Conservation and Utilization Division
Woods Hole, MA 02534

The 17th Northeast Regional Stock Assessment Workshop is documented in seven separate reports, listed below. The Northeast Fisheries Science Center Reference Documents are a series of informal reports produced by the Center for timely transmission of results obtained through work at the various NEFSC labs. The documents are reviewed internally before publication, but are not considered formal literature. The National Marine Fisheries Service does not endorse any proprietary material, process, or product mentioned in these reports. To obtain additional copies of this report contact, Information Services Unit, Northeast Fisheries Science Center, Woods Hole, MA 02543 (508-548-5123, ext. 260 or 378).

## Reports of the 17th Stock Assessment Workshop

CRD 94-01 Estimation of Discards in the Silver Hake Fisheries and a Re-analysis of the LongTerm Yield of the Stocks by T. Helser and R. Mayo

CRD 94-02 Assessment of Yellowtail Flounder Pleuronectes ferrugineus, 1993 by P. Rago, W. Gabriel, and M. Lambert

CRD 94-03 Stock Assessment of Atlantic Butterfish, Peprilus triacanthus, in the Northwest Atlantic During 1992
by J. Brodziak
CRD 94-04 Stock Assessment of Long-Finned Squid, Loligo pealei, in the Northwest Atlantic During 1992
by J. Brodziak
CRD 94-05 Stock Assessment of Short-Finned Squid, Illex illecebrosus, in the Northwest Atlantic During 1992

## INTRODUCTION

The silver hake stocks off the northeast coast of the United States have followed a "boom-andbust" cycle typical of fish stocks that have been heavily exploited. Before 1960, silver hake fishery was composed exclusively of U.S. fleets and only lightly exploited. Exploitation of the U.S. stocks intensified with the arrival of distantwater fleets (DWF) in 1962 and stock biomass declined sharply between 1965 and 1970. Unable to sustain such high rates of exploitation, total international landings fell by the late 1970s to historic lows. In addition, the age composition became highly truncated to younger ages; from a fishery whose landings were dominated by ages 3 to 5 with ages up to 10 years, to one in which more than $64 \%$ of the catch comprised age 2-3 fish, and fish older than age 5 almost disappeared from the catch.

While foreign fishing activity for silver hake in U.S. waters was either greatly reduced or ceased altogether by the late-1970s, U.S. landings have not increased and remain at low but stable levels compared to earlier years of the fishery. Throughout the last decade, little has changed in the U.S. silver hake fishery and management of these stocks has not been a priority of the regional management councils. Although there are presently no management regulations that pertain to silver hake in the Middle Atlantic and Southern New England regions, a small-mesh fishery, restricted seasonally (June through October) and spatially (SA 522), has been conducted since 1988 over an area of northern Georges Bank known as "Cultivator Shoals" (Almeida et al. 1989). Although not unlike the otter trawl fishery that has historically fished in this region, this regulated fishery allows for use of small mesh ( 2.5 in .) in a region which has minimum mesh size restrictions of 5.5 inches. About the same time, silver hake was also included in the Multispecies Fishery Management Plan in 1988 (under amendment 4).

Recently, a "juvenile whiting" fishery has developed for small silver hake that are exported to Spain and Portugal. Unlike the U.S. whiting market, in which the product demand is for larger silver hake (age 2 and 3), the export market demand is for small silver hake ( 7 to 9 in.) presumably in their first or second year of life. Exploiting younger ages of fish in the stocks has focused management questions on the affects of a "juvenile whiting" fishery on the long-term yield of the silver hake stocks. Because discards in the domestic silver hake fishery may be significant
(Anderson 1975), it is important to estimate the selection pattern of the current fishery (total catches) and determine whether a directed fishery for smaller silver hake increases the selectivity toward younger ages. Simultaneously, we must evaluate whether increased effort, and therefore fishing mortality, will likewise be directed into this emerging fishery.

The last analytical assessment of the silver hake stocks off the northeast coast of the United States was conducted in 1990 on data through 1988. Since that time, additional information on research vessel surveys, distribution patterns of adults and juveniles, and updated information on the silver hake fisheries including preliminary estimates of discards have become available. This report compiles updated information relevant for an age-structured assessment. It also presents the results of yield and spawning stock biomass per recruit analyses from catch at age matrices augmented with discards not considered in previous assessments.

## STOCK DEFINITION

The silver hake population in U.S. waters is presently assumed to comprise two major stocks (Figure 1): 1) Gulf of Maine-Northern Georges Bank (Div. 5Y, 5Ze; SA 521-522, 561) and 2) Southern Georges Bank-Middle Atlantic (Div. $5 Z \mathrm{e}$, SA 525-526, 562; Div. 5Zw, 6A-6C). These stock definitions represent a change over assessments prior to 1987 and are based on research bottom trawl surveys, U.S. and DWF commercial fishery statistics, and morphometric data collected during bottom trawl surveys in 1978-1979 (Almeida 1987a). Other studies suggest similar distinctions between silver hake populations in the northern and southern regions of the northeast U.S. continental shelf, but have placed the dividing line farther south (Conover et al. 1961; Konstantinov and Noskov 1969). Although the present definition is generally accepted, it is unlikely that these stocks are reproductively isolated nor is it known to what extent exchange between the two stocks occurs.

## HISTORY OF THE FISHERY

Silver hake (Merluccius bilinearis) is one of the most abundant demersal species inhabiting the northeast continental shelf. Its availability has made it important to both U.S. and Canadian fisheries as well as DWFs. The U.S. fishery for

Figure 1. Stock definition of the Gulf of Maine-Northern Georges Bank and the Southern Georges Bank-Middle Atlantic silver hake population in U.S. waters.
silver hake began in the middle 1800s with the principal center of activity located along the Middle Atlantic and New England coasts. Before 1920, silver hake were only lightly exploited and commercial landings rarely totaled $3,000 \mathrm{mt}$.

The U.S. commercial fishery expanded between 1920 and 1950 with the introduction of otter trawling vessels whose capacity to reach new and productive fishing grounds far surpassed that of more stationary gear. Coupled with technological advances in quick-freezing, automatic scaling machines, and developing markets, landings of silver hake rose to 45,000 mt by 1950 (Fritz 1960).

Between 1955 and 1961, an "industrial fish-
ery" developed in southern New England and landings increased by $30 \%$, averaging $62,000 \mathrm{mt}$, most of which was taken from the Gulf of MaineNorthern Georges Bank stock. This fishery was conducted primarily by otter trawling vessels fishing inshore waters using small mesh (1.5 in., 40 mm ) nets.

Exploitation intensified between 1961 and 1965 with the arrival of DWFs (principally the USSR), and total international landings increased to historic highs; reaching 94,000 mt and 307,000 mt in the Gulf of Maine-Northern Georges Bank and Southern Georges Bank-Middle Atlantic stocks, respectively (Figures 2 and 3). This fleet consisted of factory trawling vessels that were

Figure 2. Total landings of silver hake from the Gulf of Maine-Northern Georges Bank stock, 1955-1992.

Figure 3. Total landings of silver hake from the Southern Georges Bank-Middle Atlantic stock, 1955-1992.
significantly larger in size ( $1,000 \mathrm{grt}$ ) and fished with smaller mesh ( 1.5 inch, 40 mm ) nets than U.S. fleet vessels (generally vessels were 300 grt , with 2.5 in . mesh nets). As a consequence of such high exploitation, biomass and recruitment from both stocks fell sharply between 1965 and 1970 and total international landings subsequently declined; reaching $23,900 \mathrm{mt}$ (in 1969) and $27,500 \mathrm{mt}$ (in 1970) in the northern and southern stocks, respectively.

