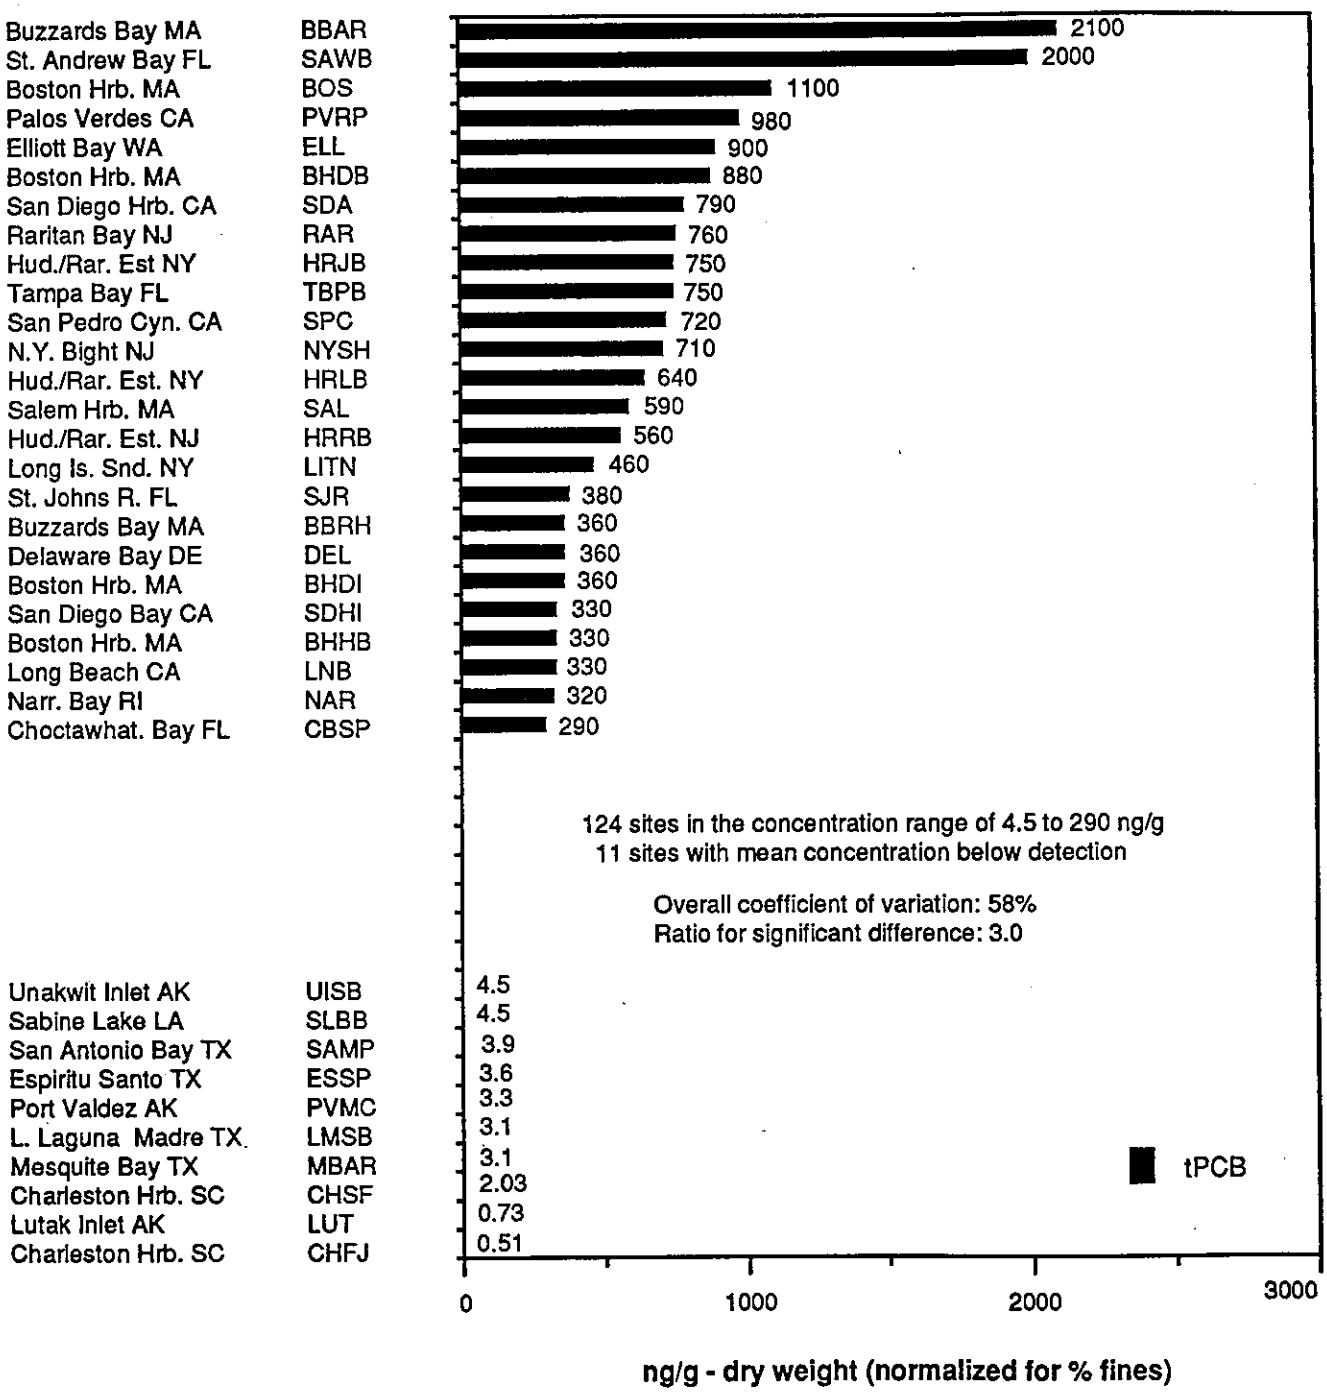
Total (non-DDT) Pesticides in Sediments



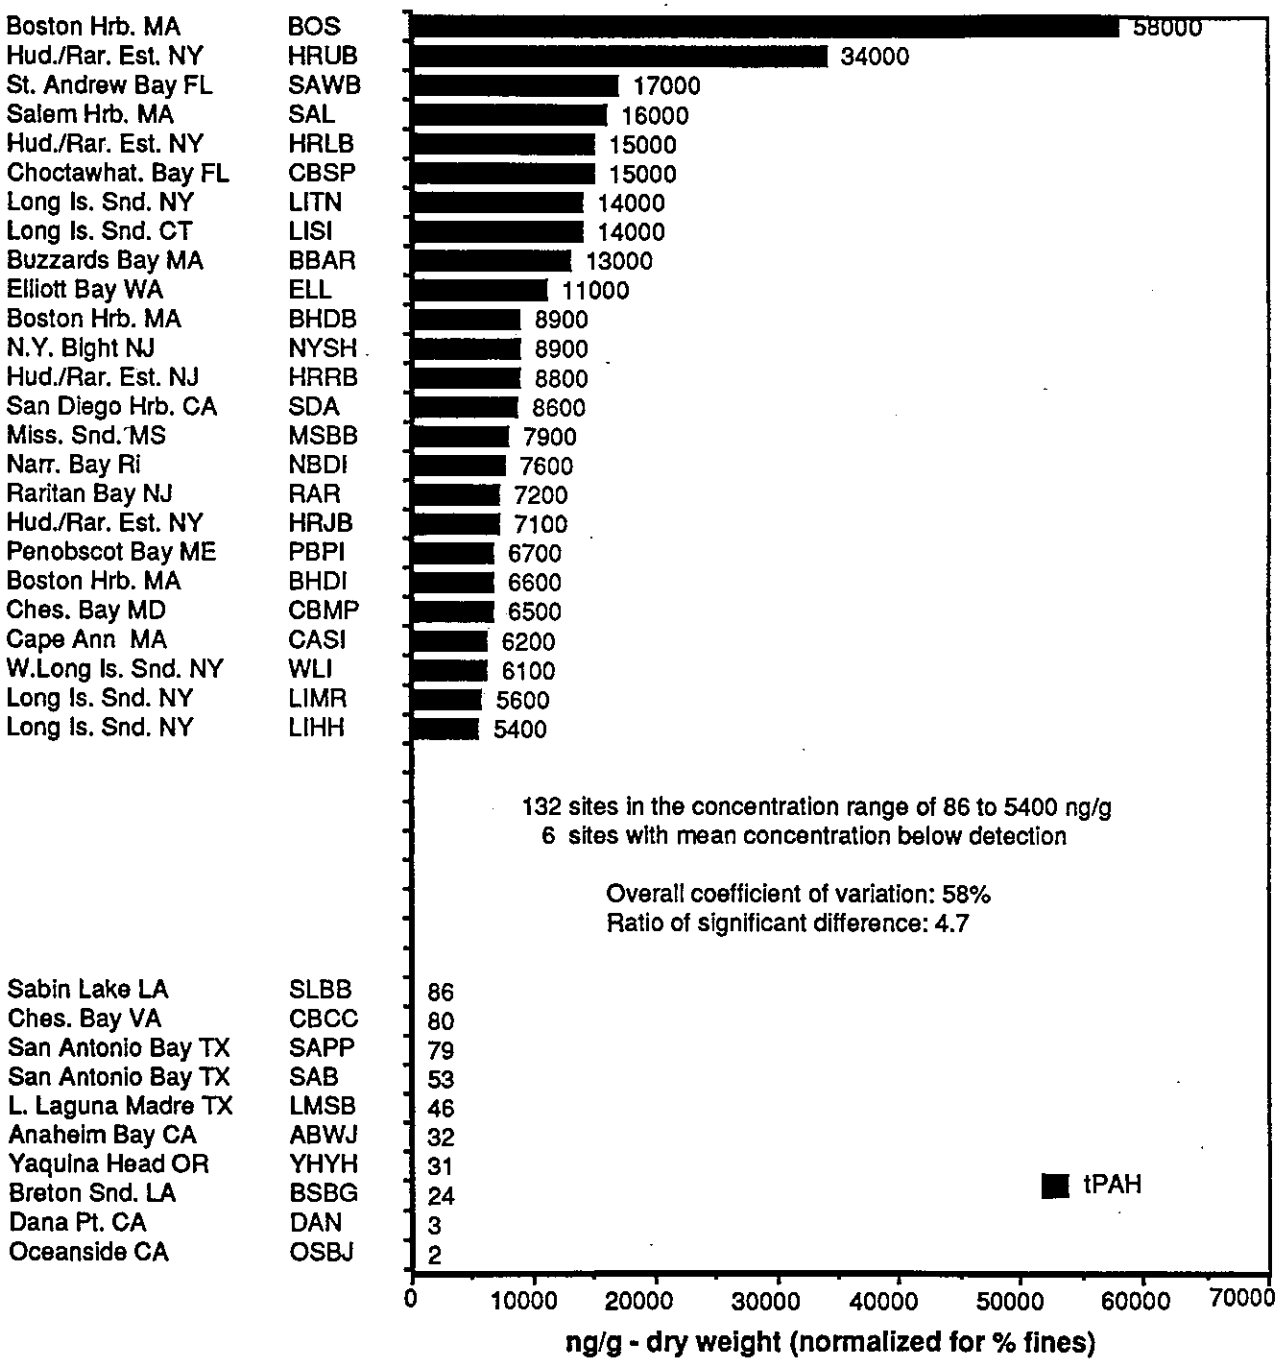
