## Northeast Fisheries Science Center Reference Documents

This series is a secondary scientific series designed to assure the long-term documentation and to enable the timely transmission of research results by Center and/or non-Center researchers, where such results bear upon the research mission of the Center (see the outside back cover for the mission statement). These documents receive internal scientific review but no technical or copy editing. The National Marine Fisheries Service does not endorse any proprietary material, process, or product mentioned in these documents.

All documents issued in this series since April 2001, and several documents issued prior to that date, have been copublished in both paper and electronic versions. To access the electronic version of a document in this series, go to http://www.nefsc.nmfs.gov/nefsc/publications/series/crdlist.htm. The electronic version will be available in PDF format to permit printing of a paper copy directly from the Internet. If you do not have Internet access, or if a desired document is one of the pre-April 2001 documents available only in the paper version, you can obtain a paper copy by contacting the senior Center author of the desired document. Refer to the title page of the desired document for the senior Center author's name and mailing address. If there is no Center author, or if there is corporate (i.e., non-individualized) authorship, then contact the Center's Woods Hole Laboratory Library (166 Water St., Woods Hole, MA 02543-1026).

## Section 1. Introduction

The Northern Demersal Working Group and the Southern Demersal Working Group met on an intermittent basis during July and August, 2000, and in joint session on 30 and 31 August, 2000 to review assessments of 19 stocks of groundfish regulated by the Northeast Multi-species Fishery Management Plan.

This report was prepared for the NEFMC Multi-Species Monitoring Committee for use in developing management advice for the 2001 fishing year. This report represents a summary of the assessment results presented to the Joint Working Group at its 30-31 August, 2000 Final Review Meeting. The report consists of this introduction, followed by a concise section for each of the 19 stocks in the review. A concluding section contains overall comments by the Joint Working Group, an evaluation of the quality of the data and assessments, and recommendations for future improvement. This Working Group report contains information on current stock status, with no explicit references to management advice.

## Terms of Reference

The agreed terms of reference for this assessment review cycle are as follows:
a) For stocks where sufficient data are available for 1999, determine 1999 fishing mortality, spawning stock biomass, and mean biomass, and stock size at the beginning of 2000.
b) For stocks where 1999 landings and indices of current biomass are available, use proxies to determine whether there has been a significant change in exploitation rate or stock biomass between 1998 and 1999.

## List of Stocks Reviewed

The letter associated with each of the stocks listed below corresponds to a section of this report following the introductory section. The 19 stocks comprised 4 categories, corresponding to the review status or assessment methodology used to determine stock status as follows:

1) Stocks reviewed by the Transboundary Resources Assessment Committee in April, 2000
A. Georges Bank Cod
B. Georges Bank Haddock
C. Georges Bank Yellowtail Flounder
2) Stocks for which a VPA was performed to estimate 1999 F
D. So. New England Yellowtail Flounder
E. Cape Cod Yellowtail Flounder
F. Gulf of Maine Cod
3) Stocks for which projection methodology was used to derive 1999 F
G. Witch Flounder
H. American Plaice
I. Georges Bank Winter Flounder
J. So. New England/Mid-Atlantic Winter Flounder
K. White Hake
4) Stocks for which index assessment methods were applied to evaluate 1999 exploitation ratios
L. Pollock
M. Redfish
N. Ocean Pout
O. Gulf of Maine/Georges Bank Windowpane
P. So. New England/Mid-Atlantic Windowpane
Q. Mid-Atlantic Yellowtail Flounder
R. Gulf of Maine Haddock
S. Atlantic Halibut

## Section 2. Stock Assessments for 19 Northeast Groundfish Stocks

The following sub-sections A-S contain a summary of the detailed assessment working papers reviewed by the joint meeting of the SAW Northern Demersal and Southern Demersal Working Groups on 30 and 31 August, 2000.

## A. Georges Bank Atlantic Cod by L. O'Brien

### 1.0 Background

This stock was last assessed and peer reviewed in April 2000 (O’Brien 2000, Transboundary Resources Assessment Committee 2000) and is summarized in this report. Fully recruited F (ages 4-8, u) was estimated to be 0.22 in 1999, the lowest in the time series (1978-1999). Spawning stock biomass was $34,800 \mathrm{mt}$ in 1999 and continued the increasing trend from the record low estimate of $20,000 \mathrm{mt}$ in 1994. Mean biomass was $43,000 \mathrm{mt}$ in 1999 and has followed trends similar to SSB. Since 1992, recruiting year classes have all been below the long term average and the 1997 year class which entered the 1999 fishery as 2 year olds, is the lowest on record. The NEFSC spring and autumn bottom trawl survey indices continue to remain near record low values. Recruitment indices for age 2 fish from the 1994, 1995, 1996, and 1997 year classes are below the time series (1963-1999) average . The most recent above average year class occurred in 1993.

### 2.0 2000 Assessment

## The Fishery

Total commercial landings of Georges Bank cod (Table A1, Figure A1) in 1999 (9,800 mt) increased $12 \%$ from 1998. USA landings increased $16 \%(8,100 \mathrm{mt})$ and Canadian landings declined $3 \%$ ( 1819 mt ) in 1999 (Table A1). No discards estimates were derived for 1999. Recreational landings were estimated at 357 mt , a decline of about $31 \%$ from 1998.

The total number of commercial length samples in 1999 were less than in 1998. The number of quarterly samples were adequate for both scrod and market size categories, but poor for the large market category. The 'large' samples were pooled on a semi-annual basis. Spatial coverage was poor for eastern Georges Bank (SA 561, 562), as it has been for several years. As in the last assessment, length samples from western Georges Bank and combined US and Canadian age samples from eastern Georges Bank were applied to characterize the landings from eastern Georges Bank. Landings were dominated in numbers by age 3 fish in both the US and Canadian fisheries and in weight by age 3 fish in the USA fishery and age 4 fish in the Canadian fishery.

## Input data and Analyses

The current assessment is an update of the 1999 assessment and employs the same VPA formulation (NDWG,NEFSC 2000). A slight variation from the previous assessment is that the number of surveys available as tuning indices in the terminal year decreases from three to two since the USA 2000 spring survey was not available when the assessment was conducted. Catch at age has been updated with total 1999 landings (USA and Canadian) and research survey indices have been estimated for the 1999 NEFSC spring and autumn bottom trawl surveys and the 2000 Canadian Department of Fisheries and Oceans (DFO) spring bottom trawl survey. A conditional non-parametric bootstrap procedure (Efron 1982) was used to evaluate the
precision of fishing mortality, spawning stock biomass, and mean biomass estimates. A retrospective analysis was performed for terminal year fishing mortality, spawning stock biomass, and age 1 recruitment.

### 3.0 Assessment Results

NEFSC spring and autumn survey abundance and biomass indices declined in 1999 to similar values observed in 1997, except for the autumn biomass index which has increased slightly since 1997. All indices, however, remain below the long term average (Table A2, Figure A2). The Canadian spring survey index of abundance increased in 1999 to similar values observed in 1996 (Figure A2). The recruitment indices for age 1 and 2 from the 1999 NEFSC autumn bottom trawl survey were well below average.

Fully recruited fishing mortality (age 4-8) was estimated at 0.22 in 1999 and the uncertainty of this estimate, as indicated by the retrospective analysis, is discussed below. The 1998 F estimate was $0.39,39 \%$ higher than initially estimated in the 1999 assessment (NDWG, NEFSC 2000) (Figure A3). Biomass weighted fishing mortality declined from a time series high of 0.64 in 1993 to 0.23 in 1999 (Table A3, Figure A3). Spawning stock biomass in 1999 was estimated at $34,800 \mathrm{mt}$, a $10 \%$ increase from 1998 and a $74 \%$ increase from the record low in 1994 (Table A3, Figure A4). Mean biomass increased from a record low 31,000 mt in 1994 to $43,000 \mathrm{mt}$ in 1999 (Table A3, Figure A4). Recruitment of the 1998 year class ( 5.3 million age 1 fish) is estimated to be similar to the 1994 year class ( 4.7 million age 1 fish) (Table A3, Figure A4). The survival ratio of recruit/SSB was above average for the 1995 and 1996 year classes and below average for the more recent year classes.

## VPA Diagnostics

Stock size estimates for ages 1-8 were well estimated with CVs ranging from 0.21 to 0.47 . The distribution of F estimates from the bootstrap analysis ranged from 0.16 to 0.40 with an $80 \%$ probability that F in 1999 was between 0.18 and 0.25 . The distribution of SSB estimates from the bootstrap analysis ranged from $28,000 \mathrm{mt}$ to $48,000 \mathrm{mt}$ with an $80 \%$ probability that SSB in 1999 was between $31,000 \mathrm{mt}$ and $39,000 \mathrm{mt}$. The distribution of the 1999 mean biomass estimates, derived from bootstrap analysis, ranged from 32,000 to $62,000 \mathrm{mt}$. There is a $80 \%$ probability that the mean biomass in 1999 was between $38,000 \mathrm{mt}$ and $48,000 \mathrm{mt}$.

A retrospective pattern exists in this model formulation back to 1994 (Figure A5). The terminal year estimates of both recruits and fishing mortality are less than converged estimates since 1994 and 1995, respectively, and SSB estimates are greater than converged estimates since 1994. This may partially be due to the lack of Canadian indices in the calibration for 1993 and 1994. Other factors influencing the retrospective pattern may include mis-reporting of catch, immigration or emigration, an unrepresentative estimate of natural mortality, and mis-specification of the model.

The fishing mortality of 0.28 that was assumed for the projection analysis in 1999 (NDWG, 2000) was not within the $80 \%$ confidence interval ( $0.18-0.25$ ) of the 1999 F derived from current VPA calibration.