After 1972, the majority of landings of silver hake tended to be taken by even smaller mesh nets than previously used by the U.S. fleet, ranging from 1.5 in . ( 38 mm ) to 2.0 in . ( 51 mm ) (Almeida and Anderson 1979). With the inception of the Magnuson Fishery Conservation and Management Act in 1977, the DWF was restricted to a fishing "window" between March 1 and June 30 in a relatively narrow portion of the U.S. continental shelf, and a minimum mesh size regulation of 2.4 in . ( 60 mm ) was imposed. While landings from the Gulf of Maine-Northern Georges Bank stock continued to drop to a historic low of $3,400 \mathrm{mt}$ in 1979, landings from the Southern Georges Bank-Middle Atlantic stock increased again during the early 1970 s to $110,000 \mathrm{mt}$, due to the restrictions imposed on the DWF, but subsequently declined by 1980 . This second decline in landings was largely attributed to a $72 \%$ drop in silver hake biomass brought about by significant increases in both the size and number of vessels in the U.S. groundfish fleet, as well as technological advances in fishing operations (Anthony 1990).During the last decade, landings from both U.S. silver hake stocks remained fairly stable, but at low levels compared to earlier years of the fishery, averaging 17,500 mt per year. Catches have been taken exclusively by the U.S. fleets, either as bycatch from other groundfish fisheries or through directed fisheries specifically for silver hake.

## GULF OF MAINE-NORTHERN GEORGES BANK

## THE FISHERY

## Commercial Landings

Total commercial landings in 1992 were 5,302 $\mathrm{mt}, 12 \%$ lower than reported in 1991 and 17\% lower than 1990 (Table 1). Since the late 1970s, silver hake have been taken exclusively by U.S. vessels and landings have been fairly stable, but at low levels compared to earlier years of the

fishery, averaging $6,000 \mathrm{mt}$. Short-term trends in U.S. landings between 1980 and 1992 show a steady increase to $8,500 \mathrm{mt}$ in 1986, but an approximate 37\% decline between 1986 and 1992.

## Recreational Fishery

No estimates of the recreational catches are available for this stock, but they are assumed to be insignificant.

Table 2. United States sampling of commercial silver hake landings by year, quarter and two-digit statistical area from the Gulf of Maine-Northern Georges Bank stock. Values in parentheses in bottom table indicate no samples were taken for given landings

## Sampling Intensity

A summary of the U.S. length frequency sampling of Gulf of Maine (SA 51) and Northern Georges Bank (SA 52) landings during 19821992 is presented in Table 2. Samples include both the small round and large round (King) market categories; but virtually all U.S. length samples were collected from otter trawl landings from the unclassified round market category, which generally constitutes more than $90 \%$ of the total commercial catch from this stock. United States length frequency sampling in the Gulf of Maine averaged one sample per 130 to 160 mt landed during 1985-1990, but prior to and after this period, sampling has been at a lower intensity (1982-1983: l sample per 800 to 960 mt ; 1991-1992: 1 sample per 660 to 990 mt ). Length frequency sampling of commercial landings from northern Georges Bank averaged one sample per 160 to 350 mt during 1982-1989; but since 1990,
sampling intensity has decreased substantially (1 sample per 500 mt in 1990-1991). In 1992, only two length frequency samples were taken from $3,300 \mathrm{mt}$ landed from northern Georges Bank, an intensity of only 1 sample per $1,600 \mathrm{mt}$.

Because of the deficiency of length samples taken from landings in the ports (particularly in quarters 3 and 4), it was necessary to use length samples taken from the Domestic Sea Sampling Program (DSSP) data base to derive the catch-atage matrix for the most recent years. Length frequency samples from sea sampling trips were available from the Gulf of Maine during quarters 3 and 4 and from northern Georges Bank during quarter 3, when landings in the commercial fishery are highest. Only one sea sample was available from northern Georges Bank during quarter 4 in 1992, representing a sampling intensity of 1 per 500 mt . Although fairly close correspondence between the length frequency distributions from sea samples and port samples

which were available was observed in some years (e.g. quarter 3 in SA 52 in 1989 and 1991), some disparity was seen in other years.

In recent years, length sampling of silver hake commercial landings has become very poor. Although a single length frequency sample (in some cases not even one sample was available) can be used to compute a mean length, at least two are required to compute variance estimates. It is recommended that port sampling coverage
for silver hake be increased so that a minimum of two samples are obtained each quarter, from in each area, and for each sample size evaluated. Although it is more desirable to use length frequency samples obtained from a length stratified random sampling design (i.e. port samples), in some cases sea samples must be used due to the difficultly in obtaining samples from some ports. Comparison of length distributions between port and sea samples indicated that sea samples
cannot directly replace port samples. Therefore, it is further recommended that sea samples be statistically evaluated and potential bias, if any, determined in estimating numbers at length.

## Age Composition

The age composition of commercial landings was estimated by applying estimated numbers at length, derived from monthly sea and port sample length frequencies, to age-length keys, derived from research vessel surveys, pooled by calendar quarter. Commercial numbers at length were estimated by dividing quarterly mean weights (obtained by applying silver hake length-weight equations to sample length frequencies) into quarterly commercial landings. Commercial numbers at length were then applied to agelength keys (quarters 1 and 2 applied to the spring survey key; quarters 3 and 4 applied to the autumn survey key) to derive estimates of the numbers at age and summed over quarter to derive the annual catch-at-age matrix (Table 3).

Strong shifts in the predominant age of commercial landings have occurred since 1955. During 1955-1971, commercial landings were dominated by age 3 and 4 silver hake (averaging $61 \%$ of the total numbers) with significant contributions from age 5 . The age composition shifted to younger ages during 1972-1974 (ages 1 and 2 constituting $81 \%$ of the total), largely due to the DWF concentrating on the strong 1971 and 1972 year classes. Since 1979, the age composition has shifted towards ages 2 to 3 , which have generally constituted at least $64 \%$ of the annual totals. In most recent years (1989 to 1992), ages 2 to 3 have constituted at least $70 \%$ of the total commercial catch at age. Since 1955, the age composition of the commercial landings has become highly truncated, with a gradual decrease in the numbers of fish age 6 and greater during 1972-1986, and almost complete disappearance of these fish since 1989.

Lack of older ages in the catch-at-age matrix, particularly in recent years, and the need to truncate age distributions makes it difficult to tume the VPA. The use of survey age-length keys to age the commercial catches at length may introduce additional uncertainty into the catch-at-age matrix. Survey age-length keys rarely encompass the full range of length classes found in the commercial catch; this is of particular concern for older ages due to the large overlaps
that exist in the size ranges among older aged fish. Therefore, it may be necessary to obtain aging structures from the commercial catches to determine the potential bias that may result in the catch-at-age matrix from using survey agelength keys.

## Mean Weights at Age

Mean weights at age in the commercial catch for ages 1 to 6+ during 1955-1992 are given in Table 4 and, based on landings patterns, are considered mid-year values. Only slight variations in mean weight at age are apparent among years during 1955-1992, and are related to variations in year class strengths as they become recruited to the fishery. No trends in mean weights during the $1955-1992$ period are evident.

## STOCK ABUNDANCE AND BIOMASS INDICES

## Commercial Catch Per Effort

Commercial CPUE indices from this stock may be influenced by market conditions (i.e. product demand) as much as availability or abundance. Nevertheless, a detailed analysis has been conducted for this stock and is included in this report. United States commercial CPUE indices (catch per unit effort; expressed in metric tons landed per day fished) were calculated by vessel tonnage class (Class 2: 5-50 GRT; Class 3: 51-150 GRT; Class 4: 151-500 GRT) from otter trawl trips in which silver hake constituted 50\% or more of the total trip catch by weight. These values are considered "directed trips" and have been calculated for the Gulf of Maine (SA 51) and northern Georges Bank (SA 52) separately because the fisheries differ between these areas and the establishment of the regulated Cultivator Shoals fishery on northern Georges Bank since 1988.

Generally, landings from directed trips have accounted for more than $80 \%$ of the total annual catch by weight during the 1973-1992 period, and since 1988 have increased to more than 87\% of the total (Table 5). This increase is largely due to the increased landings during the operation of the Cultivator Shoals fishery on northern Georges

Bank (SA 52), in which directed trips have accounted for between $46 \%$ (1988) and $63 \%$ (1991) of the total Gulf of Maine-Northern Georges Bank stock landings. Increases in the directed landings in this fishery since 1988 are also apparent for ton class 3 and 4 vessels. Concurrently, directed landings from the Gulf of Maine have declined over the same period which suggest a shift in directed effort from the Gulf of Maine to the Cultivator Shoals fishery on northern Georges Bank.