Total DDT in Sediments



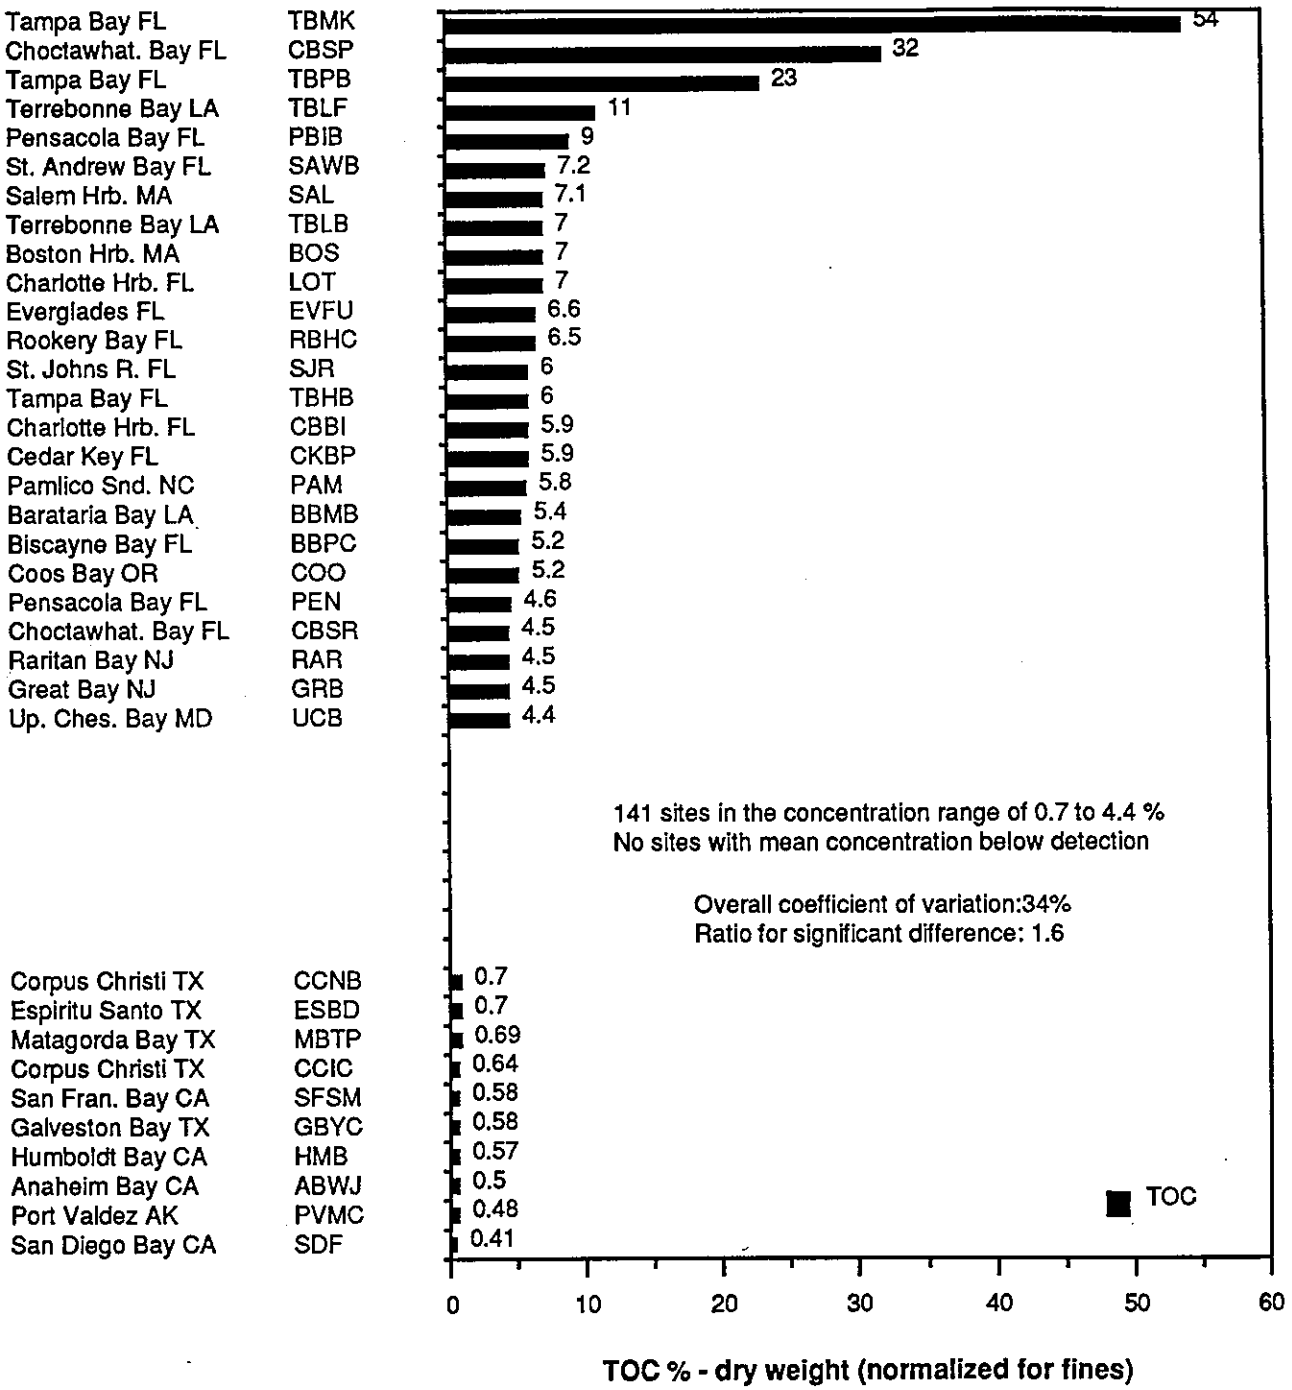
Total PCB in Sediments



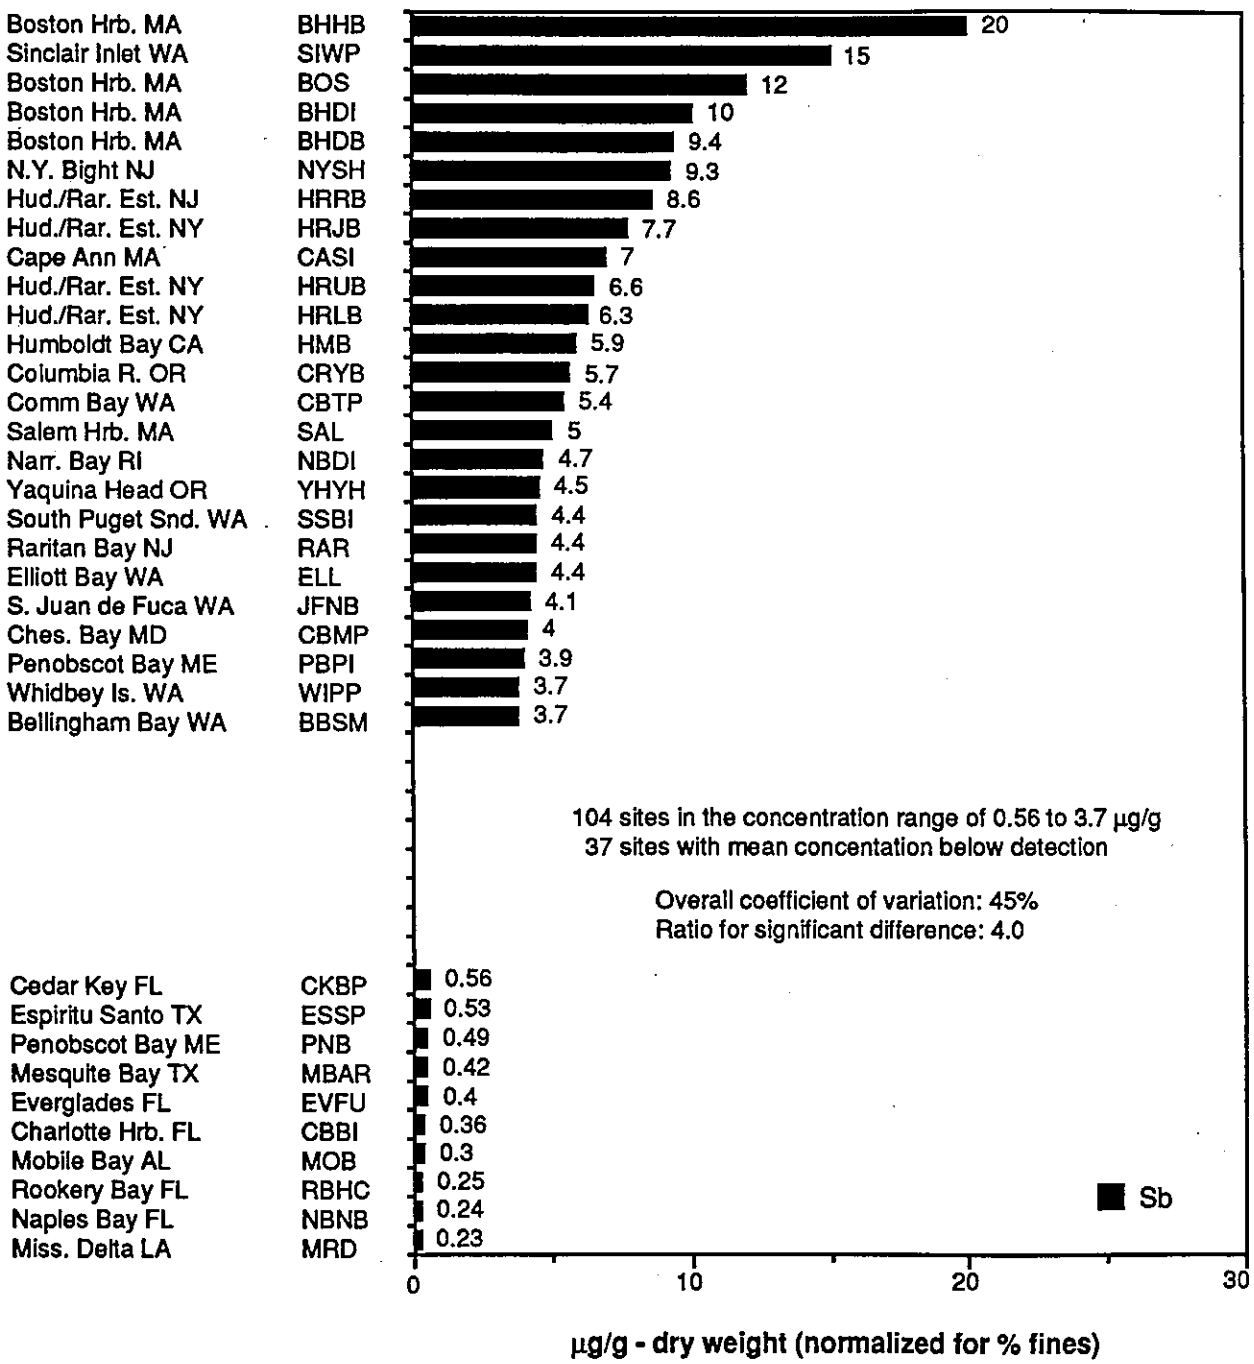