### 4.0 SFA control rule

The SFA control rule for Georges Bank cod is based on $\mathrm{B}_{\text {MSY }}(108,000 \mathrm{mt})$ and states that when the stock biomass is between $1 / 4$ and $1 / 2 \mathrm{~B}_{\mathrm{MSY}}(27,000-54,000 \mathrm{mt})$, the threshold mortality rate is defined by a five year rebuilding time period, and if the stock is between $1 / 2 B_{\text {MSY }}$ and $B_{\text {MSY }}$ the rebuilding time period is 10 years (Figure A6). In 1999, mean biomass was estimated at 43,000 mt , about $40 \%$ of the target $\mathrm{B}_{\mathrm{MSY}}$ and F weighted by biomass was estimated at 0.23 .

## 5. 0 Sources of Uncertainty

- Landings data for 1994-1999 are derived by proration and are provisional.
- There was inadequate commercial sampling in 1999 both temporally and spatially. The large market category was not well sampled by quarter, and samples from eastern GB were minimal.
- The retrospective analysis indicates a pattern in the estimates of F, SSB, and recruits in the VPA. The terminal year estimates of both fishing mortality and recruits are less than the converged estimates and SSB estimates are greater than the converged estimates.
- There are inadequate data to characterize both the recreational and discarded catch, particularly if these components increase. The SARC previously rejected using poorly sampled recreational catch since a recreational catch at age with a similar age structure to the commercial catch at age would only be a scaling factor.

[a] During 1963-1984, BMV oval doors were used in spring and autumn surveys; since 1985, Portuguese polyvalent doors have been used in both surveys. Adjustments have been made to the 1963-1984 catch per tow data to standardize these data to polyvalent door equivalents. Conversion coefficients of 1.56 (numbers) and 1.62 (weight) were used in this standardization (NEFC 1991).
[b] Spring surveys during 1980-1982, 1989-1991 and 1994 and autumn surveys during 1977-1981, 1989-1991, and 1993 were accomplished with the $R / V$ Delaware $I I$; in all other years, the surveys were accomplished using the $R / V$ Albatross $I V$. Adjustments have been made to the $R / V$ Delaware $I I$ catch per tow data to standardize these to $R / V$ Albatross $I V$ equivalents. Conversion coefficients of 0.79 (numbers) and 0.67 (weight) were used in this standardization (NEFC 1991).
[c] Spring surveys during 1973-1981 were accomplished with a '41 Yankee' trawl; in all other years, spring surveys were accomplished with a '36
Yankee' trawl. No adjustments have been made to the catch per tow data for these gear differences.
[d] Excludes unusually high catch of $1894 \operatorname{cod}(2558 \mathrm{~kg})$ at Station 230 (Strata tow 20-4).
[e] Excludes unusually high catch of $1032 \operatorname{cod}(4096 \mathrm{~kg})$ at Station 323 (Strata tow 16-7).
[f] Excludes unusually high catch of $111 \operatorname{cod}(504 \mathrm{~kg})$ at Station 205 (Strata tow 23-4).

Table A3. Estimates of beginning year stock size (thousands of fish), instantaneous fishing mortality ( F ), mean biomass ( mt ), spawning stock biomass ( mt ), and percent mature of Georges Bank cod, estimated from virtual population analysis (VPA), calibrated using the commercial catch at age ADAPT
formulation $1978-1999$

## B. Georges Bank Haddock by R.W. Brown

### 1.0 Background

The Georges Bank haddock stock was last assessed by the United States in 1999 and reviewed by the Northern Demersal Committee of the Northeast Fisheries Science Center's Stock Assessment Workshop (NDWG 2000). The current stock assessment was reviewed at the $3^{\text {rd }}$ Transboundary Resource Assessment Committee in April 2000 (TRAC 2000. Brown 2000). In addition, a Canadian assessment through 1999 was completed in the April 2000 for the 5Zj\&m portion of the stock. The 1999 U.S. assessment estimated fully recruited fishing mortality (ages $4-7$ ) in 1999 to be 0.15 ( $13 \%$ exploitation rate), which was above the fishing mortality rate ( $\mathrm{F}_{\text {target }}$ $=0.00$ ) specified by the Sustainable Fisheries Act (SFA) harvest control rule (Brown 2000). Fishing mortality was estimated to have remained between 0.1 and 0.2 between 1995 and 1998. Spawning stock biomass (SSB) was estimated to have increased from 10,900 mt in 1993 to $38,100 \mathrm{mt}$ in 1998. The age structure of the population was continuing to expand and the age $4+$ biomass was estimated to be at its highest level since the early 1980s. Preliminary estimates of the 1998 year class indicated an estimated year class size of 61.9 million fish at age 1 , the largest year class since 1978. However, there was considerable uncertainty about the size of this year class due to highly variable catches in research vessel surveys available at the time of this assessment.

### 2.0 2000 Assessment

## 1999 Fishery

U.S. trip limit regulations for haddock continued to be liberalized, and 1999 regulations were significantly in more liberal in comparison to the 1998 calendar year. The trip limit from January 1 to April 30, 1999 was 3,000 pounds/day up to a maximum of 30,000 pounds/trip, 2,000 pounds/day up to a maximum of 20,000 pounds/trip from May 1 to November 4, 1999, and 5,000 pounds/trip up to a maximum of 50,000 pounds/trip from November 5 to December 31, 1999. As a result of both increased haddock abundance and liberalization of trip limit regulations, U.S. commercial landings of Georges Bank haddock in 1999 were 2,775 mt, a $51 \%$ increase from 1998 and an $887 \%$ increase over 1996 landings (Table B1, Figure B1). U.S. landings included 2,420 mt of landings from western Georges Bank (statistical areas 521, 522, 525,526 ) and 355 mt of landings from eastern Georges Bank (statistical areas $561 \& 562$ ). U.S. catch continues to be displaced inshore as a result of Days at Sea regulations and area closures.
U.S. landings at age on western Georges Bank and south were estimated separately by market category using U.S. port sampling data. Sampling was sufficient to characterize western Georges Bank landings, but poor temporal distribution of samples made it necessary to use different temporal pooling for each of the two market categories. For the large haddock, samples were applied separately for quarters 1 and 2 and pooled for quarters 3 and 4. For scrod haddock, samples were pooled for quarters 1 and 2 , and estimated separately for quarters 3 and 4 .
U.S. port samples were insufficient to characterize U.S. landings from eastern Georges Bank, but landings from this area comprise a relatively small portion of the U.S. and total landings in the assessment. Of the 2,775 mt of U.S. haddock landings from Georges Bank, 355 mt ( $12.8 \%$ of U.S. landings and $5.5 \%$ of total landings) occurred in eastern Georges Bank. U.S. landings from eastern Georges Bank were partitioned using U.S. length samples by market category from western Georges Bank and Canadian survey ages (quarter 1) and Canadian commercial ages (quarters $2,3 \& 4$ ). Length samples and landings were pooled identically to the analysis for western Georges Bank.

Discard estimates have been added to the catch at age during the assessment when resource conditions and management actions have resulted in the generation of levels of regulatory discard significantly higher than chronic background levels. In 1974, 1977, 1978, and 1980, discarding increased sharply as three large year classes $(1972,1975,1978)$ recruited to the fishery (Overholtz et al. 1983). The catch at age in each of these years was augmented by estimates of associated discard. More recently, the catch at age was also augmented with estimates of discards from 1994 to 1998 to account for discard mortality generated in response to trip limit regulations in the U.S. fishery. Low discard rates reported in the Sea Sample and Vessel Trip Report databases are consistent with liberalized haddock trip limits that were in effect during 1999. These discarding rates are less than the rates reported in the U.S. fishery during the 1994 to 1998 period, and appear to be representative of background discarding rates reported in the Sea Sampling database from 1989 to 1993. Based on these observations and the dearth of information available to characterize the size and age distribution of U.S. discards, estimates of U.S. discards were not included in the 1999 catch at age.

Canadian catch from the Georges Bank haddock stock consisted of 3,680 mt of landings (Table B1), approximately $94 \%$ of the allocated 1999 quota of $3,900 \mathrm{mt}$ and $57 \%$ of the total haddock landings from the Georges Bank stock. Comparison of observer samples with port samples did not reveal any persistent patterns which would indicate that discarding or high grading was occurring. The size and age composition of the 1999 Canadian fishery was characterized by port and at sea samples from all principal gears and all seasons.

The combined catch at age was dominated by age 3 (1996 year class) haddock, although there were significant contributions by ages 4-6 (1995, 1994, and 1993 year classes). Although 25\% of landings by weight from the stock were accounted for by the 1996 year class, age 5 and older fish still comprised $58 \%$ of total landings by weight.

## Fishery Independent Information

Abundance (stratified mean number/tow) and biomass (stratified mean weight/tow) survey indices in the U.S. Spring survey in 1999 and 2000 remained above levels observed from 19861995 (Table B2; Figure B2). The 1999 U.S. Spring survey catch of age 1 haddock (1998 year class) was the highest level observed since 1979 (1978 year class), but the index in the 2000 U.S. Spring survey for this year class was reduced substantially. The abundance and biomass survey indices in the U.S. Autumn survey in 1999 were the highest observed since 1979 (Table B2;

Figure B2). The 1998 U.S. Autumn survey catch of age 0 haddock (1998 year class) was the highest level observed since 1985 (1985 year class), but the index for this year class at age 1 declined sharply in the 1999 survey. Aggregate abundance survey indices in the Canadian Spring survey in 2000 were the highest levels observed since the initiation of the survey in 1986, and three-fold higher than the 1999 index (Figure B2). The majority of this abundance was comprised of large catches of age 1 and 2 haddock (1999 and 1998 year classes, respectively). Each of these indices was 3 fold higher than the next index at age in the Canadian survey time series. A single large tow in the 2000 Canadian survey had a significant effect on the aggregate index value.