Directed U.S. CPUE indices for the Gulf of Maine have generally exhibited an overall declin-
ing trend during the 1973-1992 period, but two distinct peaks occurred; one in 1976-1977 and another in 1984-85 (Table 5). This trend is also apparent among vessel class categories, except tonnage class 4 which is only a minor component of the Gulf of Maine fishery. The CPUE indices on northern Georges Bank exhibit a slightly more varied trend and values from tonnage class 3 , which have dominated directed landings, have declined slightly between 1973 and 1987. Since 1988, however, CPUE has increased substantially with rates approaching values not observed before in the time series ( $60.1 \mathrm{mt} /$ day fished in

Table 5. United States commercial landings (L), days fished, and landings per days fished (L/DF), by vessel tonnage class (class 2:5-50 grt; class 3: 51-150 grt; class 4: 151-500 grt), of silver hake from the Gulf of Maine-Northern Georges Bank stock for otter trawl trips in which silver hake constituted $50 \%$ or more of the total trip catch by weight [i.e., 'directed trips']

[^0]tonnage classes were standardized by applying a three factor (year, tonnage class, and area) General Linear Model (GLM) to log CPUE data for all directed otter trawl trips within three different time blocks; 1973-1982, 1983-1987, and 19881992, with ton class 3 set as the standard. The models accounted for no less than $32 \%$ of the total variation in the CPUE data, with the model applied to the 1988-1992 period accounting for 45\% (Table 6).

Results of this analysis suggested that the relative fishing powers (expressed by GLM ton class coefficients) between ton classes 2 and 4 did not differ significantly during the 1973-1982 and 1983-1987 periods, and that both were less than ton class 3.

Retransformed coefficients indicated that ton classes 2 and 4 were only 50 to $68 \%$ as efficient as ton class 3 during these time periods (Table 6). However, during the 1988-1992 period, the relative fishing power of ton class 4 vessels was significantly greater than that of either ton class 2 or 3 , indicating that ton class 4 vessels were more than 200\% efficient. Standardized indices were obtained by dividing the CPUE values by the retransformed GLM ton-class coefficient for the 1973-1987 and 1988-1992 time blocks. Only one time block was used for the GLM analysis on CPUE data from the Gulf of Maine, 1973-1992. Standardized CPUE indices showed relatively consistent trends between the different ton classes and within the different regions (Figure 4a). The 1991 ton class 4 value, although still large relative to adjacent years, is not different from what has been observed during earlier years of the fishery. The overall trend between the Gulf of Maine (51) and northern Georges Bank (52) regions (average of all ton classes weighted by landings) show relatively consistent peaks in the standardized CPUE values, although the magni-
tude was greater on northern Georges Bank (Figure 4b). Standardized mean (weighted by landings) indices for the entire Gulf of Maine-Northern Georges Bank stock show distinct peaks in CPUE during 1975-1977 and during 1983-1985 (Figure 4b). Most recently, standardized mean CPUE has steadily increased since 1987, peaked in 1991, but has since dropped in 1992.

## Research Vessel Abundance Indices

Research vessel bottom trawl surveys have been conducted by NEFSC annually in the autumn since 1963, and in the spring since 1968. Estimates of stratified mean catch per tow in numbers and weight have been used to monitor trends in population size and recruitment and to tune VPA. Spring and autumn survey indices were calculated using Delta distribution estima-
tors (Pennington 1983, Almeida et al. 1986) for offshore strata only and the spring indices (19731981) adjusted to the \#36 Yankee trawl as the standard gear. Stratified mean catch per tow in number and weight for both spring and autumn surveys are given in Table 7 and estimates of number per tow at age since 1973 in Table 8.

The autumn offshore numbers per tow index $(0+$ ) declined in the mid- and late 1960s during the period of heavy exploitation by DWF (Figure 4). Numbers per tow increased in both the spring and autumn surveys between 1969 and 1975, due to above average recruitment in the early 1970s, but total abundance subsequently declined during the late 1970s. Trends in population abundance from the NEFSC surveys were largely consistent with standardized commercial CPUE indices (Figure 4b). Numbers per tow in the spring survey varied without trend during the early- to mid 1980s, but increased since 1987, although estimates have been highly variable. The spring index for 1992 is the highest on

Figure 4. Landings per unit effort (LPUE) standardized for differences in vessel tonnage class fishing power for the Gulf of Maine-Northern Georges Bank silver hake stock. Calculated standardized LPUE indices compared by a) two-digit statistical area (51 and 52) and vessel tonnage class; and b) by statistical area weighted by tonnage class landings.

record, at 196.4 fish per tow (Figure 5). The autumn survey indices have steadily increased since 1980 (Figure 5). The autumn index in 1992 was 129.5, also the largest on record since the mid-1960s, and is strongly represented by the 1989, 1990, and 1991 year classes. Juvenile and adult silver hake distributions from U.S. research vessel surveys during 1982-1992 (Figure 6) suggest that silver hake may seasonally migrate across the presently assigned stock boundaries. Such migrations may affect interpretations concerning the indices of abundance. Distributions vary seasonally by size/age and probably in response to hydrographic changes.

During the spring, large concentrations of juveniles are observed on northern Georges Bank and in the Gulf of Maine just east of Cape Ann, while the greatest adult concentrations occur along the continental slope of the southeastern rim of Georges Bank (Figure 6). Distributions shift significantly by the autumn; the large concentrations of adults, formerly on southern Georges Bank, are absent and adults appear in significant numbers on northern Georges Bank and in the Gulf of Maine (Figure 6). Juveniles are widely distributed over all of Georges Bank and into the Middle Atlantic during the autumn. In addition, Figure 6 clearly suggests a general northward

Figure 5. Stratified mean number and weight (kilograms) per tow of Gulf of Maine-Northern Georges Bank silver hake from the NEFSC spring and autumn bottom trawl surveys.
movement of fish from the southern and middle Atlantic areas into southern New England waters during the summer and autumn. It may be equally likely that silver hake migrate across Georges Bank during this season.

The question of interest in the silver hake assessment is whether migrations of fish are occurring across the presently assigned stock boundaries, and if so, to what extent do the indices confound the VPA tuning. Mixing between the stocks and seasonally shifting stock boundaries may lead to a misallocation of landings to the stocks and a mismatch between catch-at-age matrices and survey strata sets between seasons. Therefore, it may be important to investigate further whether stock boundaries have changed and, if so, where should stocks be divided or whether the stocks can be assessed as one unit.

## MORTALITY

## Natural Mortality

Instantaneous natural mortality (M) for the Gulf of Maine-Northern Georges Bank stock is assumed to be 0.40. Substantial changes in the age composition of the stock (i.e. substantial numbers of age 8 and $9+$ during the earlier history of the fishery) may suggest that $M$ has also changed. Although an M of 0.40 is high, compared with that of other adult gadid fish, given the extensive cannibalism in this stock, it is possible $M$ could be even higher or that the natural mortality rate varies significantly with age.

## Total Mortality

Pooled estimates of instantaneous total mortality ( Z ) were calculated for four time periods encompassed by the NEFSC autumn and spring offshore bottom trawl surveys: 1974-1977, 19791982, 1984-1987, and 1989-1992 (Table 9). Total mortality was calculated from survey catch per tow in numbers at age for fully recruited age groups (age $2+$ ) by the $\log _{\mathrm{e}}$ ratio of the pooled age $2+$ /age $3+$ indices in the autumn surveys, and the pooled age $3+$ /age $4+$ indices in the spring surveys. The geometric mean of the spring and autumn values were also computed. These calculations are given as:

## Autumn

$\ln (\Sigma$ age $2+$ for year $i-1$ to $j-1 / \Sigma$ age $3+$ for year $i$ to $j)$

## Spring

$\ln (\Sigma$ age $3+$ for year $i$ to $j / \Sigma$ age $4+$ for year $i+1$ to $j+1$ )
Pooled estimates indicated that total mortality was lowest during the 1974-1977 period ( $\mathrm{Z}=0.86$ ). Total mortality increased during the next two subsequent periods: 1979-1982 $Z=0.97$ and $1984-1987 \mathrm{Z}=0.90$. During the most recent period, 1989-1992, the estimate of $Z(0.80)$ decreased slightly from all earlier periods, although this estimate is provisional. During all periods, estimates of total mortality were lower from autumn survey data than the spring. Except for the most recent period 1989-1992, total mortality has been high ( $\mathrm{Z}>1.0$ ) in the spring survey, but has decreased steadily since 1974. In comparison, total mortality was rather low ( $\mathrm{Z}<0.5$ ) in the autumn survey during the 1974-1977 period, but has since more than doubled.