Total PAH in Sediments



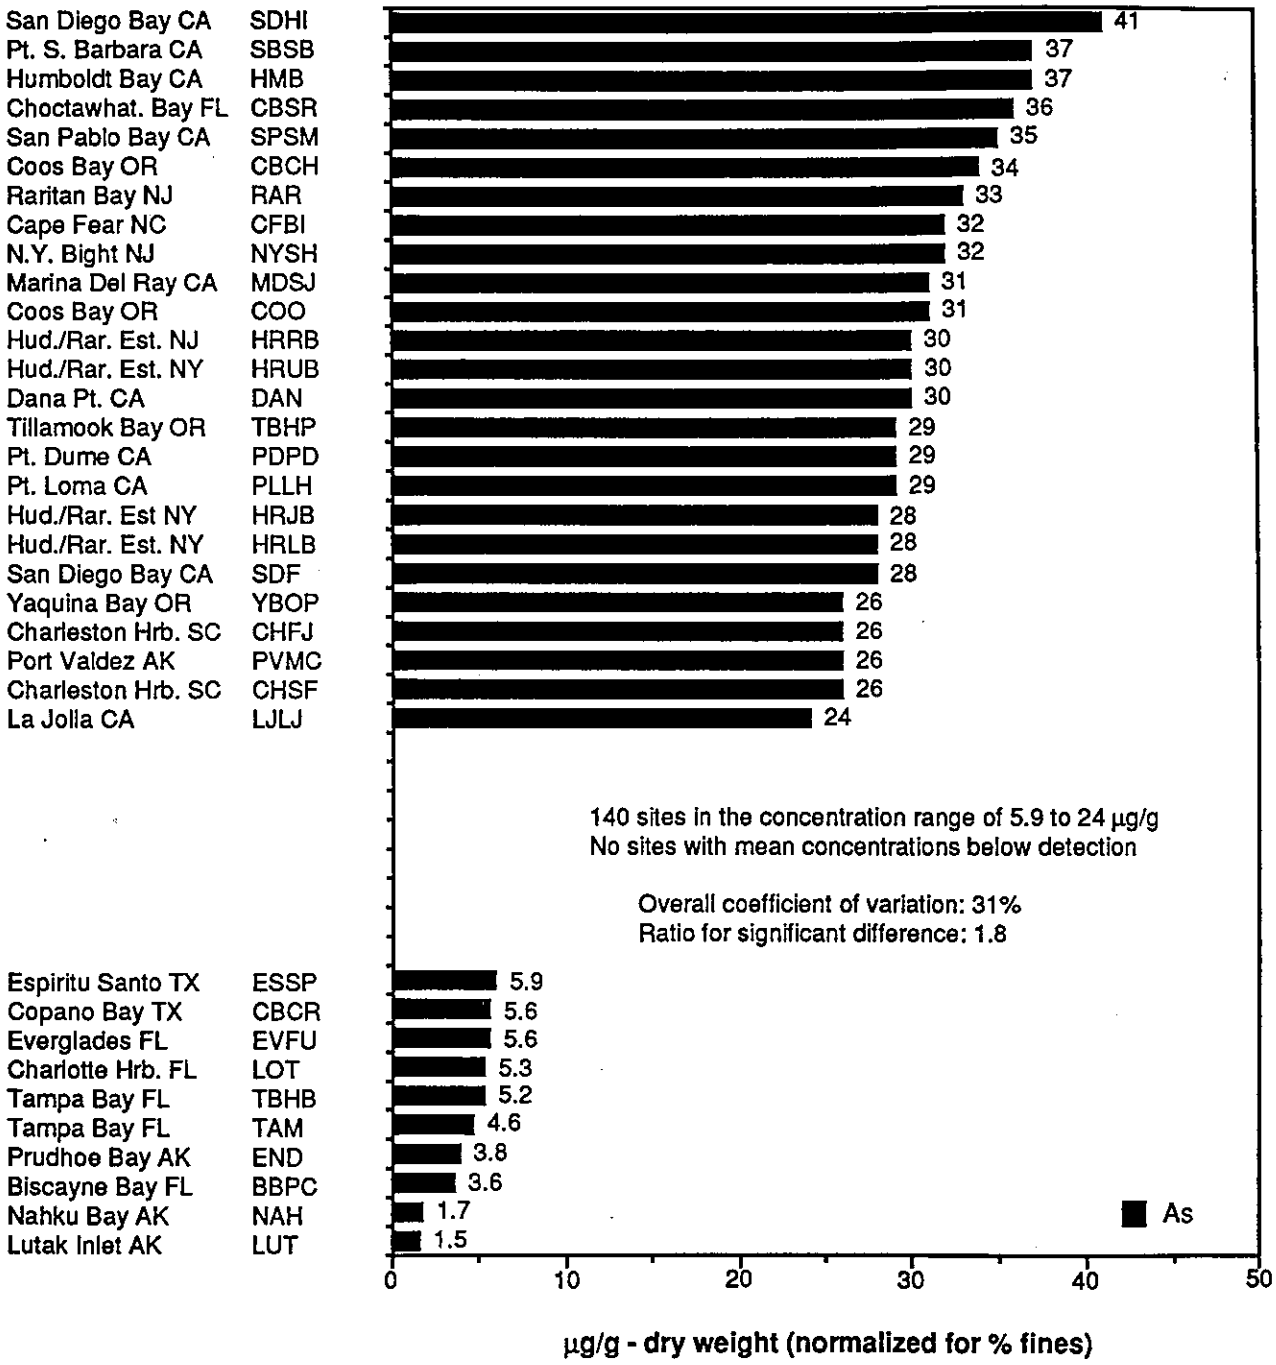
Total Organic Carbon in Sediments