## Input Data and Analysis

The present assessment represents a one-year update to the previous U.S. assessment (NDWG 2000). The VPA formulation used for the current assessment was identical to the one used in the 1999 U.S. assessment, except for the addition of the terminal year of catch at age (1999) and research survey data (U.S. Spring 1999, U.S. Autumn 1999, Canadian Spring 2000). Very minor revisions were made to 1997 catch at age to incorporate revisions to the estimate of 1997 Canadian catch at age.

Precision of the 2000 stock sizes and 1999 fishing mortality and SSB estimates was derived from 1000 bootstrap simulations of the 1999 VPA formulation. A retrospective analysis of terminal year estimates of stock size, fully recruited fishing mortality and SSB was carried out to 1995.

### 3.0 Assessment Results

The current assessment continues to consistently estimate the strength of incoming year classes, indicating that the 1992 ( 15.3 million at age 1), 1993 ( 12.4 million), and 1996 ( 19.5 million) were stronger than other year classes since 1988 (Table B3; Figure B3). Based on the consistent strength of age $0+$ and 1 survey indices, the 1998 and 1999 year classes are estimated to be 48.8 and 35.2 million fish at age 1, respectively. If these estimates are reliable, the 1998 and 1999 year classes would be the third and fourth largest year class since 1964, although smaller than the 1975 (103.3 million at age 1) and 1978 ( 84.0 million) year classes (Table B3). There is considerable uncertainty about the relative size of these two year classes due to highly variable results from research vessel surveys conducted to date. The size of these year classes will remain uncertain until additional fishery dependent and independent information is collected and analyzed. The age distribution of the stock continues to show evidence of broadening.

SSB has continued to increase steadily since 1994 and was estimated to be $48,500 \mathrm{mt}$. Although SSB is threefold higher than was estimated in 1993, it remains less than $50 \%$ of the $\mathrm{B}_{\text {MSY }}$ level of $105,000 \mathrm{mt}$ established by harvest control rules. Fully recruited fishing mortality (ages 4-7) in 1999 is estimated to be 0.16 , a slight increase from the fishing mortality estimated for 1998 (Table B3; Figure B4).

## VPA Diagnostics

The sums of squares and mean squared residuals from the VPA were within the range of accepted VPAs from the last four U.S. assessments of Georges Bank haddock. The coefficients of variation on estimated age 1-8 stock sizes (range 0.25-0.61) were slightly nearly identical to those observed in recent U.S. assessments. Other VPA diagnostics including the range of CV's on survey $q$ estimates, the number of large standardized residuals and the maximum partial variance estimates are consistent with previous U.S. haddock assessments. There were no outstanding residual patterns detected during an analysis of standardized residuals. Residual patterns for the 1998 and 1999 year classes exhibit a general trend reflecting consistently higher Canadian survey indices which are contrasted by consistently lower U.S. Autumn survey indices.

Accounting for precision in the current assessment, there is a $80 \%$ probability that fully recruited F in 1999 was between 0.14 and 0.18 , and that SSB in 1999 was between 43,800 and $54,500 \mathrm{mt}$. There was a $14.9 \%$ change that SSB in 1999 exceeded the limit threshold ( $53,000 \mathrm{mt}$ ) and a zero percent chance that SSB in 1999 had exceeded the target biomass threshold $(68,000 \mathrm{mt})$.

Retrospective patterns for fishing mortality were similar to those observed in the 1999 assessment of this stock, indicating that terminal year estimates of fishing mortality and SSB are relatively well estimated in the terminal year of the assessment. The alternating pattern of slightly overestimated and slightly underestimated terminal year estimates indicates that there is not a retrospective pattern in the terminal year estimates of these parameters.

Terminal year estimates of age 1 recruitment were more variable with a significant tendency to overestimate age 1 recruitment in some years (1995 year class in 1996, 1998 year class in 1999). The retrospective analysis of age 1 stock sizes reinforces the need for additional survey information on incoming recruitment before firm estimates of year class strength can be made.

## Harvest Control Rule

The SFA harvest control rule for Georges Bank haddock is based on MSY-based reference point proxies (Figure B5). When SSB is greater than $105,000 \mathrm{mt}$, the overfishing limit is $\mathrm{F}_{0.1}$ (currently estimated to be 0.26 ), and the target F is $75 \%$ of the $\mathrm{F}_{\text {MSY }}$ proxy ( 0.20 ). The limit F decreases linearly from 0.26 at $105,000 \mathrm{mt}$ of SSB to zero at $53,000 \mathrm{mt} \mathrm{SSB}$, and the target F decreases linearly from 0.20 at $105,000 \mathrm{mt}$ of SSB to zero at $68,000 \mathrm{mt}$ of SSB.

### 4.0 Consistency of 1999 Projection Forecast with 2000 Assessment Results

Projections conducted during the 1999 assessment (NDWG 2000) were based on the 1999 assessment results, assumed that $\mathrm{F}_{1999}=\mathrm{F}_{1998}=0.15$, and estimated that SSB would rise to 44,700 mt in 1999. The 2000 assessment estimated $\mathrm{F}_{1999}=0.16$ and SSB at 48,500 mt (Table B3). The fishing mortality assumption made during the 1999 assessment was reasonable ( 0.15 vs. realized F of 0.16) and the resulting SSB projection for $1999(48,500 \mathrm{mt})$ is within the $80 \%$ confidence
interval (40,000-49,800 mt) of the 1999 assessment projection. The 2000 assessment resulted in improved SSB estimates for 1997-1999, based on relatively stronger contributions from the 1994 and 1996 year classes.

### 5.0 Sources of Uncertainty

a) Sampling of U.S. landings and discards was insufficient to accurately characterize the size and age distribution of the catch. There is a critical need for increased biological sampling for Georges Bank haddock.
b) There is considerable uncertainty regarding the size of the 1998 and 1999 year classes. Survey indices for these year classes are highly variable and there is conflicting information about the relative size of these year classes from U.S. and Canadian surveys.

### 6.0 Conclusions

The Georges Bank haddock stock remains in an overexploited condition based on the current low level of biomass in relation to management rebuilding thresholds and pre-collapse stock levels. The assessment indicates that fishing mortality has been reduced from pre-1994 levels, and $\mathrm{F}_{1999}(0.16$ or $13 \%$ exploitation) indicates that fishing mortality has remained stable and at relatively low levels since 1994. The age structure of the population is continuing to expand and the age $4+$ biomass is at its highest levels since 1982. Recruitment continues to improve and the 1998 and 1999 year classes are currently estimated to be the largest observed since 1978. There is considerable uncertainty about the absolute size of these year classes due to the influence of large tows that have a significant influence on available survey indices. Spawning stock biomass (SSB) in 1998 was estimated to be 48,500 mt, a 3-fold increase over levels estimated in 1993 but less than $50 \%$ of the $\mathrm{B}_{\mathrm{MSY}}$ of $105,000 \mathrm{mt}$ established by U.S. harvest control rules.

Observed increases in SSB of Georges Bank haddock have resulted from conservation of a series of relatively weak year classes. This was a necessary first step in the stock rebuilding process. Spawning stock has been rebuilt and age structure has been restored to the point where recruitment appears to be improving significantly. If incoming recruitment from the 1998 and 1999 year classes is conserved, growth and maturation of these year classes will result in significant increases in SSB. Based on historical stock recruitment relationships for this stock, as SSB increases, the probability of additional strong recruitment events will be significantly enhanced. Maintenance of low fishing mortality rates to promote continuous rebuilding of SSB is essential to achieving biomass rebuilding targets for this stock. Given the potential growth trajectories for this stock, maintenance of current low fishing mortality rates should still allow for significant increases in available landings to both the U.S. and Canadian fisheries over the next several years.

## C. Georges Bank Yellowtail Flounder by S.X. Cadrin

### 1.0 Background

In 1998, the stock was at $75 \%$ of $\mathrm{B}_{\text {MSY }}$ with low F (fully recruited F was 0.21 , Neilson et al. 1999). This report summarizes the 2000 Transboundary Resources Assessment Committee stock assessment (Cadrin et al, 2000; NEFSC 2000), which updated catch and survey indices, and estimated 1999 fishing mortality and 2000 stock size.

### 2.02000 Assessment

### 2.1 1999 Landings

U.S. landings were prorated as described in Cadrin et al. (1998; Table C1; Figure C1). Landings from Georges Bank yellowtail (including Canadian landings) increased 31\% from 1998.

Sampling intensity of landings in 1999 was poor. There were samples of Georges Bank yellowtail flounder for the U.S. fishery in the third quarter of 1999, and no age samples were available from the Canadian fishery. Landings at length were estimated by half year and market category. Canadian landings at age were estimated from Canadian port sample lengths and NEFSC fall survey ages (Table C2a); U.S. landings at age and mean weights at age are reported in Table C2b.

### 2.2 1999 Discards

Discarded catch was estimated from logbook information on discard to kept ratios by half-year and gear (Cadrin et al. 1998), except for discards from the scallop exemption program, which was estimated from relatively intensive observer sampling. Discard ratios from the trawl fishery were $4 \%$ and $6 \%$ for the first and second half, respectively. Total discarded catch from the trawl fishery was estimated to be 89 mt . Total discarded yellowtail catch from the scallop dredge fishery was 395 mt , which was predominantly from the exemption program. Discards at age were estimated from sea sampled lengths and pooled commercial-survey age-length keys. Discards at age and recent mean weights at age are reported in Table C3.