Table 9. Estimates of instantaneous total mortality (Z) and fishing mortality (F) ${ }^{1}$ for the Gulf of Maine-Northern Georges Bank silver hake stock derived from NEFSC offshore spring and autumn bottom trawl survey data $^{2}$

$z$ Recreational catch estimates taken from Almeida (1987b).

Changes in catchability are a possible explanation for the inconsistency of estimates of total mortality between the spring and autumn surveys. Although both surveys indicated a strong decline in catch per tow between ages 3 and 4, numbers of older fish appear to be less available
during the spring survey. This may result from a general offshore movement of adult fish, perhaps beyond the present stock boundaries, during the over-wintering period, which may be evident from concentrations of adults observed on the slope of southeastern Georges Bank (Figure 6).

Table 11. United States sampling of commercial silver hake landings by year, quarter and two-digit statistical area from the Southern Georges Bank - Middle Atlantic stock. Values in parentheses in lower table indicate that no samples were taken for given landings.

## SOUTHERN GEORGES BANKMIDDLE ATLANTIC

## THE FISHERY

## Commercial Landings

Total commercial landings from this stock in 1992 were $10,300 \mathrm{mt}$, a slight increase over 1991 and approximately $24 \%$ lower than the $13,600 \mathrm{mt}$ reported for 1990 (Table 10). Landings in 1990
from the U.S. commercial fisheries were the largest since 1966. Since 1980, the U.S. commercial fishery has accounted for at least $80 \%$ of the total landings, which have remained steady without trend, averaging 12,000 mt (Figure 3).

## Recreational Catches

Recreational catches of silver hake have been reported for this stock but have generally been a minor component of the total catch, averaging

777 mt per year and ranging from 0 to $1,974 \mathrm{mt}$ (Table 10). Details of recreational catch estimates can be found in Almeida (1987b).

## Sampling Intensity

A summary of the U.S. length frequency sampling by two-digit statistical area (SA) for which significant commercial landings occur and by quarter during 1982-1992 is given in Table 11. United States length frequency sampling intensity has generally been high in SA 61 and SA 62, and lower in SA 52 and SA 53. Landings taken from SA 62 were generally oversampled (averaging 1 sample per $21-170 \mathrm{mt}$ ), particularly since commercial landings from this area are low. In SA 61, length frequency sampling was adequate during 1982-1992, averaging from one sample per 100-280 mt. Sampling in SA 53 averaged one sample per 150 to 290 mt during 1984-1991, but decreased prior to 1984 and in 1992 (1982-1984: 1 sample per 450 to 660 mt ; 1992: 1 sample per 500 mt ). Sampling has been generally poor in SA 52 , particularly since 1988 , averaging one sample per 350 to 730 mt . Length frequency samples from sea sampling trips during 1989-1992 were also available and used to augment port sample length frequencies (Table 11). As for the Gulf of Maine-Northern Georges Bank stock, some disparity was observed between length frequency distributions when comparing port and sea samples. Virtually all U.S. length samples were collected from otter trawl landings from the unclassified round market category, which generally constitutes more than $90 \%$ of the total commercial catch from this stock.

The sampling recommendations discussed for the Gulf of Maine-Northern Georges Bank stock should be applied.

## Age Composition

The age composition of commercial landings was estimated by applying estimated numbers at length derived from monthly sea and port sample length frequencies to age-length keys derived from research vessel surveys, pooled by calendar quarter. Commercial numbers at length were estimated by dividing quarterly mean weights (obtained by applying silver hake length-weight equations to sample length frequencies) into quarterly commercial landings. Commercial numbers at length were then applied to agelength keys (quarters 1 and 2 applied to the
spring survey key; quarters 3 and 4 applied to the autumn survey key) to derive estimates of the numbers at age and summed over quarter to derive the annual catch-at-age matrix (Table 12).

Similar shifts in the predominant ages constituting the commercial landings have been observed for this stock since 1955. The age composition of the commercial catch in the 1950s and 1960s was composed of predominantly age 2 to 4 fish (averaging about $86 \%$ of the total catch each year). During 1972-1974 the age composition shifted to younger fish (ages 1 to 3), due to several strong year classes recruiting to the fishery. As those year classes grew through the fishery during 1975-1978, the age composition again shifted toward older fish (age 2 to 4 ), constituting approximately $90 \%$ of the total catch. Since 1979, the commercial catch has been made up of primarily of age 2 to 3 fish (about $65 \%$ of the total each year), and since 1988 significant contributions have been made by age 4 fish.

## Mean Weights at Age

Mean weights at age in the commercial catch for ages 1-6+ during 1955-1992 are given in Table 13 and, based on landings patterns, are considered mid-year values. During the 19551992 period, mean weights at age varied annually, but without consistent trend.

## STOCK ABUNDANCE AND BIOMASS INDICES

## Commercial Catch Per Effort

United States commercial CPUE indices (catch per unit effort; expressed in metric tons landed per day fished) were calculated by vessel tonnage class (Class 2: 5 to 50 grt ; Class 3: 51 to 150 grt ; Class 4: 151 to 500 grt ) from otter trawl trips in which silver hake constituted $50 \%$ or more of the total trip catch by weight. These values are considered "directed trips" and have been computed for those areas in which significant silver hake landings occur (Table 14). Since 1980, when U.S. commercial landings constituted the greatest proportion of the total international catch of silver hake, directed landings from U.S. fleets have constituted at least $46 \%$ of the total international catch and at least $50 \%$ of the total U.S. catch. In recent years, since 1987, landings from

Table 14. United States commercial landings (L), days fished (DF), and landings per days fished (L/DF), by vessel tonnage class (Class 2:5-50 grt; Class 3: 51-150 grt; Class 4: 151-500 grt), of silver hake from the Southern Georges Bank-Middle Atlantic stock for otter trawl trips in which silver hake constituted $50 \%$ or more of the total trip catch by weight [i.e., 'directed trips']

[^1]directed trips have increased to at least $60 \%$ of the total catch. United States landings from directed trips in SA 53 and SA 61 have varied annually but generally without trend since the late 1970s. However, since the early 1980s, commercial landings from directed trips have increased in the southern Georges Bank area (SA 52), primarily from the ton class 4 fleet.

United States directed commercial CPUE indices since the late 1970s from SA 53 and 61 have gradually declined, with peak values during 19811984 and another smaller peak during 19881990 (Figure 7). Despite decreases in these
areas, CPUE in the southern Georges Bank region (SA 52) has steadily increased since 1980.

Commercial CPUE indices were standardized by applying a three-factor (year, tonnage class, and area) GLM to log CPUE data for directed otter trawl trips from 1973 through 1992. The model accounted for just over $30 \%$ of the total variation in the data. Retransformed log year coefficients were multiplied by the 1973 base year CPUE to derive standardized indices. Despite increases in the CPUE index from SA 52, the standardized indices that account for area and ton class effects show a declining trend (Figure 7).

Table 16. Stratified mean number-per-tow (linear estimate) at age for silver hake from the Southern Georges Bank-Middle Atlantic Stock (offshore strata 1-19, 61-76; inshore strata 1-46, 52, 55) from NEFSC spring and autumn bottom trawl surveys

[^2]

Figure 8. Stratified mean number and weight (kilograms) per tow of Southern Georges Bank-Middle Atlantic silver hake from the NEFSC spring and autumn bottom trawl surveys.

## Research Vessel Abundance Indices

Spring and autumn bottom trawl survey indices (linear estimate) are calculated using inshore/offshore data combined and the \# 36 Yankee trawl as the standard gear. Surveys that used the \# 36 Yankee trawl but did not include inshore strata (spring 1968-1972 and autumn 19631973) were adjusted using ratios given in Table 15. See Almeida ( 1987 b ) for more details of the calculations of these adjustment coefficients. Stratified mean catch per tow in number and weight for both spring and autumn survey are given in Table 15 and estimates of number per tow at age since 1973 in Table 16.