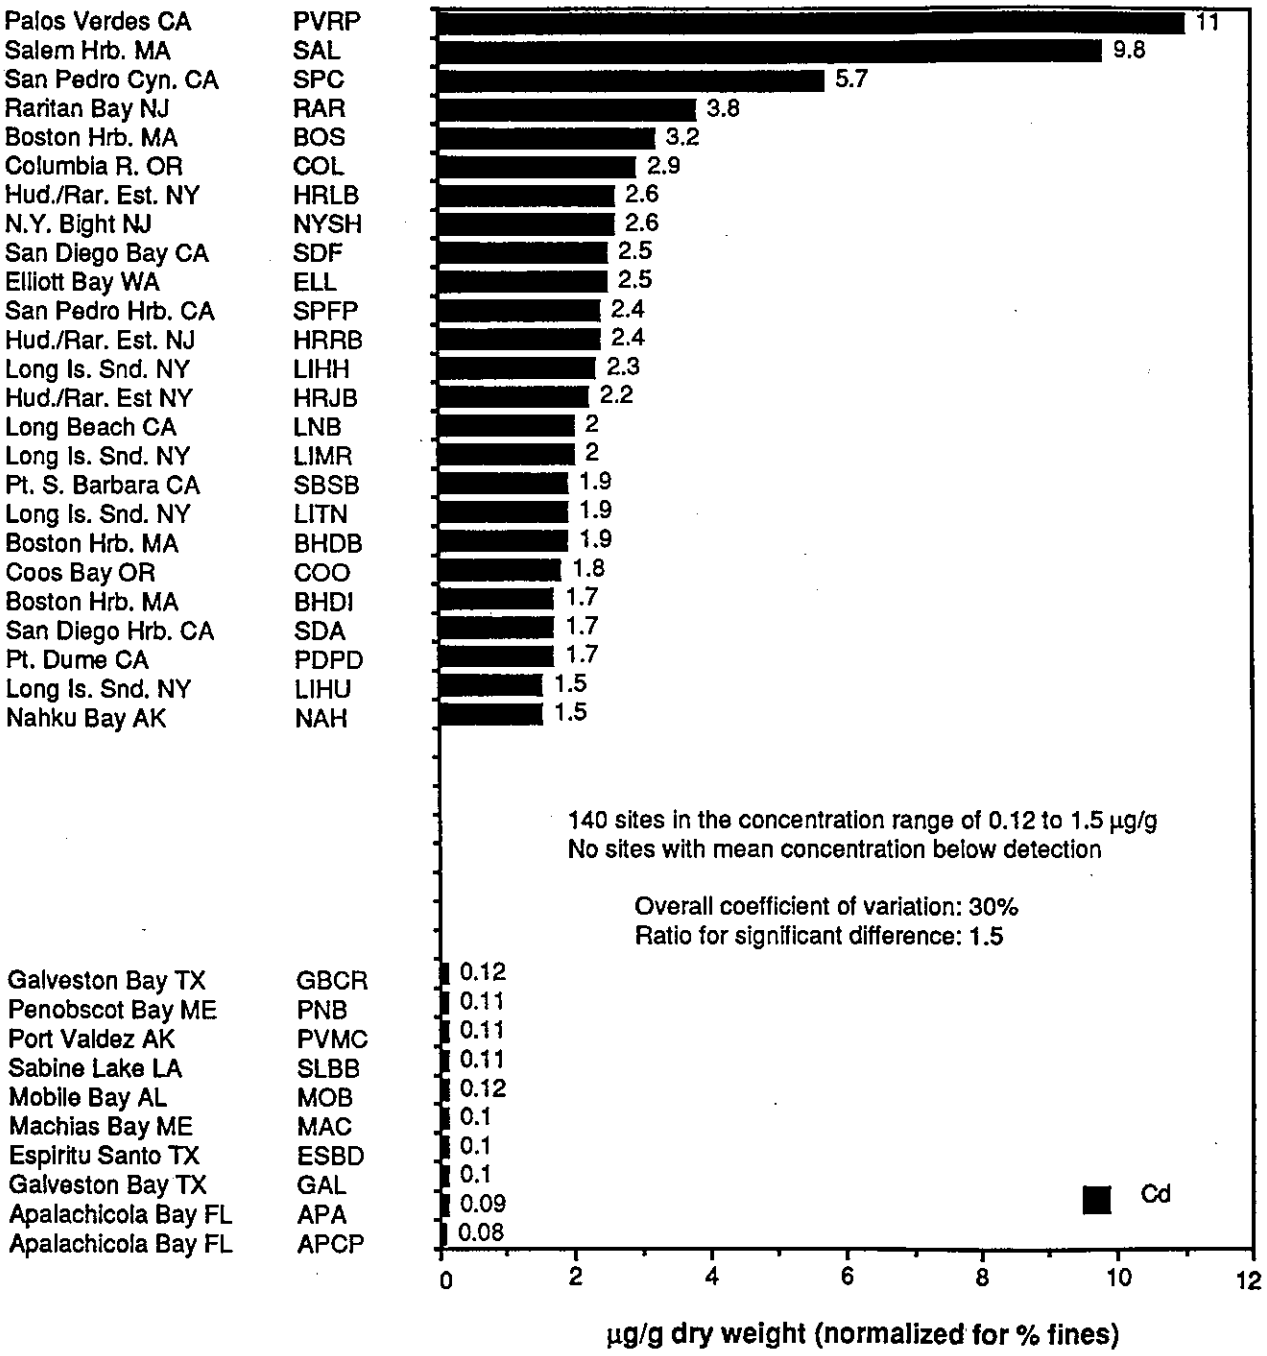
Antimony in Sediments



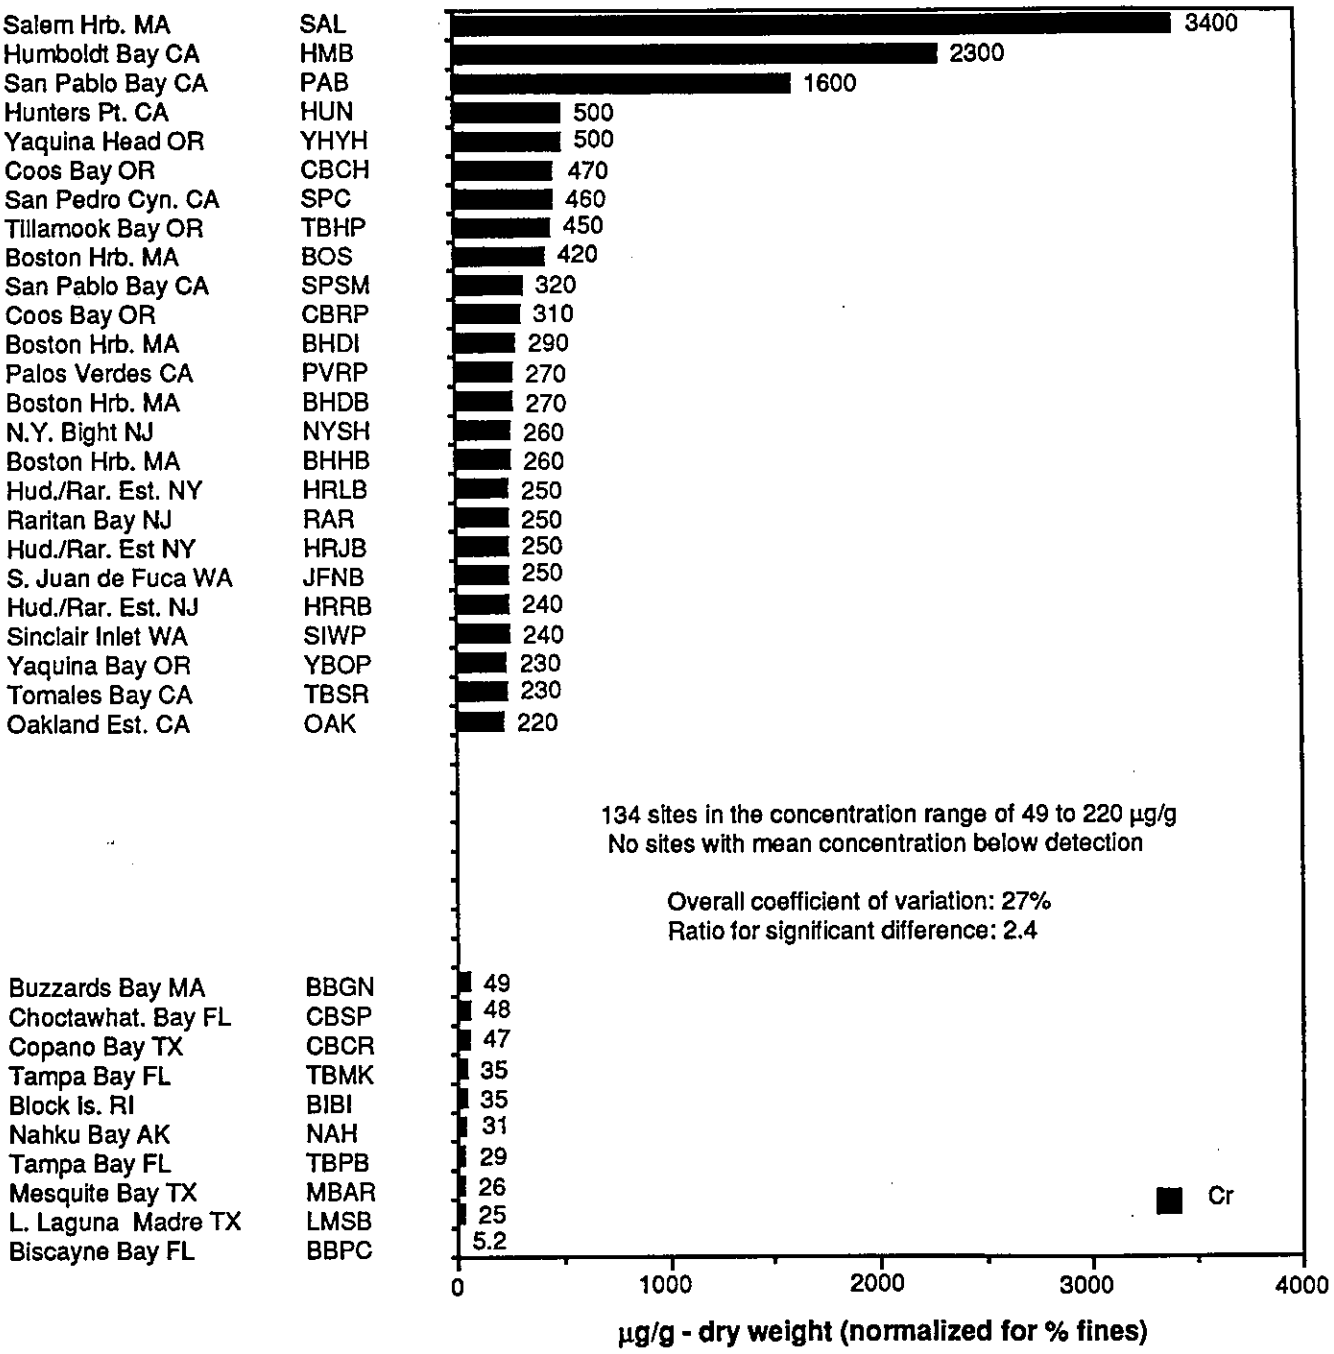
Arsenic in Sediments