### 2.3 1999-2000 Survey Indices

Survey abundance and biomass indices are reported in Table C4. Estimates are from valid tows on Georges Bank (offshore strata 13-21; scallop strata 54, 55, 58-72, 74), standardized according to net, vessel, and door changes (Cadrin et al. 1998). All survey indices of total abundance and total biomass increased for Georges Bank yellowtail in 1999 and 2000 (Figure C2).

### 3.0 Assessment Results

### 3.1 Age-Based Analysis

An updated VPA calibration for Georges Bank yellowtail is summarized in Table C5. Results indicate that F remained low ( $\mathrm{F}_{4-5}=0.13 ; \mathrm{F}$ on biomass $=0.09$ ), and biomass continued to rebuild in 1999 ( $33,500 \mathrm{mt}$ of spawning biomass and 49,600 mt of mean total biomass; Figures C3 and C4). Retrospective analysis indicates a strong tendency for terminal year estimates of F to be less than converged estimates, and terminal year estimates of biomass to be greater than converged estimates (Figure C5). Bootstrap analysis indicates that abundance was estimated with moderate to high precision ( $\mathrm{CV}=14-34 \%$ ), there is an $80 \%$ probability that fully-recruited F in 1999 was $0.11-0.15$, SSB in 1999 was $27,700-38,800 \mathrm{mt}$, and mean biomass in 1999 was $41,000-59,000 \mathrm{mt}$. However, bootstrap estimates of uncertainty do not account for retrospective error.

The value of F assumed for 1999 by the previous assessment $\left(\mathrm{F}_{4-5}=0.20\right.$; Cadrin 2000) was substantially greater than that estimated by this updated analysis ( $\mathrm{F}_{4-5}=0.13$ ). As a result, the projected SSB in $1999(28,000 \mathrm{mt})$ and mean biomass in $1999(43,400 \mathrm{mt})$ were substantially less than indicated by this analysis ( $\mathrm{SSB}=33,500 \mathrm{mt}$ and mean biomass $=49,600 \mathrm{mt}$ ).

### 3.2 Biomass-Based Analysis

Due to continued poor sampling and resulting problems estimating catch at age, surplus production analysis (ASPIC) was updated to provide alternative perspectives on stock status. Results for the Georges Bank stock are similar to those from VPA; biomass increased to $99 \%$ of $\mathrm{B}_{\text {MSY }}$ in 1999 at low F (Figure C4). Estimates of MSY (16,600 mt) and $\mathrm{B}_{\text {MSY }}(54,000 \mathrm{mt}$ ) are greater than previous estimates (Cadrin 2000), but the estimate of $\mathrm{F}_{\text {MSY }}$ ( 0.31 on biomass) was similar.

### 4.0 Harvest Control Rule

The SFA control rule specifies a biomass threshold of $25 \% \mathrm{~B}_{\mathrm{MSY}}$, a maximum F threshold of $\mathrm{F}_{\text {MSY }}$, and F on biomass $(1+, \mathrm{wb})$ as the metric for fishing mortality. When biomass is less than $\mathrm{B}_{\mathrm{MSY}}$, threshold F is the maximum F that allows rebuilding to $\mathrm{B}_{\text {MSY }}$ in 5 years at the estimated intrinsic rate of increase. When biomass is below $1 / 4 \mathrm{Bmsy}$, threshold $\mathrm{F}=0$. When biomass exceeds $\mathrm{B}_{\text {MSY }}$, target F is the tenth percentile of the $\mathrm{F}_{\text {MSY }}$ estimate. When biomass is less than $\mathrm{B}_{\mathrm{MSY}}$, target F is based on rebuilding to $\mathrm{B}_{\mathrm{MSY}}$ at the tenth percentile of the intrinsic rate of increase estimate (Figure C4). Current biomass is approaching $\mathrm{B}_{\mathrm{MSY}}$ and current F is well below the control rule target (Figure C4).

### 5.0 Sources of Uncertainty

- Estimates of catch at age may not be reliable due to poor sampling intensity. Therefore VPA estimates may be misleading. Retrospective patterns may indicate inadequate sampling and mis-allocation of catch at age.
- Retrospective patterns indicate that VPA estimates of biomass and F may be overly optimistic. Updated VPAs may indicate that 1999 biomass levels are lower, and 1999 F was greater than reported here.
- Although a historical perspective from production models is valuable, current biomass levels may not be reliable, because recruitment is implicitly assumed to be a function of stock biomass. Statistical problems were also encountered in finding a stable solution for the production model.
- Estimates of prorated landings and discard ratios are based on preliminary logbook data and are subject to change.

### 6.0 Acknowledgments

This assessment was completed cooperatively with John Neilson, Stratis Gavaris and Peter Perley, Canada Dept. Fisheries and Oceans, St. Andrews, New Brunswick. Technical review was provided by the Transboundary Assessment Working Group and the Transboundary Resources Assessment Committee.

## D. Southern New England Yellowtail Flounder by S.X. Cadrin

### 1.0 Background

The southern New England yellowtail stock was at low biomass (less than $25 \% \mathrm{~B}_{\text {MSY }}$ ) at relatively low F (fully recruited F was 0.2 ) in 1998 (Cadrin 2000). This report updates catch and survey indices and estimates 1999 fishing mortality and 2000 stock size.

### 2.02000 Assessment

### 2.1 1999 Landings

U.S. landings were prorated as described in NEFSC (1998; Table D1; Figure D1). Landings from southern New England increased 89\% from 1998 to 1999.

Sampling intensity of landings in 1999 was poor (Table D2). The 1999 southern New England yellowtail fishery was not sampled from April to December, 1999, which accounts for $53 \%$ of the annual landings. Landings at length and age were estimated for the entire year by market category for an exploratory VPA.

### 2.21998 Discards

Estimates of total discards were attempted from logbook information on discard to kept ratios by half-year and gear (NEFSC 1998; Table D3). Discards at age were estimated from sea sampled lengths and pooled commercial-survey age-length keys for the exploratory VPA. However 1998 samples were used to characterize trawl discards, because no observations of 1999 trawl discards were available. Alternatively, discards were estimating by projecting the 1999 VPA abundance with observed landings and recent average discard ratios (methods described in Cadrin 2000).

### 2.3 1998-1999 Survey Indices

Survey abundance and biomass indices are reported in Table D4. Estimates are from valid tows in southern New England (offshore strata 5, 6, 9, 10; scallop strata 33-48), standardized according to net, vessel, and door changes (NEFSC 1998). All survey indices of total abundance and total biomass decreased in 2000 (Figure D2).

### 3.0 Assessment Results

### 3.1 Age-Based Analysis

An updated VPA calibration of southern New England yellowtail was attempted, but was rejected because of inadequate sampling of catch at age in 1999 (e.g., there were no samples after the first quarter). Estimating catch at age directly using only first quarter samples
underestimates weight at age and overestimates numbers at age. Retrospective analysis of the exploratory VPA indicated a strong tendency for terminal year estimates of F to be less than converged estimates, and terminal year estimates of biomass to be greater than converged estimates.

Alternatively, projections from the 1999 VPA (methods described in NEFSC 2000) were revised with the estimate of 1999 landings. Results from the revised projection indicate that F increased in $1999\left(80 \%\right.$ confidence of $\mathrm{F}_{3-6}=0.23-0.39 ; \mathrm{F}$ on biomass $\left.=0.09-0.18\right)$, and there was approximately $75 \%$ probability of being greater than $\mathrm{F}_{0.1}(0.27)$ (Table D5, Figure D3). The value of F assumed for 1999 by the previous assessment $\left(\mathrm{F}_{3-6}=0.20\right.$; Cadrin 2000) was less than that estimated by this revised projection. The projected estimate of SSB increased (4,100-7,000 mt with $80 \%$ confidence), but there was negligible chance of being greater then the Amendment $\# 7$ rebuilding target of $10,000 \mathrm{mt}$. The projected estimate of mean biomass increased $(4,700-$ $9,600 \mathrm{mt}$ with $80 \%$ confidence). These bootstrap confidence intervals do not include the substantial retrospective error in VPA estimates (Cadrin 2000).

### 3.2 Biomass-Based Analysis

Due to continued poor sampling and resulting problems estimating catch at age, surplus production analysis (ASPIC) was updated to provide alternative perspectives on stock status. The estimate of $\mathrm{F}_{\text {MSY }}(0.20)$ was similar to the 1998 SARC estimate ( 0.23 ), but the estimate of $\mathrm{B}_{\text {MSY }}(92,400 \mathrm{mt})$ was substantially greater than the 1998 SARC estimate $(61,500 \mathrm{mt}$; NEFSC 1998). Estimates of biomass and F are generally similar to the VPA, but 1999 F ( F on biomass $=$ $0.04-0.12$ with $80 \%$ confidence) is less than indicated by the VPA projection, and the estimate of 1999 biomass (5,100-19,400 mt with $80 \%$ confidence) is substantially greater than the VPA estimate (Figure D4).