The spring and autumn survey number per tow indices have been highly variable and have generally shown inconsistent trends in population abundance, except during 1973-1978. During this period, the number per tow indices increased reaching a series high in 1974 and in 1977 for the spring and autumn surveys, respectively; after this, both sets of indices subsequently declined (Figure 8). Increases in number per tow indices resulted from strong year classes during the mid-1970s and were consistent with trends for the Gulf of Maine-Northern Georges Bank stock during this period. The spring index increased again during 1982-1986, but has shown a generally declining trend through 1993; the

autumn indices have varied annually without trend since 1980, except for an unusually high index in 1985.

## MORTALITY

## Natural Mortality

Instantaneous natural mortality (M) for the Southern Georges Bank-Middle Atlantic stock is assumed to be 0.40 . Changes in natural mortality rates over time and varying by age, as was discussed for the Gulf of Maine-Northern Georges Bank stock, apply here.

## Total Mortality

Estimates of instantaneous total mortality $(Z)$ were calculated in the same manner as for the Gulf of Maine-Northern Georges Bank stock and values were obtained for the same time periods (Table 17).

Pooled estimates indicated that total mortality on this stock was lowest during the earlier periods of the time series; $Z=0.77$ during 19741977 and $Z=0.67$ during 1979-1982. Total mortality significantly increased in the next two subsequent periods (Table 17); from 0.67 during 1979-1982 to 1.11 during 1984-1987. Total mortality reached its highest value of 1.56 during 1989-1992. Estimates of total mortality were roughly equal between the spring and autumn surveys over all periods.

## ESTIMATION OF DISCARDS AND ITS IMPLICATIONS ON YIELD AND SPAWNING STOCK BIOMASS PER RECRUIT

Because discards in the domestic silver hake fishery may be significant (Anderson 1975) an important aspect of this analysis deals with estimating the selection pattern of the current fishery (total catches) and determining whether a directed fishery for smaller silver hake increases the selectivity toward younger ages. Simultaneously, the analysis must consider whether increased effort, and therefore fishing mortality, will likewise be directed into this emerging fishery.

To estimate the selection pattern of the current fishery for silver hake, the landings-at-age matrix was augmented to account for the numbers of silver hake at age discarded at sea. This required: 1) a discard estimator for each cell within defined temporal and spatial strata; 2) an expansion factor to adjust the cell's discard estimates to fleetwide estimate of discards by strata; and 3) samples of the size composition of discards by strata, from which the average weight can be used to estimate numbers of fish discarded by length and age. It is assumed that fishing patterns and recorded weight and size composition of discards from observed trips in the Domestic Sea Sampling Program (DSSP) are representative of the overall fishing fleet.

Statistical areas and meshes were aggregated into categories large enough to provide adequate

Table 19. Landings (metric tons) by region and quarter, and number of discarded silver hake length samples (\# fish measured) from U. S. Domestic Sea Sampling Program (DSSP) by defined strata (year, region, quarter and mesh category) for the Southern Georges Bank-Middle Atlantic Stock

samples to stratify temporally and spatially because discard rates are likely to vary by size composition of the fish in the population and operating characteristics of the fleets (i.e. mesh size). No statistically based means of deriving strata were used. Because seasonal growth of fish in the population appeared to have an effect on the modal length and size composition of each mesh, quarter was retained as the temporal stratum.

Similarities in the length frequency distributions by mesh and area were used as the basis for defining the spatial stratum and mesh stratum within each stock unit: 1) Gulf of Maine-Northern Georges Bank stock consists of Gulf of Maine Region (SA 511-515) and Northern Georges Bank Region (SA 521-523); and 2) Southern Georges Bank-Middle Atlantic stock consists of Southern Georges Bank region (SA 524-526), Southern New England region (SA 537-613), and Middle Atlantic region (SA 614-636). In addition, meshes were aggregated into mesh categories as follows:
mesh category 1: mesh in codend $\leq 3.5 \mathrm{in}$.,
mesh category 2: $3.5 \mathrm{in} .<$ mesh in codend $<5.5 \mathrm{in}$., mesh category 3: mesh in codend $\geq 5.5$ inches).

Tables 18 and 19 give number of individual length samples and number of fish measured of discarded silver hake in the DSSP data base by stratum (year, quarter, region, and mesh).

## DISCARD ESTIMATOR

The weight (in pounds) of silver hake discarded to days fished was chosen as the discard ratio estimator for the silver hake fishery. In the DSSP, observers who are placed aboard a given vessel for a trip duration record tow-by-tow weight of discards as well as effort data. Although tows are not independent, the trips themselves may be, and trips that caught silver hake were defined as the population of sampling units of interest. This population comprised trips that landed all silver hake, landed and discarded silver hake, and discarded all silver hake. Preliminary computation of discard rates (lb/day fished) indicated that rates were generally much lower for $100 \%$ discard trips, which might be expected for a nontargeted fishery, and it would, therefore be desirable to stratify. However, the weighout data base only records effort associated with trips landing silver hake and thus, trips in which the practice of full discarding occurred would not be included in the effort expansion factor. There-
fore, $100 \%$ discard trips were excluded at the cost of lower overall sample size available for estimation of discard rates. The net effect of this exclusion is higher discard rates for many of the strata, although effort used in the expansion factor will be lower because it excludes effort from trips that discarded the entire catch, probably resulting in an underestimate of total discards.

The trip or sampling unit (a trip that caught silver hake and did not fully discard) comprises a group or cluster of elements that are the observed tows in the DSSP data base containing discard and effort information. The sampling unit (i.e. trip) is calculated as:

$$
\begin{equation*}
R=\frac{\sum_{1}^{n} y_{i}}{\sum_{i}^{n} x_{i}} \tag{1}
\end{equation*}
$$

where $y_{i}=$ the weight of discarded silver hake in the $i t h$ observed tow and $x_{i}=$ the effort expended (days fished) for the ith observed tow. Each sampling unit can fall into any cell defined by the above strata or domains ( $k=1,2, \ldots, n_{j}$ ) and therefore the population parameter to be estimated is the ratio of means (Cochran 1963) within the kth domain;

$$
\begin{equation*}
\hat{R}_{k}=\frac{\sum_{k=1}^{n_{j}} \frac{y_{j k}}{n_{j}}}{\sum_{k=1}^{n_{j}} \frac{x_{j k}}{n_{j}}}=\frac{\overline{y_{j}}}{x_{j}} \tag{2}
\end{equation*}
$$

where: $\hat{R}_{k}=$ discard ratio estimator in the $k t h$ domain,
$y_{j k}=$ the mean weight of discards over $j$ trips in the kth domain,
$x_{j k}=$ the mean effort (days fished) over $j$ trips in the $k$ th domain,
$n_{j}=$ the number of sampling units (trips) that fall into the $k$ th domain.

For convenience with subsequent computations, the discard ratio estimator, $\hat{R}_{k}$, is redefined for the ith year, the $j t h$ region, the $k t h$ quarter and the lth mesh and given as:

$$
\begin{equation*}
\hat{R}_{i j k l} \tag{3}
\end{equation*}
$$

Table 20. Mean discard rates (pounds/day fished) ${ }^{1}$, coefficients of variation ( $\mathrm{CV} \times 100$ ) and sample sizes ( N ) by defined strata (year, region, quarter and mesh category) for the Gulf of Maine-Northern Georges Bank Stock. Rates are computed from observed tows within trips that caught silver hake but did not discard the entire catch. Values in parentheses represent means computed from strata expanded to yr, stock, half year (i.e. quarters 1-2 and quarters 3-4), and mesh category.

${ }^{1}$ Discard rates are estimated as the ratio of the means (Cochran 1963):

$$
R_{k}=\frac{\sum_{k=1}^{n_{j}} \frac{y_{j k}}{n_{j}}}{\sum_{k=1}^{n_{j}} \frac{x_{j k}}{n_{j}}}=\frac{\overline{y_{j}}}{\overline{x_{j}}}
$$

where; $R_{k}=$ discard ratio estimator in the $k$ th strata, $y_{j k}=$ the mean weight of discards over $j$ trips in the $k$ th strata, $x_{j k}=$ the mean effort (days fished) over $j$ trips in the $k$ th strata, and $n_{j}=$ the number of sampling units (trips) that fall into the $k t h$ strata.
${ }^{2}$ Gulf of Maine region $=$ Statistical Areas 511-5I5
3 Georges Bank region $=$ Statistical Areas 521-523

* Mesh category 1: mesh codend $\leq 3.5$ in.