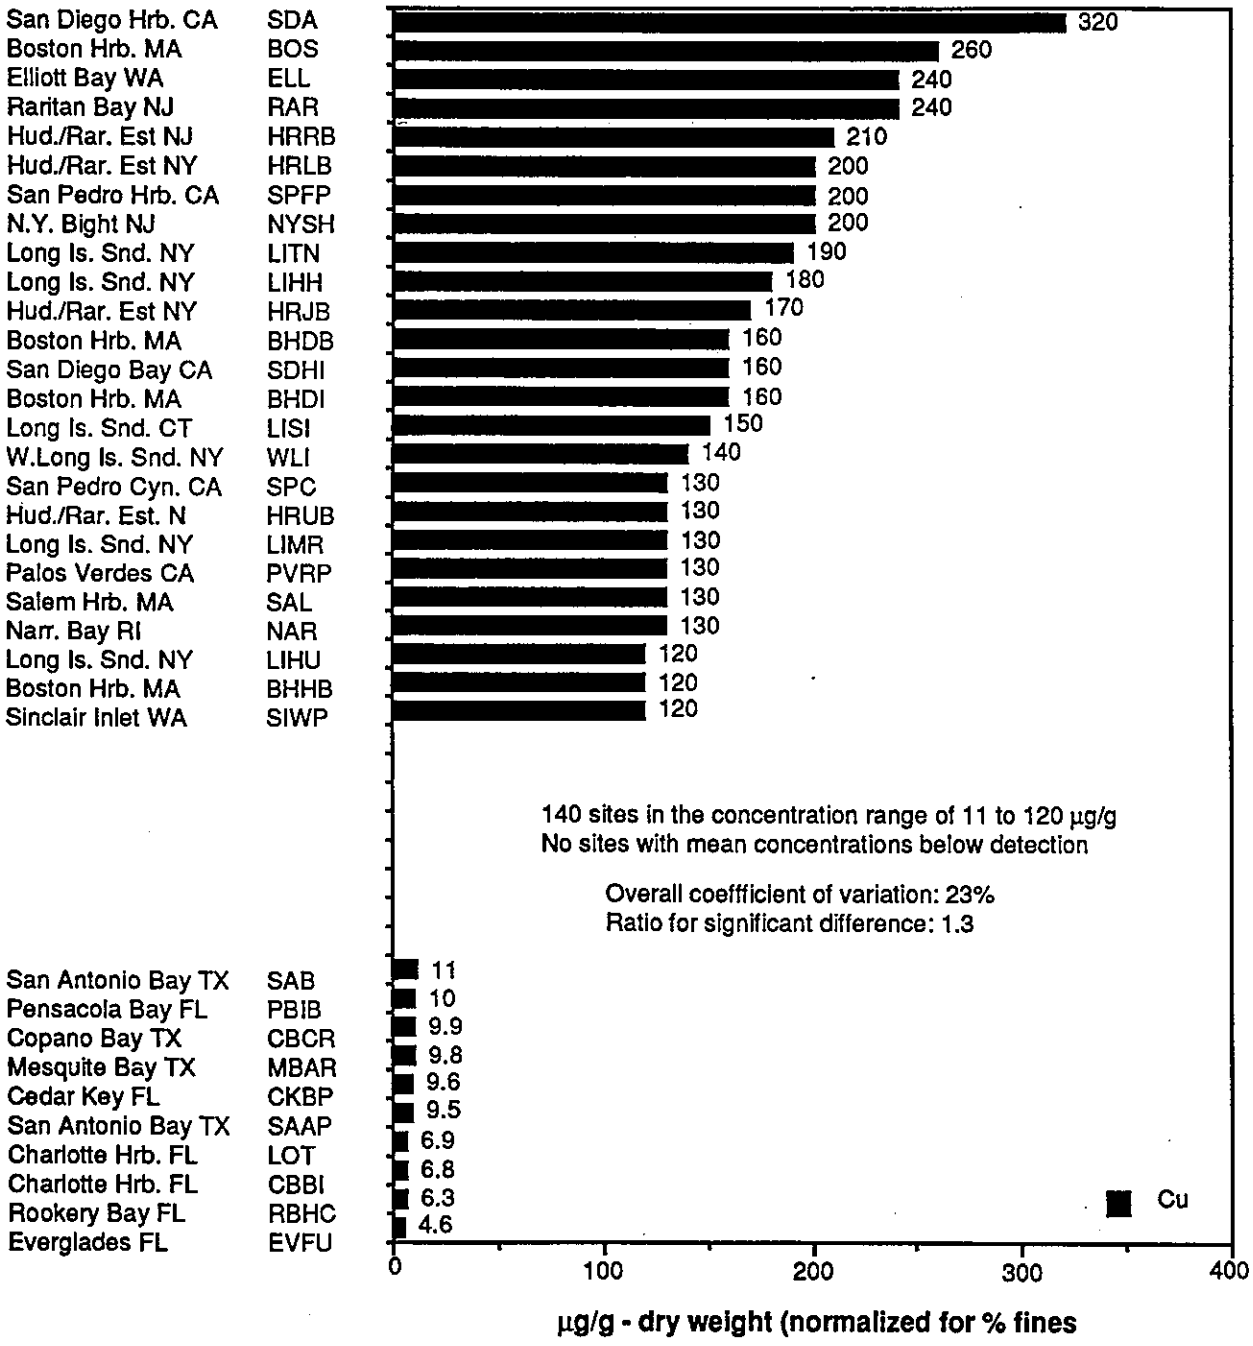
Cadmium in Sediments



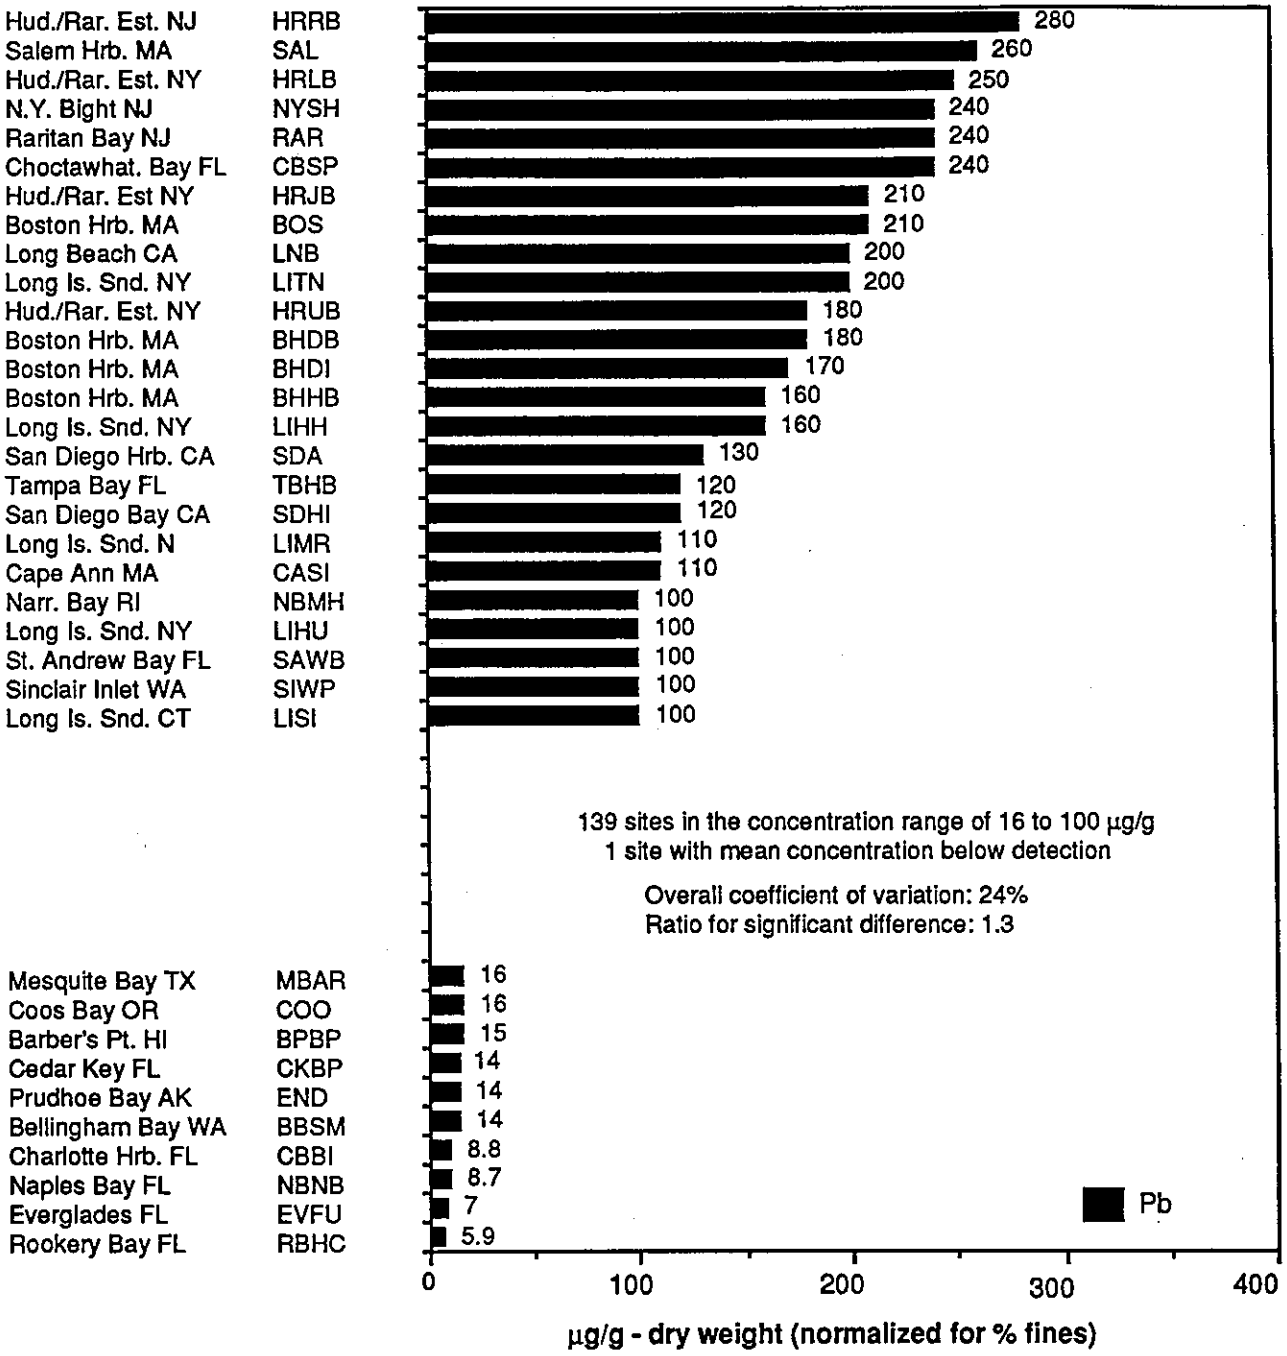
Chromium in Sediments