### 4.0 Harvest Control Rule

The SFA control rule specifies a biomass threshold of $25 \% \mathrm{~B}_{\mathrm{MSY}}$, a maximum F threshold of $\mathrm{F}_{\mathrm{MSY}}$, and F on biomass $(1+, \mathrm{wb})$ as the metric for fishing mortality. When biomass is less than $\mathrm{B}_{\text {MSY }}$, threshold F is the maximum F that allows rebuilding to $\mathrm{B}_{\text {MSY }}$ in 5 years. When biomass is below $1 / 4 \mathrm{Bmsy}$, threshold $\mathrm{F}=0$. When biomass exceeds $\mathrm{B}_{\mathrm{MSY}}$, target F is the tenth percentile of the $\mathrm{F}_{\text {MSY }}$ estimate. When biomass is less than $\mathrm{B}_{\text {MSY }}$, target F is based on rebuilding to $\mathrm{B}_{\text {MSY }}$ at the tenth percentile of the intrinsic rate of increase estimate (Figure D4). Stochastic projections from the VPA indicate that there was less than 5\% chance that mean biomass in 1999 was greater than the Amendment \#9 biomass threshold ( $1 / 4 \mathrm{~B}_{\text {MSY }}=15,800 \mathrm{mt}$, NEFSC 1998). The production model indicates less than $25 \%$ chance that 1999 biomass was greater than the Amendment \#9 biomass threshold.

### 5.0 Sources of Uncertainty

- Estimates of catch at age are not reliable due to poor sampling intensity. Therefore VPA will not be possible until sampling improves.
- Although historical perspective from production models are valuable, current biomass levels may not be reliable, because recruitment is implicitly assumed to be a function of stock biomass.
- Inappropriate stock delineation may result in underestimated removals (e.g., from adjacent areas in the mid-Atlantic Bight).
- Estimates of prorated landings and discard ratios are based on preliminary logbook data and are subject to change.

## E. Cape Cod Yellowtail Flounder by S.X. Cadrin and J. King

### 1.0 Background

The Cape Cod yellowtail flounder stock was at low biomass ( $50 \%$ of $\mathrm{B}_{\mathrm{MSY}}$ ) and was overexploited (fully recruited F was 0.41 ) in 1998 (Cadrin 2000). This report updates catch and survey indices and estimates 1999 fishing mortality and 2000 stock size.

### 2.02000 Assessment

### 2.1 1999 Landings

U.S. landings were prorated as described in Cadrin et al. (1999; Table E1; Figure E1). Landings from the Cape Cod stock decreased by 7\% from 1998 to 1999.

Sampling intensity of landings in 1999 was poor. Only eight trips from the 1999 Cape Cod yellowtail fishery were sampled, and no samples were taken during the third quarter, when $16 \%$ of annual landings were taken. Landings at length were estimated by half year and market category. Landings at age and mean weights at age are reported in Table E2.

### 2.21999 Discards

Discarded catch was estimated from logbook information on discard to kept ratios by half-year and gear. However, discards of Cape Cod yellowtail are substantially less than those estimated in recent years, presumably because previous estimates were based on observer data by fishery (Cadrin et al. 1999). Therefore, the level of discards for Cape Cod yellowtail may be underestimated and should be considered preliminary. Discards at age were estimated from sea sampled lengths and pooled commercial-survey age-length keys. Discards at age and recent mean weights at age are reported in Table E3.

### 2.3 1999-2000 Survey Indices

Survey abundance and biomass indices are reported in Table E4. Estimates are from valid tows on the Cape Cod grounds (offshore strata 25, 26; inshore strata 56-66; Massachusetts strata 1736) standardized according to net, vessel, and door changes (NEFSC 1998). Recent survey indices of Cape Cod yellowtail greatly increased (Figure E2).

### 3.0 Assessment Results

### 3.1 Age-Based Analysis

An updated VPA calibration of Cape Cod yellowtail is summarized in Table E5. This analysis updates the assessment reported in Cadrin (2000) by including 1999 landings and provisional
discards, 1999 fall indices, and 2000 NEFSC spring indices. Results indicate that $F$ decreased $\left(\mathrm{F}_{4-5}=0.59, \mathrm{~F}\right.$ on biomass $\left.=0.31\right)$ and biomass increased in $1999(1,900 \mathrm{mt}$ of spawning biomass and $3,900 \mathrm{mt}$ of mean total biomass; Figures 3 and 4). Retrospective analysis indicated a strong tendency for terminal year estimates of F to be less than converged estimates since 1996, and terminal year estimates of biomass to be greater than converged estimates since 1994. Bootstrap analysis indicates that abundance was estimated with moderate precision ( $\mathrm{CV}=29-41 \%$ ), $\mathrm{F}_{4-5}$ was $0.43-0.90$ with $80 \%$ confidence, SSB was $1,500-2,400 \mathrm{mt}$. Mean biomass had an $80 \%$ confidence interval of $3,100-4,700$.

The value of F assumed for 1999 by the previous assessment ( $\mathrm{F}_{4-5}=0.41$; Cadrin 2000) was substantially less than that estimated by this updated analysis $\left(\mathrm{F}_{4-5}=0.59\right)$. The projected SSB in $1999(1,900 \mathrm{mt})$ is similar to the estimate from this updated analysis, but the projected mean biomass in $1999(3,600 \mathrm{mt})$ is less than indicated by this analysis $(3,900 \mathrm{mt})$.

### 4.0 Harvest Control Rule

The SFA control rule specifies a biomass threshold of $50 \% \mathrm{~B}_{\mathrm{MSY}}$, a maximum F threshold of $\mathrm{F}_{\mathrm{MSY}}$, and F on biomass $(1+, \mathrm{wb})$ as the metric for fishing mortality. When biomass is less than $\mathrm{B}_{\mathrm{MSY}}$, threshold F is the maximum F that allows rebuilding to $\mathrm{B}_{\mathrm{MSY}}$ in 5 years. When biomass is below $1 / 4 \mathrm{Bmsy}$, threshold $\mathrm{F}=0$. When biomass exceeds $\mathrm{B}_{\mathrm{MSY}}$, target F is the tenth percentile of the $\mathrm{F}_{\text {MSY }}$ estimate. When biomass is less than $\mathrm{B}_{\text {MSY }}$, target F is based on rebuilding to $\mathrm{B}_{\text {MSY }}$ at the tenth percentile of the intrinsic rate of increase estimate (Figure E4). The estimate of mean biomass in 1999 was greater than the biomass threshold ( $1 / 2 \mathrm{~B}_{\mathrm{MSY}}$ proxy $=3,050 \mathrm{mt}$ ) with greater than $90 \%$ probability, but F exceeded the rebuilding threshold.

### 5.0 Sources of Uncertainty

- Estimates of catch at age may not be reliable due to poor sampling intensity. Therefore VPA results may be misleading. Extreme estimates of mean weights (e.g. ages 2-3), odd exploitation patterns, and retrospective patterns may indicate inadequate sampling and mis-allocation of catch at age.
- Retrospective patterns since the mid 1990s indicate that VPA estimates of biomass and F may be overly optimistic. Updated VPAs may indicate that 1999 biomass levels are substantially lower, and 1999 F was substantially greater than reported here.
- Estimates of prorated landings and discard ratios are based on preliminary logbook data and are subject to change.
- The magnitude of discards in 1999 are probably underestimated.

## F. Gulf of Maine Cod by R.K. Mayo

### 1.0 Background

The Gulf of Maine cod stock was last assessed in 1999 (Mayo MS 1999; Northern Demersal Working Group 2000) and the 1998 assessment was reviewed by the SARC at SAW 27 (Mayo et. al 1998; NEFSC 1998). In the 1999 assessment, fully recruited fishing mortality (ages $4+$ ) in 1998 was estimated to be 0.64 , and the 1997 F , which had been estimated at 0.75 in 1998 was estimated to be 0.85 . Spawning stock biomass was estimated to have declined to $8,300 \mathrm{mt}$ in 1998, a decline from a recent high of $14,200 \mathrm{mt}$ in 1995 and a series high of 26,200 mt in 1989.

The strength of the most recent recruiting year classes was estimated to be very low. The 1994, 1995 and 1996 year classes continue to be estimated as the lowest in the VPA series dating back to 1982 (1980 year class). The recruit/SSB survival ratios for these most recent year classes were also estimated to be very low compared to previous year classes.

NEFSC spring and autumn research vessel bottom trawl survey indices for Gulf of Maine cod had declined to record low levels in the mid-1990s; indices from both surveys continue to fluctuate at relatively low levels. Recruitment indices for the 1994-1996 year classes derived from the NEFSC and Commonwealth of Massachusetts surveys were also among the lowest in the respective series, but the Mass. DMF survey indicated that the 1998 year class may be larger than the recent average.

### 2.0 The Fishery

Commercial landings of Gulf of Maine cod declined to 1,636 metric tons (mt) in 1999, a $61 \%$ decline from 1998 (Table F1; Figure F1). Discard estimates have been derived on a gearquarterly basis from 1989 through 1999; these results indicate a substantial increase in the overall discard /kept ratio in 1999 compared to previous years. The estimated recreational catch of Gulf of Maine cod (retained component only) remained the same in 1999 as in 1998 at approximately 822-824 mt.

The number of commercial port samples for this stock declined from 74 in 1997 to 46 in 1998 to 16 in 1999. Sampling was not well distributed among quarters and market categories in recent years, as only 1 biological sample was taken in the $3^{\text {rd }}$ and $4^{\text {th }}$ quarter of 1999 , requiring substantial pooling over quarter. In 1999 samples from each market category were pooled on an annual basis. As has generally been the case, the landings at age in 1999 were dominated by age 3 and 4 cod.