5 Mesh category 3 : mesh codend $\geq 5.5 \mathrm{in}$.
and the standard error of $\hat{R}$, is:

$$
\begin{equation*}
s(\hat{R})=\frac{1}{\sqrt{n} \bar{X}} \sqrt{\frac{\sum y_{i}^{2}-2 \hat{R} \sum y_{i} x_{i}+\hat{R}^{2} \sum x_{i}^{2}}{n-1}} \tag{4}
\end{equation*}
$$

The sampling distribution of $\hat{R}$ is rather complicated, because both the numerator and denominator vary from sample to sample, and for small samples its distribution is skewed and usually slightly biased (Cochran 1963). Nonetheless, this serves as the best and least biased
of the ratio estimators for the present application. Coefficients of variation can be calculated from (4) using, $s(R) / R^{*} 100$. Tables 20 and 21 give the estimated mean discard rates (lb discarded/ day fished) along with coefficients of variation and sample sizes by strata. Cells in Tables 20 and 21 with values in parentheses (originally missing values for which there was effort associated with that stratum) represent the ratio estimator for strata expanded to year, stock, half year (i.e. quarters 1-2 and quarters 3-4), and mesh category.

## DISCARD ESTIMATE EXPANSION

The discard rates estimated in the prior section were derived from only a fraction of the total number of trips by vessels within each stratum. To derive fleetwide discard estimates, $\hat{R}$ must be raised by the expansion factor, $E$, defined as the total days fished for trips that landed silver hake within a given stratum, which is obtained from the weighout data base. Total effort was defined as the summation of all days fished for those trips that landed silver hake (Tables A1 and B1 in Appendix 1). While the strata (as defined earlier) for year, region, and quarter can be obtained from all trips in the weighout data base, the strata for mesh can only be obtained from those trips that were interviewed. Therefore, total days fished within a given stratum were allocated to a given mesh category on the basis of the proportion of days fished by mesh category for interviewed trips only (Appendix 1, Tables A2 and B2). In addition, Tables A2 and B2 give the interview coverage (both by trips and days fished) by stratum. It should be noted that trips (and therefore effort) that landed silver hake given here are only a subset of the total number of trips that catch silver hake, because some vessels will discard $100 \%$ of silver hake at sea. As stated earlier, $100 \%$ discard trips cannot be identified in the weighout data base and therefore $100 \%$ discard trips in the DDSP data base were not used in the estimation of discard rates. As such, the present discard estimates are considered minimum estimates. The extent to which these are lower than would be obtained from all trips (and its associated effort) can be inferred to some extent from the proportions of the total days fished in the DSSP data base from trips that did not discard the entire catch of silver hake (Tables A3 and B3 in Appendix 1). Proportions are highly variable, but some pattern appears evident which suggests that most of the total days fished are accounted for by trips not discarding the entire catch for that segment of the fleet using mesh category 1 (ranging from $62 \%$ to $100 \%$ ). Unfortunately, most of the total effort used in the expansion is associated with mesh category 3 from the Gulf of Maine region, where there is generally a lower proportion of the effort from trips not discarding the entire catch.

The total discards (in weight) of silver hake by stratum (Tables 22 and 23) were obtained using

$$
\begin{equation*}
W_{i j k l}=\hat{R}_{i j k l}{ }^{*} E_{i j k} * P_{i j k l} \tag{5}
\end{equation*}
$$

where: $W_{\text {gkl }}=$ total weight of discards (lb) in year $i$, region $j$, quarter $k$, and mesh $i$;
$\hat{R}_{i j k l}=$ mean discard estimator in year $i$, region $j$, quarter $k$, and mesh $l$;
$E_{i j k}=$ the total effort (days fished) in year $i$, region $j$, and quarter $k$; and
$P_{i j k l}=$ proportion of total effort from interviewed trips in year $i$, region $j$, quarter $k$, and mesh $l$.

Total discards (weight) of silver hake in both the northern and southern stock fisheries, although variable by mesh and over years, can comprise a significant proportion of the total landings (Tables 24 and 25). Estimated discards of silver hake ranged from $26 \%$ ( $1,695 \mathrm{mt}$ in 1991) to $156 \%(7,236 \mathrm{mt}$ in 1989$)$ of total Gulf of MaineNorthern Georges Bank landings over the 19891992 period for which data were available. Comparison of discards by mesh suggests that substantial discarding of silver hake by weight in the Gulf of Maine-Northern Georges Bank stock occurs in both the small mesh shrimp and silver hake fisheries ( $<3.5 \mathrm{in}$.) and the large mesh ( $>5.5$ in.) groundfish fisheries (Table 24). In the Southern Georges Bank-Middle Atlantic, silver hake stock discards ranged from $12 \%(1,249 \mathrm{mt}$ in 1991) to $76 \%(10,000 \mathrm{mt}$ in 1989) of total landings (Table 25). Here, the overwhelming majority of silver hake discarding by weight occurs in the small mesh fisheries ( $<3.5$ inches). Estimates of total silver hake discarded by weight in the northern stock over the 1989-1992 period are similar to those estimated by Anderson (1975) for the U.S. Gulf of Maine-Northern Georges Bank fishery over the period 1965-1974. Except for rather high estimates from 1971 to 1973 (averaging $8,600 \mathrm{mt}$ ), discards ranged between 437 mt and $2,100 \mathrm{mt}$ over the 1965 - 1970 period. No previous discard estimates have been made for the fisheries in the Southern Georges Bank-Middle Atlantic silver hake stock.

## NUMBER OF DISCARDS AT LENGTH AND AGE

The age composition of fish discarded in the silver hake fisheries was estimated by applying estimated numbers of discards at length derived from DSSP length frequency samples to agelength keys derived from NEFSC research vessel surveys, pooled by calendar quarter. Discarded numbers were estimated by dividing mean weights obtained by applying a length-weight equation

Table 21. Mean discard rates (pounds/day fished) ${ }^{1}$ coefficients of variation (CV x 100) and sample sizes (N) by defined strata (year, region, quarter and mesh category) for the Southern Georges Bank-Middle Atlantic stock. ${ }^{1}$ Discard rates are estimated as the ratio of the means (Cochran 1963):

$$
R_{k}=\frac{\sum_{j=1}^{a_{j}} \frac{y_{j k}}{n_{i}}}{\sum_{i=1}^{a_{i}} \frac{x_{i k}}{n_{j}}}=\frac{\overline{y_{j}}}{x_{j}}
$$

where; $R_{k}=$ discard ratio estimator in the $k$ th strata, $y_{j k}=$ the mean weight of discards over $j$ trips in the kth strata, $x_{j k}=$ the mean effort (days fished) over $j$ trips in the $k$ th strata, and $n_{j}=$ the number of sampling units (trips) that fall into the $k$ th strata.

2 Southern Georges Bank Region = Statistical Areas 524-526
${ }^{3}$ Mesh category l: mesh codend $\leq 3.5$ in.
4 Mesh category 2: $3.5 \mathrm{in} .<$ mesh codend $<5.5 \mathrm{in}$.
5 Mesh category 3: mesh codend $\geq 5.5 \mathrm{in}$.
6 Southern New England Region = Statistical Areas 537-613
7 Middle Atlantic Region $=$ Statistical Areas 614-636
( $W=.00000593 L^{3.05}$ ) to DSSP length frequency samples into the total estimated discarded weight of silver hake by stratum (Appendix 2 Tables A5 and B5). Cells or strata without length frequency samples to compute mean weights were assigned values computed from expanding strata to year, stock, and mesh, and are represented as values in parentheses. Total numbers discarded were then multiplied back into proportions at length
by stratum to derive numbers at length. Numbers at length were summed across mesh categories, across regions, and across quarters 1-2 and across quarters $3-4$ within each stock and applied to age-length keys (quarters 1-2 applied to the spring survey key; quarters 3-4 applied to the autumn survey key) and summed again over quarter to derive estimates of the number of discards at age by stock.

Table 22. Total discards of silver hake in weight (pounds) and numbers by stratum (year, region, quarter and mesh category) in the Gulf of Maine-Northern Georges Bank stock. Discard in numbers is computed by dividing mean weight into discarded weight. Values of mean weight in parentheses represent means from strata expanded to year, stock, quarter, and mesh category.