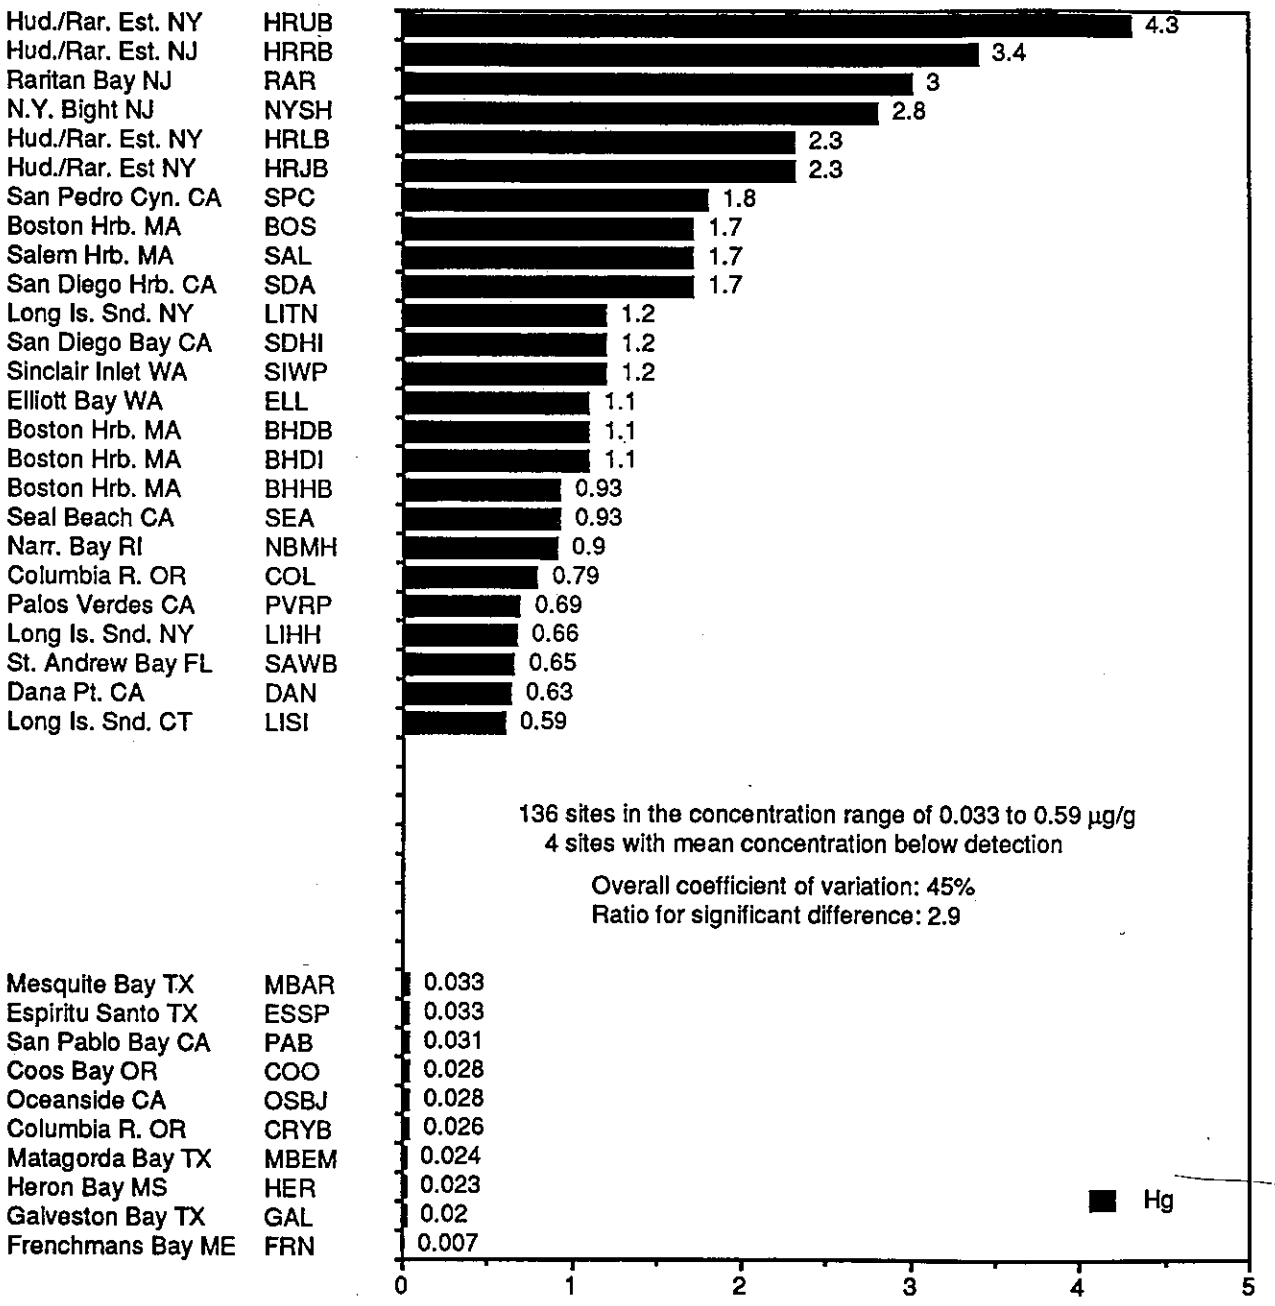
Copper in Sediments



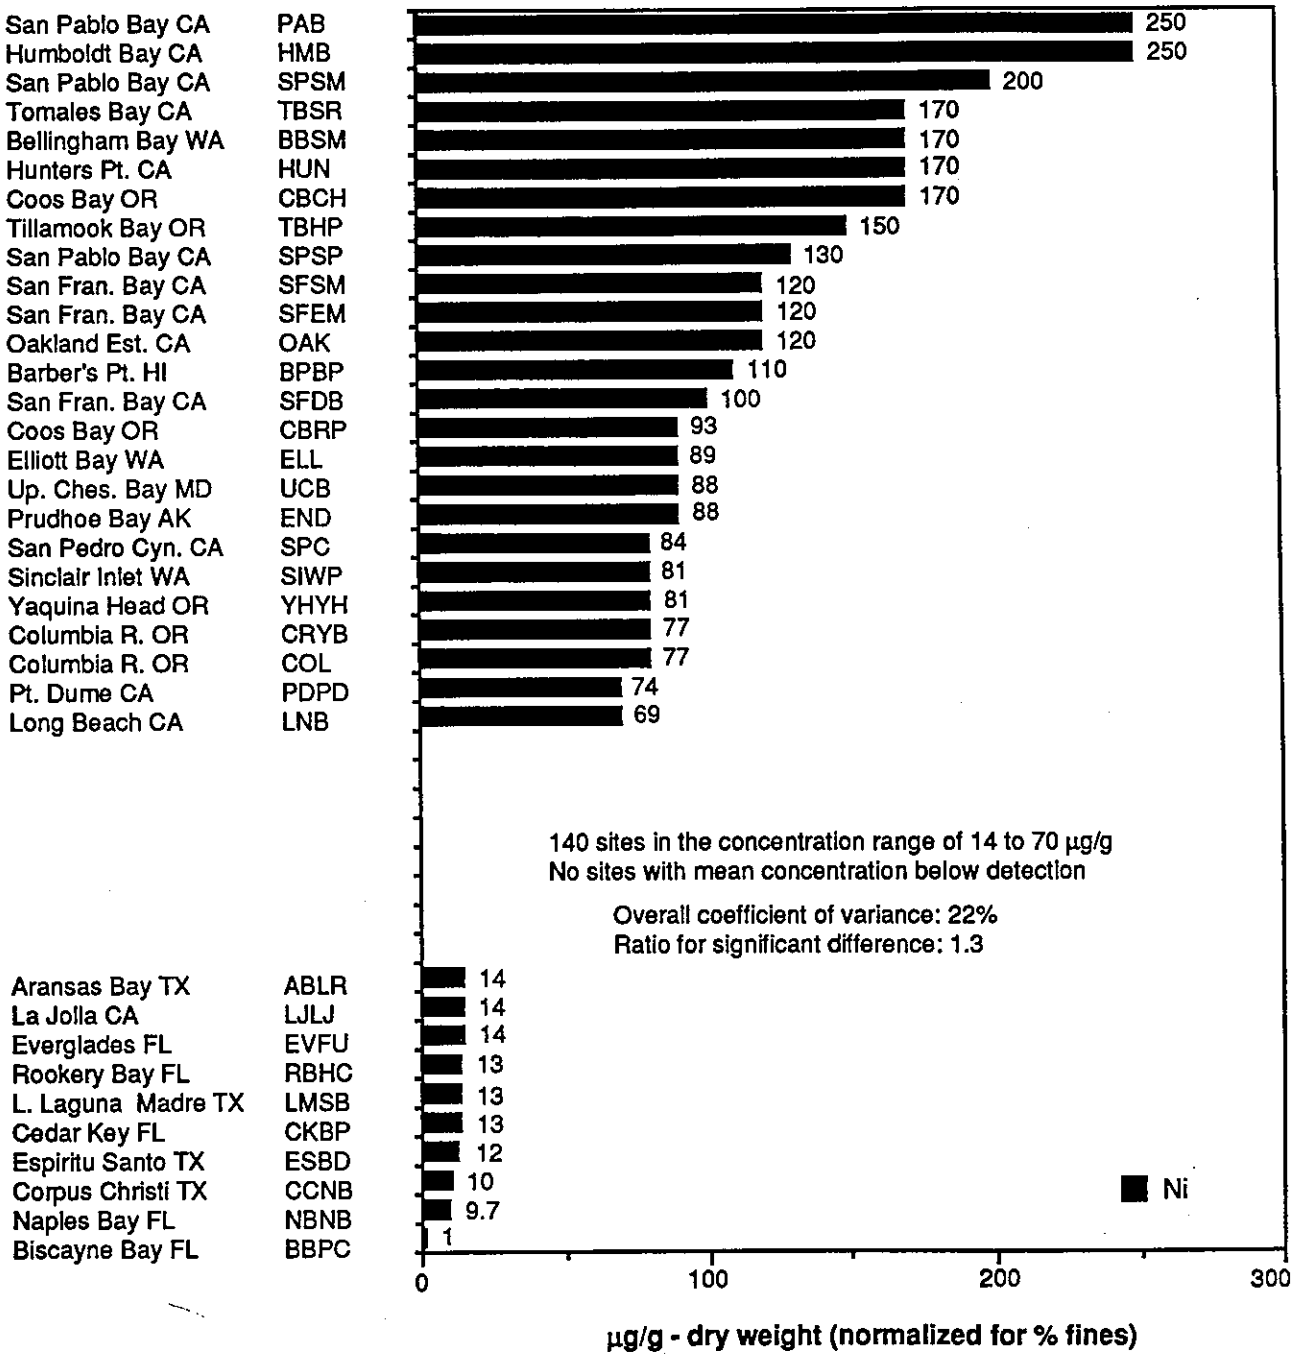
Lead in Sediments