The seasonal distribution of landings changed somewhat in 1999 compared to previous years. This may have been related to the imposition of very restrictive trip limits beginning in the latter part of the $3^{\text {rd }}$ quarter of 1999. As a result, biological samples weighted toward the first half of the year may still be representative of the overall length and age composition of the landings,
although it is likely that annual numbers landed may have been overestimated. The following table illustrates the shift in the seasonal distribution of commercial landings between 1998 and 1999, and the corresponding trip limit regulations imposed during 1999.

| Quarter | $\begin{gathered} \text { Landings \% } \\ 1998 \end{gathered}$ | $\begin{gathered} \text { Landings \% } \\ 1999 \end{gathered}$ | 1999 Trip Limit Restrictions |
| :---: | :---: | :---: | :---: |
| 1 | 26 | 34 | 400 lbs Jan-Mar |
| 2 | 42 | 42 | 400 lbs Apr; 200 lbs May, Jun (part); 30 lbs Jun (part) |
| 3 | 14 | 10 | 30 lbs Jul; 30 lbs Aug(part); 100 lbs Aug (part)-Sep |
| 4 | 18 | 14 | 100 lbs Oct-Dec |

### 3.0 Research Vessel Surveys

NEFSC research vessel bottom trawl survey abundance and biomass indices for Gulf of Maine cod remained relatively low through autumn 1999 and spring 2000 (Table F2; Figure F2). The autumn 1999 indices increased slightly from 1998, while the spring 2000 indices decreased slightly from the 1999, and remain no higher than indices observed in 1996 and 1997.

Recruitment indices for the 1994-1997 year classes derived from the NEFSC and Mass. DMF bottom trawl surveys are among the lowest in the respective series, although indices for the 1998 and 1999 year classes appears to be above the recent average (Figures F3a-b).

Autumn biomass indices were also partitioned into inshore (strata 26 and 27; area 1,734 square miles) and offshore (strata 28-30, $36-40 ; 16,158$ square miles) Gulf of Maine regions. When expressed in this manner, stratified mean weight per tow indices may be seen to represent comparative biomass density rather than as indices of absolute biomass (Figure F4a). However, when appropriate weighting by area is applied to the respective inshore and offshore indices to allow comparison of absolute biomass between regions, the weighted indices provide a perspective on trends in absolute biomass (Figure F4 b). These results suggest that biomass has declined more precipitously in the offshore regions of the Gulf of Maine, while biomass in the inner region has declined at a lesser rate.

### 4.0 Assessment

## Input Data and Analyses

The present assessment represents a one-year update to the previous assessment (Mayo MS 1999; NEFSC 2000). The same VPA formulation used in the previous assessment was employed in the present update, including the addition of current year (2000) spring survey data. Catch at age data for 1999, and NEFSC and Mass. DMF survey abundance indices (stratified mean number per tow at age) were updated through spring 2000. As in the most recent VPAs, commercial CPUE indices were included only through 1993.

Given the uncertainty in the amount of catch to include in the 1999 catch at age (due to uncertainty in the magnitude of 1999 discards), no precision estimates of the 2000 stock sizes and 1999 fishing mortality and SSB estimates were derived. No retrospective analysis of terminal year estimates of stock sizes, fully recruited fishing mortality and SSB were carried out. However, the sensitivity of the VPA to terminal year catch assumptions was examined by performing the VPA under several discarding scenarios in 1999. The 1999 catch at age was adjusted upward by the ratio of landings plus discard to landings under various assumptions of discards ranging from 500 mt to $2,500 \mathrm{mt}$. Preliminary estimates of 1999 discards of Gulf of Maine cod range as high as $2,630 \mathrm{mt}$ when the gear-quarter approach used in previous assessments is applied to 1999 Observer Program data

## Assessment Results

Fully recruited fishing mortality (ages $4+$ ) in 1999 is estimated to range from 0.29 (base run, assuming no discards) to 0.76 (assuming $2,500 \mathrm{mt}$ discarded), while estimates of 1999 spawning stock biomass varied only slightly, ranging from $8,700 \mathrm{mt}$ to $9,400 \mathrm{mt}$ in 1999 (Table F12). Biomass-weighted fishing mortality (ages $1+$ ) in 1999 is estimated to range from 0.10 (base run, assuming no discards) to 0.24 (assuming $2,500 \mathrm{mt}$ discarded), while estimates of 1999 mean stock biomass (ages 1+) varied only slightly, ranging from 17,000 mt to $17,100 \mathrm{mt}$ in 1999 (Table F12). However, almost one-half of the increase in age 1+ mean biomass between 1998 and 1999 can be attributed to the recruitment estimate for the 1998 year class at age 1 in 1999. Age 1 fish are not part of the exploitable biomass of Gulf of Maine cod; therefore the increase in age $1+$ mean biomass overstates the apparent increase in the exploitable portion of the stock.

Regardless of the discard assumption employed in the analyses, recent recruiting year classes are estimated to be poor (Table F12). The 1993, 1994, 1995 and 1996 year classes are still estimated to be the lowest in the VPA series dating back to 1982.

## VPA Diagnostics

No bootstrap runs or retrospective analyses were performed.

### 5.0 Forecasts

No forecasts of stock size and landings were performed.

### 6.0 Harvest Control Rule

According to the SFA control rule for Gulf of Maine cod, when the mean stock biomass is between $1 / 4$ and $1 / 2 \operatorname{Bmsy}$ ( $8,250-16,500 \mathrm{mt}$ ), a 5 -year rebuilding period may be appropriate. The control rule and stock rebuilding harvest plan are based on the relation between mean biomass and biomass-weighted fishing mortality for ages $1+$. Given that only ages 2 and older
are represented in the catch throughout the VPA series, a more appropriate control rule should be based on mean biomass and biomass-weighted F for ages $2+$.

### 7.0 Conclusions

Given the uncertainty in the amount of discarding in 1999, it is not possible at this point to determine current fishing mortality. However, it may be considered that the fully recruited F and the biomass-weighted F derived from the base run (assuming no discards in 1999) may be considered as minimum estimates for these measures of 1999 fishing mortality. However, the maximum values for these measures of fishing mortality in 1999 is uncertain.

### 8.0 Sources of Uncertainty

- A substantial discarding event is likely to have occurred in 1999, but the magnitude is not precisely known. Until further information on effort is available, the degree of uncertainty in the current assessment cannot be determined.
- Poor biological sampling in 1998 and very poor sampling in 1999.

Incomplete seasonal coverage and apparent incomplete sampling of larger cod may have resulted in an underestimate of the number of larger, relatively older cod in the 1998 and 1999 commercial landings. This would result in an overall lower mean weight, higher numbers landed and a greater dominance of younger fish in the estimated landings. The over-estimate of younger fish may have inflated the size of recruiting year classes in 1998 and 1997. No age 2 cod were detected in the biological samples in 1999, the first time ever.

- The proportion of unaccounted recreational catch in the 'total' catch used to model the dynamics of this stock has increased substantially in recent years.

The landed component of the recreational catch represented $34 \%$ of the total commercial plus recreational landings in 1999, compared to $10-20 \%$ prior to 1999 . This trend may affect current perceptions of fishing mortality unless all sources of fishing mortality are taken into account.

- Recent retrospective pattern inVPA.

Fully recruited F has been under-estimated since 1995. Thus, short-term projections are likely to be optimistic if fishing mortality is actually higher in 1998 and 1999 than initially estimated.

| 2000 | 3.08 | 3.2 |  |  |

[a] During 1963-1984, BMV oval doors were used in the spring and autumn surveys; since 1985, Portugeuse polyvalent doors have been used in both surveys. Adjustments have been made to the 1963-1984 catch per tow data to standardize these data to polyvalent door equivalents. Conversion coefficients of 1.56 (numbers) and 1.62 (weight) were used in this standardization (NEFSC 1991).
[b] Spring surveys during 1973-1981 were accomplished with a '41 Yankee' trawl; in all other years, spring surveys were accomplished with a ' 36 Yankee' trawl. No adjustments have been made to the catch per tow data for these differences.
[c] In the Gulf of Maine, spring surveys during 1980-1982, 1989-1991 and 1994, and autumn surveys during 1977-1978, 1980, 1989-1991 and 1993 were accomplished with the R/V DELAWARE II; in all other years, the surveys were accomplished using the R/V ALBATROSS IV. Adjustments have been made to the R/V DELAWARE II catch per tow data to standardize these to R/V ALBTATROSS IV equivalents. Conversion coefficients 0.79 (number) and 0.67 (weight) were used in this standardization (NEFSC 1991).

## G. Witch Flounder by S. E. Wigley

### 1.0 Background

Witch flounder, Glyptocephalus cynoglossus, are assessed as a unit stock from the Gulf of Maine southward. An analytical assessment was conducted on this species in 1999 (Wigley et al. 1999) and reviewed at SAW 29 (NEFSC 1999). At that time, average fishing mortality (ages 7-9, unweighted) increased from 0.21 in 1982 to 0.59 in 1985, declined to 0.24 in 1990, increased to 0.86 in 1996, then declined to 0.37 ( F on $3+$ biomass was 0.13 ) in 1998. Mean 3+ biomass declined steadily from $27,930 \mathrm{mt}$ in 1982 to $7,742 \mathrm{mt}$ in 1994, then sharply increased to 18,934 mt by 1998. Spawning stock biomass declined from 18,000 tons in 1982 to about 4,000 tons in 1993 and then increased sharply to $8,600 \mathrm{mt}$ in 1998. However, spawning stock biomass was at a low level relative to the long-term survey biomass indices. Since 1982, recruitment at age 3 has ranged from approximately 3 million fish (1984 year class) to 38 million fish (1996 year class) with a mean of 14 million fish. Recent recruitment had been above average, and the 1995 and 1996 year classes were estimated to be among the highest in the time series.

Assuming 1999 catches will equal 1998 catches, the 1999 fully recruited fishing mortality rate was estimated to be 0.20 , and the target fishing mortality (F on biomass) prescribed by the control rule for the 1999 stock size was 0.096 , which was approximately equivalent to 0.19 on fully recruited ages assuming the current age structure of the population (NEFSC 1999). The estimated mean 3+ biomass in 1999 was projected to be $26,048 \mathrm{mt}$ (above the overfishing threshold and near Bmsy) and the F on 3+ biomass was estimated to be 0.096 (slightly lower that the overfishing threshold and near F target). Based in the 1999 estimates, the stock was considered to be near target biomass and fishing mortality levels (NEFSC 1999).