Because the size composition of discards consists of generally smaller silver hake than are taken in the landings the actual numbers of fish discarded can be quite large (Tables 24 and 25). Numbers of silver hake discarded ranged from $47 \%$ ( 16.6 million in 1990) to $296 \%$ ( 75.6 million in 1989) of the total numbers landed in the fisheries in the Gulf of Maine-Northern Georges Bank stock (Table 24). In the Southern Georges Bank-Middle Atlantic stock fisheries, numbers discarded ranged between $18 \%$ ( 9.7 million in 1991) to $108 \%$ ( 80.7 million in 1989) of the total numbers of silver hake landed (Table A5). Numbers of discarded silver hake were overwhelmingly greater in the small mesh fisheries ( $<3.5$ in.).

Discarded numbers of silver hake represent the greatest proportion at size and age for smaller and younger fish in the stock, respectively. In the Gulf of Maine-Northern Georges Bank stock, significant discards in numbers occurred generally between 15 and 25 cm (Figure 9) and represented the greatest proportion of age 1 and a smaller but still significant proportion of age 2 fish (Figure 10). Anderson (1975) also found significant numbers of silver hake discarded at age 1 for the 1965-1974 period, but found almost equal numbers of age 0 which were not apparent from estimates here. The size composition of discarded silver hake in the Southern Georges Bank-Middle Atlantic fisheries, although slightly larger in size compared to the northern stock, were clearly of a smaller size composition than the landings; with significant numbers between 21 and 30 cm (Figure 11). Discarded silver hake dominated numbers at age for age 2 with significant numbers at age 1 and in some years even age 3 (Figure 12).

## SELECTION PATTERN AT AGE

An untuned Virtual Population Analysis (Gulland 1965) was applied to the silver hake landings at age and catch at age (landings + discards) matrices to determine the effect on the relative selection pattern at age of the current fishery for silver hake when the landings at age are augmented with discards. Since discard estimates were only available for the years 1989 to 1992 , the VPA was run and examined to determine the extent to which estimates of fishing mortality at age had converged over the 19891992 period, first using the silver hake landings at age matrix and then using the catch at age matrix. In both cases, natural mortality (M) was
assumed to be 0.4 for both northern and southern silver hake stocks and VPA runs were preformed with varying levels of terminal fishing mortality to derive relative exploitation patterns (Tables A4 and B4 in Appendix 2). In all cases, from low to high terminal F's, convergence was achieved across ages $1-3$ by 1989 and to some extent by 1990. In the northern stock, inclusion of the discards in the catch at age increased the F at age 1 from about 5 to $7 \%$ of the age 3 F (assumed full) to about $30 \%$ of the age 3 F . In the southern stock, F at age 1 remained low relative to the age 3 F , but F at age 2 increased from about $25 \%$ of the age 3 F to about $45 \%$ of the age 3 F .

Sensitivity runs on the catch at age matrices indicated a flat-topped exploitation pattern and increasingly higher fishing mortalities at age with full exploitation on age 3 from high and intermediate terminal $F$ runs for the northern and southern stock, respectively. These were chosen as the most likely exploitation patterns. An average of the 1989-1990 F's at age were then taken because changes in the exploitation pattern between years, particularly when the VPA is applied to the catch at age matrix, suggests that discarding may be affected by year class strength. Thus, the final exploitation pattern (Table 26) indicated as the reference pattern, reflects the effects of discarding from a large year class (1988) and a weaker year class (1989). In addition, subsequent yield per recruit and spawning stock biomass per recruit calculations were also conducted using exploitation patterns other than the reference pattern to account for uncertainty in its estimation as well as possible changes which may result from re-directed fleet effort to younger ages associated with a "juvenile" whiting fishery. Yield and SSB per recruit simulations were conducted on six exploitation patterns; $25 \%$ and $50 \%$ of the reference pattern and increases of $150 \%, 175 \%$, and $200 \%$ of the reference pattern.

## YIELD AND SSB PER RECRUIT

A yield-per-recruit and spawning stock biom-ass-per-recruit analysis (Thompson and Bell 1934) was conducted to determine the effect on long-term yield of silver hake when losses of fish due to discarding are considered. Losses through wasteful fishing practices such as discarding do not contribute to the fishery's yield, while they can significantly reduce the stock's spawning biomass, resulting in an inaccurate perception of the long-term yield from the stock. Although the

Table 23. Total discards of silver hake in weight (pounds) and numbers by stratum (year, region, quarter and mesh category) in the Southern Georges Bank-Middle Atlantic stock. Discard numbers computed by dividing mean weight into discarded weight. Values of mean weight in parentheses represent means computed from strata expanded to year, stock, quarter and mesh category.

quantity of discarding has been estimated, the quantity of landings and extent of targeted effort for fish in the "juvenile" fishery are presently not known. Therefore, the analysis here assumes that the selection pattern that is obtained when discards are used to augment the landings at age matrix is an indication of the selectivity of a fishery that lands juvenile fish. For this analysis, yield and spawning stock biomass (SSB) per recruit were accumulated separately over both the "juvenile" and the "adult" life history phases of a cohorts entire life span and used to examine the likely outcome of harvesting for both a juvenile (ages 0 through 2) and adult (age 3+) silver hake fishery. At age two roughly $50 \%$ of fish have matured (O'Brien et al. 1993). Yield and SSB were calculated for the selection (or exploitation) pattern at age obtained with (catch analysis) and without (landings analysis) discard estimates (taken from the untuned VPA results). Results of this analysis were also compared with another run, which increased the natural mortality rates on younger ages of fish ( $\mathrm{M}=0.80$ on age $0, \mathrm{M}=0.6$ on age 1 , and $\mathrm{M}=0.4$ on age $2+$ ) to account for cannibalism of silver hake (Edwards and Bow-
man 1979) and growth compensatory responses to population density (Ross and Almeida 1986). In addition, yield and SSB analyses were performed using only a few of many other possible exploitation patterns, as given in Table 26.

For the landings analysis, mean weights at age for the application to yield-per-recruit were obtained as the arithmetic average of the landings mean weights at age over the 1989-1992 period (Tables 4 and 13). Mean weights for the catch analysis were calculated as the average of the mean weights from the landings and discards at age matrices weighted by numbers at age over the 1989-1992 period. Stock weights used in the subsequent analysis were taken as the weight from the length-weight equation applied to mean lengths at age derived from von Bertalanffy growth equations (Penttilla et al. 1989). Input mean weights for yield per recruit analyses are given in Table 27. Maturation ogives at age of northern and southern silver hake stocks for application of the spawning stock biomass-per-recruit analyses were taken from O'Brien et al. (1993). All initialization parameters were set equal for each stock and for the landings and catch analyses: 1)

natural mortality (M) was assumed to be 0.40 and equal for all ages; and 2) proportion of $F$ and $M$ before spawning was set to 0.66 and 0.50 for the northern and southern stocks, respectively.

Based on the relative selection pattern derived from VPA, when discards are used to augment the catch at age matrix, there was a greater selection for younger fish in the stock (i.e. age 1 3 ), indicative of the possible impact of a "juvenile"

Figure 10. Estimated numbers of landed and discarded silver hake at age from the Gulf of Maine-Northern Georges Bank stock over 1989-1992 period.
silver hake fishery. As a result, yield per recruit analyses suggested that while yield taken from the "juvenile" fishery is higher, yield from the "adult" fisheries on the silver hake stocks is actually lower than when the exploitation pattern accounts for the taking of juvenile fish (Figures 13 and 14). Maximum yield from the northern "adult" silver hake fishery occurred at an F of 0.40 from the catch analysis; a decrease

Figure 11. Estimated numbers of landed and discarded silver hake by length from the Southern Georges Bank-Middle Atlantic stock over 1989-1992 period.
from $\mathrm{F}_{\text {max }}$ of 0.60 from the selection pattern derived from landings at age (See Tables A4 and B4 in Appendix 2). In addition, yield was 15\% less at $\mathrm{F}_{\text {max }}$ when the exploitation pattern was derived from catch at age (Figure 13). Similarly, in the "adult" fishery of the southern stock yield was $18 \%$ lower at $\mathrm{F}_{\max }$ from the catch analysis as compared to the selection pattern derived from landings at age, and $F$ corresponding to maximum yield decreased from an $F$ of 0.75 to 0.60 (Figure 14). Increasing natural mortality on younger ages resulted in an overall decrease in

Figure 12. Estimated numbers of landed and discarded silver hake at age from the Southern Georges Bank-Middle Atlantic stock over 1989-1992 period.
yield by about $50 \%$, without changing the general shape of the yield functions derived from the catch analysis for either stock (Figures 13 and 14). Thus, further analyses using alternate exploitation patterns considered only an $\mathrm{M}=0.40$ that was constant across all ages.