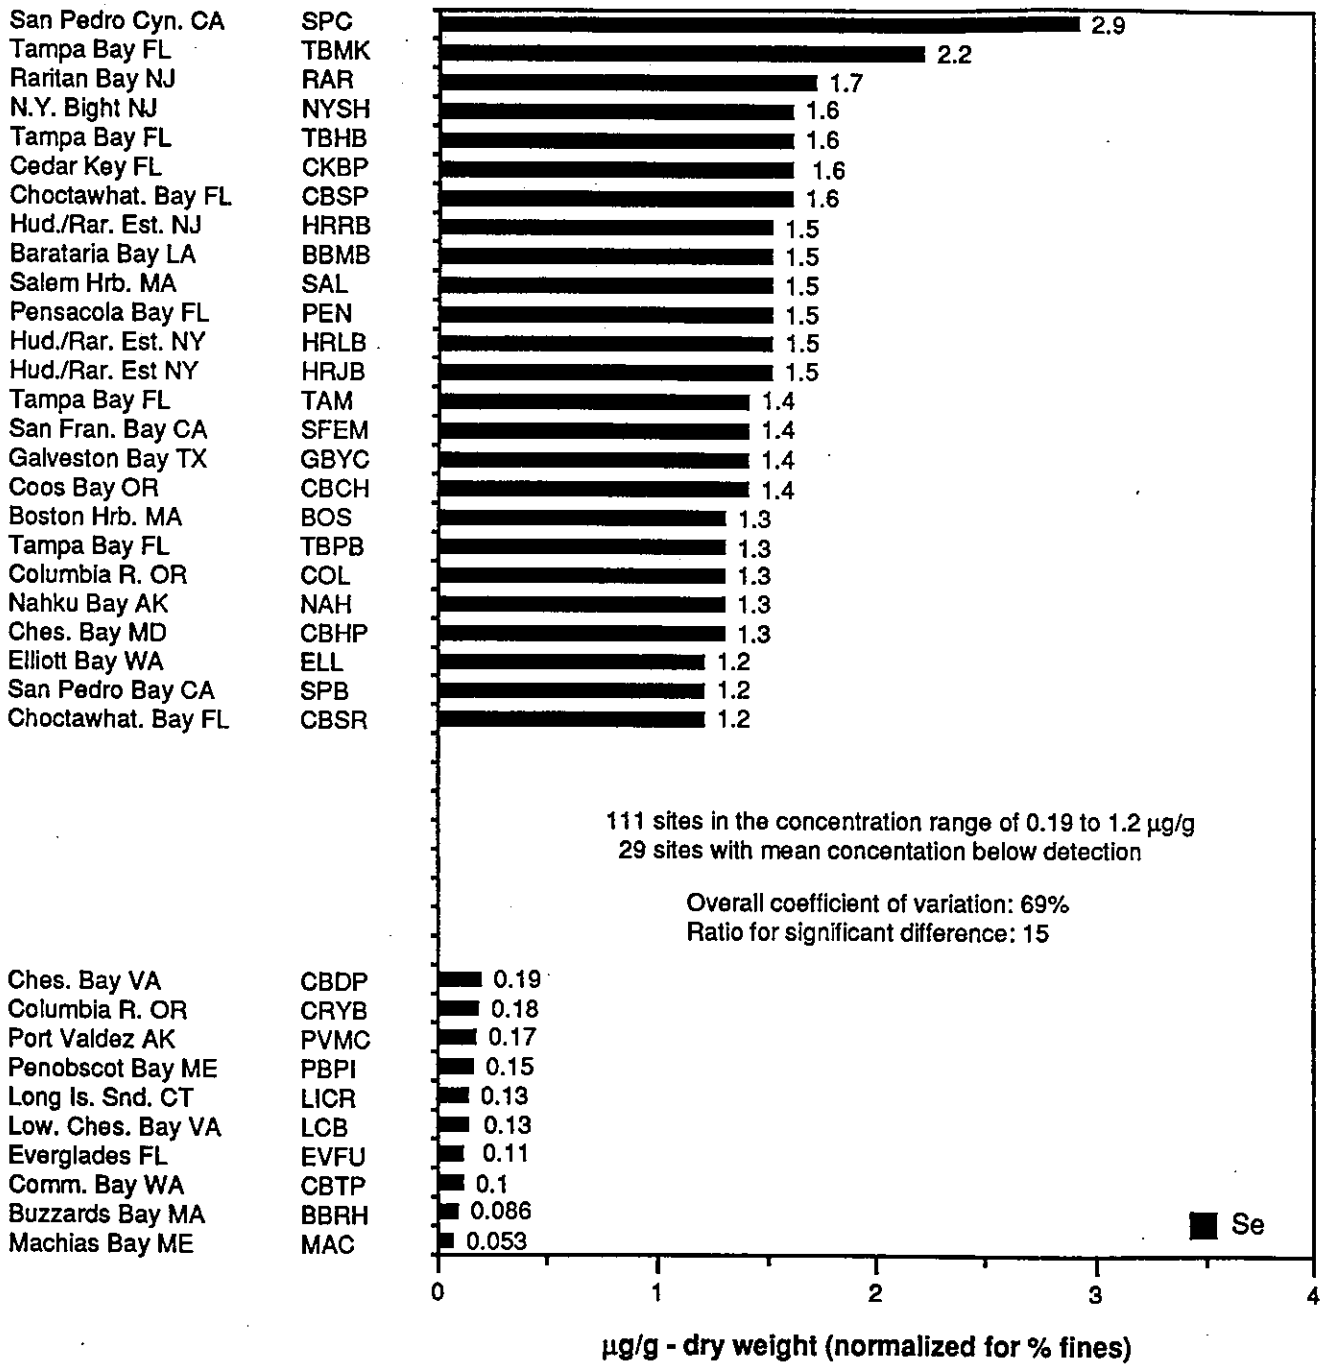
Mercury in Sediments



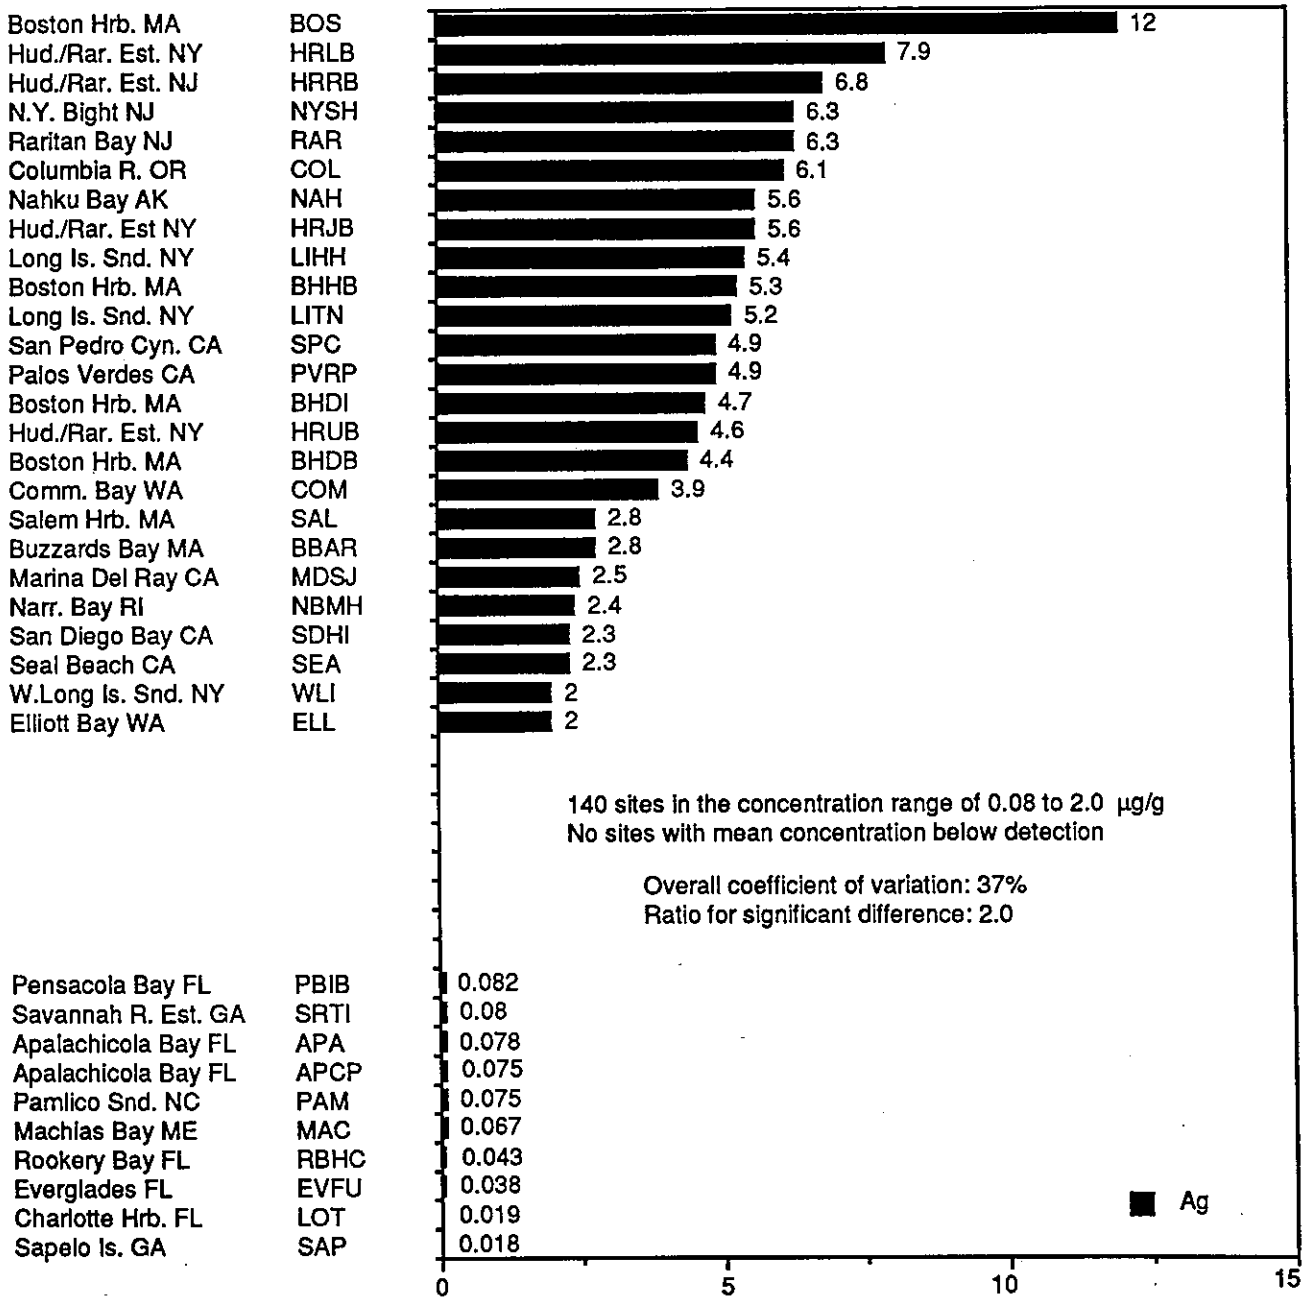
Nickel In Sediments