### 2.0 The Fishery

Historically, significant proportions of the U.S. nominal catch have been taken both on Georges Bank and in the Gulf of Maine; but in recent years most of the U.S. catch has come from the Gulf of Maine area. Canadian landings from both areas have been minor (never more than 68 mt annually). Distant-water fleet catches averaged $2,700 \mathrm{mt}$ in 1971-1972, but subsequently declined sharply and have been negligible since 1976. Total landings peaked at more than 6,000 mt in 1971, declined to an annual average of $2,800 \mathrm{mt}$ during 1973-1981, and then increased sharply to $6,700 \mathrm{mt}$ in 1984. Landings then declined steadily to only $1,500 \mathrm{mt}$ in 1990 , the lowest value since 1964. Landings for 1991-1998 averaged 2,200 mt annually. Total landings in 1999 were $2,123 \mathrm{mt}$ (Table G1, Figure G1), $15 \%$ higher than the estimated landings used in the 1999 assessment. Based upon the 1998 percentage of discard/landings (18\%), discard weight in 1999 was estimated to be 382 mt .

### 3.0 Research Vessel Survey Indices

The NEFSC autumn bottom trawl survey biomass index declined from an average of 3.6 kg per tow in 1966-1970 to 0.9 kg per tow in 1976 following heavy exploitation by distant-water fleets. The index increased in 1977-78 but then declined to 0.2 kg per tow in 1992, the lowest level on record. Since 1993, the survey biomass index has remained at low levels, averaging 0.7 kg per tow. The 1999 biomass index was 0.9 kg per tow (Table G2, Figure G1). The maximum age of witch flounder observed in the 1999 research vessel surveys was age 10 , the lowest maximum age in the 20 year time series, indicating the age structure of the population remains truncated. The low number of older fish may adversely impact the stock's reproductive potential output.

### 4.0 Assessment Results

Results of the projection analysis indicate that the 1999 fully recruited F was 0.23 ( $0.18-0.30$ with $80 \%$ confidence) and that F on $3+$ biomass was 0.109 . The 1999 assumed fully recruited F ( 0.2 ) from the previous assessment was slightly lower, but falls within the confidence band of the current analysis. The 1999 mean $3+$ biomass was $25,509 \mathrm{mt}(19,235-34,631 \mathrm{mt}$ with $80 \%$ confidence), slightly lower than the estimate from the previous assessment ( $26,048 \mathrm{mt}$ ), but within the confidence band of the current analysis (Table G3, Figure G2). The index assessment presented above reveals that landings and survey trends have remained stable indicating that no substantial change in stock status has occurred since the last analytical assessment.

### 5.0 Harvest Control Rule

The harvest control rule for witch flounder states that when the stock biomass exceeds $\mathrm{B}_{\text {msy }}$, the overfishing threshold is $F_{\text {msy }}$, and target $F$ is the lower $80^{\text {th }}$ percentile (or $10^{\text {th }}$ percentile) of $\mathrm{F}_{\text {msy }}$. When stock biomass is less than $B_{\text {msy }}$, the overfishing threshold is based on maximum F that would allow rebuilding to $\mathrm{B}_{\text {msy }}$ in five years. When biomass is less than the biomass threshold, F $=0$. The biomass threshold is defined by the minimum stock size that is projected to rebuild to $\mathrm{B}_{\text {msy }}$ in 5 years at $\mathrm{F}=0$. The harvest control rule was updated during the 1999 analytical assessment with revised estimates of $\mathrm{F}_{\text {msy }}(0.106), \mathrm{B}_{\text {msy }}(25,000 \mathrm{mt})$, biomass threshold $(13,200$ $\mathrm{mt})$ and the tenth percentile of $\mathrm{F}_{\text {msy }}(0.090)$. MSY is estimated as $2,684 \mathrm{mt}$ (Figure G2).

### 6.0 Sources of Uncertainty

- VPA results indicate the mean biomass 3+ trend has increased in recent years and is near Bmsy, however, the survey biomass indices have remained low. This inconsistency may be due to the variability in age at full recruitment to the survey sampling gear, and/or Bmsy may not be well estimated.
- The sources of uncertainty associated with the 1999 assessment identified by the SARC/SAW 29 are still unsolved, and are listed in NDWG 2000.

Note: During 1963-1984, BMV oval doors were used in the spring and autumn surveys; since 1985, Portuguese polyvalent doors have been used in both surveys. No significant differences in catchability were found for witch flounder, therefore no adjustments have been made (Byrne and Forrester, MS 1991). No significant differences were found between research vessels, and no adjustment have been made (Byrne and Forrester, MS 1991). Spring surveys during 1973-1981 were accomplished with a 41 Yankee trawl; in all other years, a 36 Yankee trawl was used. No adjustments have been made.

Results:

Figure G1. Trends in total landings and NEFSC autumn survey biomass indices for witch flounder (Note: USA landings from the Grand Banks have been excluded; landings prior to 1960 are provisional landings taken from Lange and Lux (1978).

Figure G2. Harvest control rule for witch flounder.

## H. Gulf of Maine-Georges Bank American Plaice by L. O’Brien

### 1.0 Background

This stock was last assessed in 1998 (O'Brien et al. 1999) and reviewed by the $28^{\text {th }}$ Northeast Regional SAW (NEFSC 1999). Fully recruited F (ages 5-8, u) in 1997 was estimated to be 0.47 , a decrease of $10 \%$ from 1996. Spawning stock biomass was $13,500 \mathrm{mt}$ in 1997, an increase of $11 \%$ from 1996. Recruitment since 1993 has been near record low and the 1996 year class (age 1 fish) was estimated to be the lowest in the time series (1980-1997) with a less than average recruit/SSB survival ratio.

The NEFSC spring and autumn bottom trawl survey indices indicated a decline in abundance and biomass each year from spring of 1995 to the spring of 1998. Similarly, the MADMF abundance indices declined each year during 1994-1998. Recruitment indices were below average for the 1994-1996 year classes.

### 2.0 2000 Assessment Update

## The Fishery

Total commercial landings of Gulf of Maine-Georges Bank American plaice in 1999 were 3,257 mt, a $12 \%$ decline from 1998 and a 19\% decline from 1997 (Table H1, Figure H1). Discards were not estimated. Canadian fisheries landed 123 mt in 1999, about $4 \%$ of the total landings.

## Research Survey Indices

The NEFSC indices of abundance and biomass indicate an increase in the spring 2000 indices and in the autumn 1998 and 1999 indices (Table H2, Figure H2 and H3). Recruitment indices of age 1 fish from NEFSC autumn surveys indicate that both the 1997 and 1998 year classes are above average and similar in size to the 1992 year class (Table H3, Figure H4). The same year classes are just below the time series average in the Massachusetts autumn survey (Table H4).

## Mortality and Stock Size

Landings have been gradually declining since 1992 and fishing mortality declined during 1995 to 1997. A projection analysis based on 1998 and 1999 landings and an empirical resampling model predicted that fishing mortality declined from 1997 to 1999 (Table H5, Figure H5). Spawning stock biomass was predicted to remain relatively stable during 1998 and 1999 and similar to the 1997 estimate (13,500 mt) (Figure H6).

Comparison of these results to the projection analyses conducted in 1999 (Northern Demersal Working Group 2000) indicate very similar results. Fishing mortality in 1999 had previously been assumed to be 0.32 , equivalent to the 1998 F . The assumed 1999 F was only slightly higher
than the projected $1999 \mathrm{~F}=0.27$ and within the projected $80 \%$ confidence limits. The 1999 SSB had previously been predicted to be about $13,755 \mathrm{mt}$ compared to the current projection of $13,837 \mathrm{mt}$ and was within the projected $80 \%$ confidence limits.

### 3.0 SFA Control Rule

The SFA control rule for Gulf of Maine-Georges Bank American plaice is based on $\mathrm{SSB}_{\text {MSY }}$ which is currently estimated at $24,200 \mathrm{mt}$ (Figure H 7 ). The rule states that $\mathrm{F}_{0.1}$ will be the maximum fishing mortality threshold when the stock is above $\mathrm{SSB}_{\text {MSY }}$ then decrease linearly to zero at $1 / 4 \operatorname{SSB}_{\text {MSY }}(6,050 \mathrm{mt})$. The target F will be $60 \%$ of $\mathrm{F}_{0.1}$ when the stock is above $\mathrm{SSB}_{\text {MSY }}$ and would decrease linearly to zero at $1 / 2$ of $\operatorname{SSB}_{\text {MSY }}(12,100 \mathrm{mt})$. F in 1999 was projected to be 0.27 and SSB in 1999 was projected to be $13,837 \mathrm{mt}$.

### 4.0 Sources of Uncertainty

- No estimation of discards for the 1998 and 1999 fishery.
- Assessment is based on projection analysis of landings instead of a calibrated VPA.

## From the previous update (Northern Demersal Working Group 2000) :

- VPA estimates of 1998 calibrated age 1 stock size were not available. The derived estimates may be optimistic.
- Projections of SSB are likely to be optimistic if recruits are overestimated.