Examination of yield using exploitation patterns other than the reference that was obtained from the VPA applied to the catch at age indicated a significant trade-off between increasing harvest on younger ages of fish in the population and loss of yield to the "adult" fishery. Increasingly

${ }^{1}$ Average weight taken from Tables 4 and 13 over the 1989-1992 period.
${ }^{2}$ From applying length-weight equation ( $W=0.00000593 L^{3.05}$ ) to mean length at age from vonBertalanffy growth equations (Penttilla et al 1989).
higher selection (exploitation) of ages 1 and 2 resulted in increasingly greater yield from a "juvenile" fishery, with maximum yield being obtained from lower levels of $F$ as exploitation was increased to $150 \%, 175 \%$ and $200 \%$ of the reference pattern (Figures 15 and 16). Yield functions from both the northern and southern "juvenile" components become more asymptotic as exploitation was increased with nearly maximum yield ( 0.045 kg ) occurring at an F of around 2.0. Although
yield increased from the "juvenile" component with increasing exploitation on younger ages, it resulted in a significant adverse effect on an "adult" fishery; as selection on ages 1 and 2 was increased to $200 \%$ above the reference pattern maximum yield decreased by nearly $35 \%$ (Figure 17 and 18). In addition, $F$ required to achieve maximum yield from the fishery decreased from around 0.6 to 0.3 .

These results suggest that a harvesting strat-

Figure 13. Yield and spawning stock biomass (SSB) per recruit from fisheries on "juvenile" and "adult" components of the Gulf of Maine-Northern Georges Bank silver hake stock. Graphs compare yield and SSB per recruit obtained from exploitation pattern derived from landings and catch at age under two assumed vectors of natural mortality at age: top) $\mathrm{M}=0.4$ constant over all ages; and bottom) $\mathrm{M}=0.8$ on age 0 , $M=0.6$ on age 1 , and $M=0.4$ on ages 2 and above.
egy directed toward younger ages of fish (as might occur in a "juvenile" whiting fishery) may be incompatible with objectives to maintain an "adult" component that has traditionally supported the silver hake fishery. While overall yield to the "adult" fishery was significantly reduced using the different series of exploitation scenarios in this analysis, percent maximum spawning potential (currently used as the overfishing definition) did not decrease as much as might be expected, probably because three-quarters of the stock has matured by age 2 (Figure 17 and 18). Fishing mortality rates at $31 \%$ and $42 \%$ MSP declined from 0.51 to 0.36 and from 0.39 to 0.34 , for the northern and southern stocks, respectively, when greater exploitation on juveniles was taken into account using the reference exploitation pattern. If effort is redirected on concentra-

Figure 14. Yield and spawning stock biomass (SSB) per recruit from fisheries on "juvenile" and "adult" components of the Southern Georges Bank-Middle Atlantic silver hake stock. Graphs compare yield and SSB per recruit obtained from an exploitation pattern derived from landings and catch at age under two assumed vectors of natural mortality at age: top) $\mathrm{M}=0.4$ constant over all ages; and bottom) $\mathrm{M}=0.8$ on age $0, \mathrm{M}=0.6$ on age 1 , and $\mathrm{M}=0.4$ on ages 2 and above.
tions of juvenile silver hake as indicated by the $200 \%$ exploitation pattern, F at $31 \%$ MSP decreases to 0.29 and F at $42 \%$ MSP decreases to 0.25 for the northern and southern stocks, respectively. It should be emphasized that the length at $50 \%$ maturation for either stock is about 23 cm (age 2), and as such increased effort on younger ages ( 1 and 2) of fish increases the likelihood of driving the population below the minimally accepted MSP threshold.

## RESEARCH

 RECOMMENDATIONSThe following recommendations, which apply to both silver hake stocks, provide future

Figure 15. research necessary to resolve the problems noted in the report of SARCI7.

1) Re-evaluation of the stock structure of the silver hake resource. The geographic distribution of survey catches of silver hake, particularly juveniles during the autumn, suggests that considerable mixing between the two stocks may occur, particularly for years with large year-classes. The distribution of adult fish also suggests that the stock boundary may shift seasonally, potentially resulting in a misallocation of landings in the catch-at-age matrix to the stocks and a mismatch with the survey strata sets between seasons. Therefore, the most appropriate spatial and temporal aggregation of landings must be determined based on stock boundaries for constructing the catch-at-age matrix.
2) The research survey catch data should be evaluated to a) determine appropriate survey strata sets to apply to catch-at-age matrices from the different stocks and to account for possible differences in spatial distribution between years; and b) determine the effect of transformations (e.g., logarithmic vs. delta) in reducing the impact of unusually high numbers in a tow.
3) Inadequate port sampling of silver hake length frequencies as well as use of survey caught fish for constructing age-length keys may introduce additional uncertainty in the catch-at-age matrix. Therefore, port sampling of length frequencies and age structures must be adequate if a reasonable catch-at-age matrix is to be constructed for VPA. Where port sampling is problematic, age structures should be collected from the sea sampling.
4) Preliminary analysis indicated that discarding of silver hake may be substantial. Therefore, the adequacy of the statistical design of the sea sampling data base needs to be evaluated for deriving estimates of silver hake discarding.

Table A2. Total days fished by mesh category ${ }^{1}$ within defined strata (year, region, quarter and mesh category) for vessels fishing the Gulf of Maine-Northern Georges Bank stock area expanded by multiplying proportion of days fished by mesh from interviewed trips in weighout data base to total days fished (see Table A1 Appendix 1). Included is fractional interview coverage in Days fished (DF) and by trip.

[^0]:    ${ }^{1}$ Adjusted from \#41 trawl catches to equivalent \#36 trawl catches using a $334: 1$ ratio.
    ${ }^{2}$ Estimates from autumn bottom trawl survey not available.

[^1]:    ${ }^{1}$ Adjusted from offshore \#36 trawl catches to equivalent inshore-offshore \#36 trawl catches using a $.960: 1$ ratio.
    ${ }^{2}$ Adjusted from offshore \#41 trawl catches to equivalent inshore-offshore \#36 trawl catches using a .320:1 ratio.
    ${ }^{3}$ Adjusted from offshore \#41 trawl catches to equivalent inshore-offshore \#36 trawl catches using a .334:1 ratio.
    ${ }^{4}$ Adjusted from offshore \#36 trawl catches to equivalent inshore-offshore \#36 trawl catches using a .890:1 ratio.
    ${ }^{5}$ Strata 1-19 only.
    ${ }^{6}$ Estimates from autumn bottom trawl survey not available.

[^2]:    ${ }^{1}$ Adjusted from offshore \#41 trawl catches to equivalent inshore-offshore \#36 trawl catches using a .320:1 ratio.
    ${ }^{2}$ Adjusted from offshore \#41 trawl catches to equivalent inshore-offshore \#36 trawl catches using a . 334:1 ratio.
    ${ }^{3}$ Adjusted from offshore \#36 trawl catches to equivalent inshore-offshore \#36 trawl catches using a $.890: 1$ ratio.

[^3]:    ${ }^{1}$ Instantaneous natural mortality rate assumed to be 0.40
    ${ }^{2}$ Estimates derived from:
    Autumn: $\quad \ln \left(\Sigma\right.$ age $2^{+}$for year $\mathrm{i}-1$ to $j-1 / \Sigma$ age $3^{+}$for year i to j
    Spring: $\quad \ln \left(\Sigma\right.$ age $3^{+}$for year $i$ to $j / \Sigma$ age $4^{+}$for year $i+1$ to $j+1$
    ${ }^{3}$ Provisional estimate, does not include spring 1993 survey abundance estimates