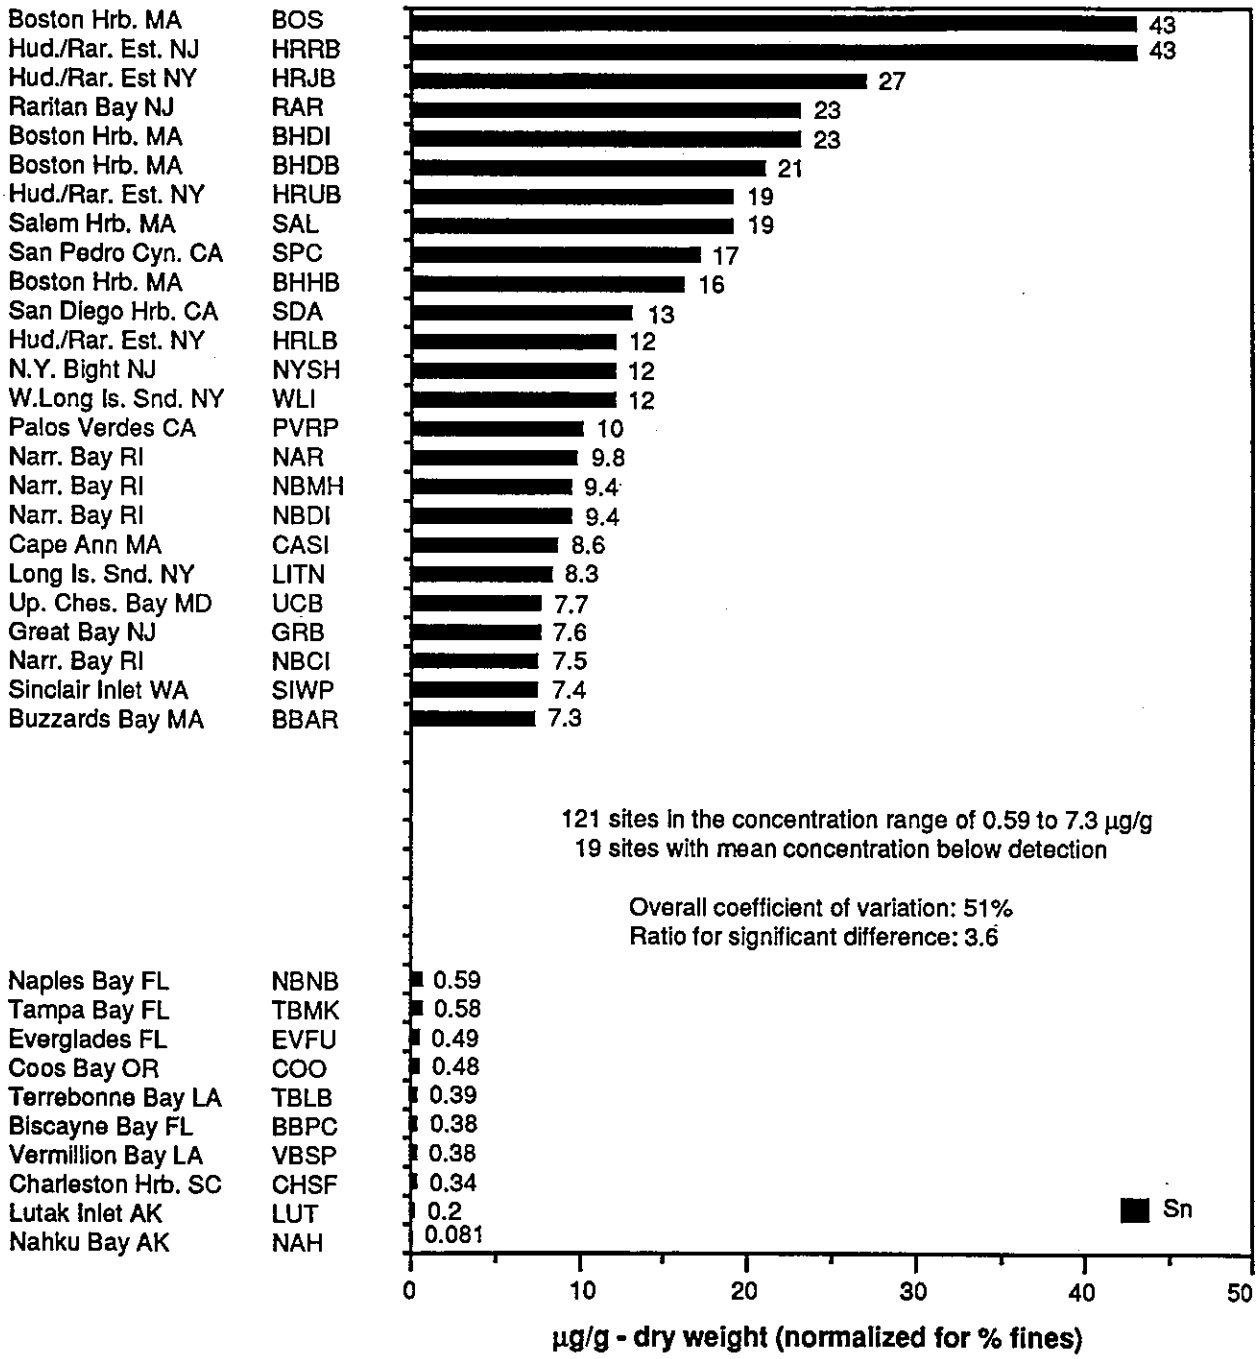
Selenium in Sediments



Silver in Sediments



Tin In Sediments



Zinc in Sediments