## I. Georges Bank Winter Flounder by Lisa Hendrickson

### 1.0 Background

The Georges Bank winter flounder stock was last assessed in 1998 at SAW/SARC 28 (NEFSC 1999). The 1998 VPA assessment incorporated a catch at age from 1982-1997 and research survey indices from the U.S. autumn (1963-1997) and spring (1968-1998) surveys, as well as the Canadian spring (1987-1998) surveys. Fully-recruited F (ages 4-6) in 1997 was estimated to be 0.41 and spawning stock biomass was estimated to be $3,500 \mathrm{mt}$.

In 1999, medium term stochastic projections were generated (NDWG 2000) by deriving a 1998 fishing mortality rate ( $=0.42$ ) based on annual landings, then assuming a 1999 fishing mortality rate equal to 1998. Medium term projections were performed by applying the harvest control rule to determine the corresponding level of fishing mortality for 2000-2008.

### 2.0 2000 Assessment Update

## The Fishery

Total commercial landings (U.S. and Canadian) of Georges Bank winter flounder have declined since $1997(1,430 \mathrm{mt})$ to $1,328 \mathrm{mt}$ in 1998 and $1,019 \mathrm{mt}$ in 1999 (Table I1; Figure I1). Since the late 1960's, U.S. landings have been the predominant component of the total commercial landings. Canadian landings have averaged $0.1 \%$ to $2.7 \%$ of the total landings since 1970 .

Canadian landings in 1997 (143 mt) reached their highest levels since 1966, but have since declined during 1998 and 1999, to 91 mt and 76 mt , respectively. U.S. landings have also declined since 1997. Landings for 1998 and 1999 were estimated, based on prorations, at 1,237 mt and 943 mt , respectively. Discarding of winter flounder occurs at low levels in both the otter trawl and scallop dredge fisheries. However, lack of reliable information to estimate either the magnitude or characterize the size and age distribution of discards precluded discard estimation.

## Research Survey Indices

Stratified mean weight ( kg ) per tow and mean number per tow from the NEFSC spring (April 1968-1999) and autumn (October 1963-1999) bottom trawl surveys, as well as the Canadian spring (1987-1999) bottom trawl surveys, are presented in Table I2. NEFSC autumn survey biomass indices are also shown in relation to the landings for this stock in Figure I1. While landings declined during 1998 and 1999, autumn survey biomass indices increased slightly, reaching their 1996 level in 1999 ( $1.756 \mathrm{~kg} /$ tow $)$.

### 3.0 Harvest Control Rule

The MSY-based control rule for Georges Bank winter flounder adopted in Amendment 9 was derived from survey-based proxies of biomass and exploitation. The parameters of this control rule were revised during SAW/SARC 28 due to revised estimates of landings and a revision to the strata set used to develop survey indices for the NEFSC spring and autumn surveys. The revised control rule defined maximum sustainable yield as $2,700 \mathrm{mt}$, and survey equivalents of MSY-based reference points. The $\mathrm{F}_{\text {MSY }}$ proxy is defined as catch / NEFSC autumn survey biomass index and the $\mathrm{B}_{\text {MSY }}$ proxy is defined as an autumn survey biomass index value. Threshold F is defined as an $\mathrm{F}_{\text {MSY }}$ proxy $(=1.125)$ when the NEFSC autumn survey biomass index is greater than $2.73 \mathrm{~kg} /$ tow and declines linearly to zero at $1 / 2$ the $\mathrm{B}_{\text {MSY }}$ proxy $(=1.37$ $\mathrm{kg} /$ tow $)$. The target exploitation rate was defined as $75 \%$ of the $\mathrm{F}_{\text {MSY }}$ proxy $(=0.84)$ when the NEFSC autumn survey biomass index is greater than $2.73 \mathrm{~kg} /$ tow and declines linearly to zero at $1.37 \mathrm{~kg} /$ tow (Figure I2).

Exploitation indices (catch/NEFSC autumn survey biomass index) during 1964-1999 are presented, in Table I3 and Figure I3, in relation to the harvest control rule $\mathrm{F}_{\text {MSY }}$ proxy ( $=1.125$ ). The 1997-1999 mean exploitation index equals 0.787 and the 1997-1999 mean NEFSC autumn survey biomass index equals 1.618 (Figure I2).

The availability of an analytical assessment for this stock provides an opportunity to update the harvest control rule. A revised control rule which incorporated estimates of mean biomass and F weighted by biomass would eliminate the necessity of translating between mean biomass and autumn survey units.

### 4.0 Forecasts

No stochastic projections were performed for 2000-2001. However, the 1999 U.S. and Canadian landings were used to recalculate the realized $\mathrm{F}_{1999}(=0.34)$. The projected $\mathrm{F}_{1999}(=0.41)$ from the analysis conducted in 1999 (NDWG 2000) was assumed to equal the $\mathrm{F}_{1998}$. This projected value for $\mathrm{F}_{1999}$ is within the $80^{\text {th }}$ percentile of the recalculated $\mathrm{F}_{1999}$ value $(=0.34)$ (Tables I4 and I5).

### 5.0 Sources of Uncertainty

- Sampling of U.S. commercial landings may be inadequate to characterize the size and age composition, particularly in the years since 1992. This leads to uncertainty in the age composition of landings in the catch at age matrix.
- The exclusion of U.S. otter trawl and scallop dredge discards most likely results in an underestimation of fishery removals from the younger age classes (ages 0 to 3). Indications from both the sea sample and vessel trip record databases suggests that scallop dredge discards may have increased since the implementation of groundfish retention restrictions resulting in an underestimation of fishery removals of both younger and older age classes.
- There is some uncertainty about the accuracy of reported Canadian landings because of the non-targeted nature of the Canadian fishery and the tendency to report landings of some flatfish species, including winter flounder, as unclassified flounders.
- The Canadian fishery has no formal sampling program to estimate the size and age composition of Canadian landings. This assessment assumed that the size and age composition of Canadian landings was identical to the overall size and age composition in the U.S. fishery. This assumption is sensitive to the possibility that selectivity patterns may be different between the fisheries in each country.

## J. Southern New England/Mid-Atlantic Winter Flounder by P. Nitschke

### 1.0 Background

The Southern New England/Mid-Atlantic stock complex of winter flounder was last assessed by SAW 28 in December 1998, with catches through 1997 (NEFSC 1999). The assessment is for the entire stock complex, which includes several inshore spawning aggregations that individually may not demonstrate the same trend in abundance as the complex. Fully recruited (ages 4-6) fishing mortality in 1997 was estimated at 0.31 , corresponding to a biomass weighted $\mathrm{F}=0.24$ (given current age structure). Mean stock biomass in 1997 was estimated to be $17,900 \mathrm{mt}$. Forecasts made in 1999 (Northern Demersal Working Group 2000) indicate that fully recruited F (age 4-6) in 1998 was 0.33 , corresponding to a biomass weighted F (ages 1 and older) of 0.19 . In the SAW 28 assessment, $\mathrm{B}_{\text {MSY }}$ was estimated to be $27,810 \mathrm{mt}$, MSY was estimated to be $10,200 \mathrm{mt}, \mathrm{F}_{\text {MSY }}$ was estimated to be biomass weighted $\mathrm{F}=0.37$, and the FMP Amendment 9 ten year rebuilding target biomass weighted fishing mortality was estimated to be $\mathrm{F}_{\text {target10 }}=0.24$.

### 2.0 2000 Assessment Update

## The Fishery

Commercial and recreational catch was updated through 1999 (Table J1). Commercial discards were assumed to be $7 \%$ of the landings, as in SAW 28 projections, and were calculated to be 242 mt for 1999. Recreational landings were taken from the MRFSS, and estimated to be 322 mt in 1999. Recreational discards were taken from the MRFSS, and estimated to be 12 mt in 1999. Total landings were estimated to be $3,779 \mathrm{mt}$, total discards were estimated to be 254 mt , and total catch was estimated to be $4,033 \mathrm{mt}$ in 1999. Total catch has remained relatively stable and low since 1993 ( $4,041 \mathrm{mt}$ ) in comparison to a high of $15,657 \mathrm{mt}$ in 1981 (Figure J1).

## Research Survey Indices

NEFSC spring and autumn survey indices were updated though spring 2000 (Table J2; Figure J1). NEFSC survey indices show an increase in stock biomass since 1993. The NEFSC spring 1999 ( $1.245 \mathrm{~kg} /$ tow) and 2000 ( $1.123 \mathrm{~kg} /$ tow) survey biomass index are among the highest since 1985 ( $1.983 \mathrm{~kg} /$ tow). The NEFSC autumn 1999 survey biomass index ( $1.549 \mathrm{~kg} /$ tow) has decreased since 1997 ( $2.583 \mathrm{~kg} /$ tow $)$ but remain among the highest since 1983 ( $2.691 \mathrm{~kg} / \mathrm{tow}$ ). The MDMF 1999 spring survey biomass index ( $4.44 \mathrm{~kg} /$ tow) has decreased from 1998 (7.99 kg/tow; Figure J2).

## Assessment Results

Projections based on 1998 and 1999 total catch indicate that fully recruited F (age 4-6) declined slightly from 0.33 to 0.29 , respectively (Table J3). The assumed $1999 \mathrm{~F}=0.33$ used in the 1999 projection (Northern Demersal Working Group 2000) is slightly higher but does fall within the
updated $1999 \mathrm{~F}=0.2980 \%$ confident interval ( $0.23-0.36$ ). The updated 1999 stock biomass $(25,300 \mathrm{mt})$ is therefore slightly higher than the estimated biomass from the 1999 projection $(25,000 \mathrm{mt})$. Fishing mortality in 1999 likely remained at status quo given that total landings have remained stable and that survey indices have not changed greatly from 1998.

### 3.0 Harvest Control Rule

The target fishing mortality to be used when stock biomass is greater than $\mathrm{B}_{\mathrm{MSY}}(27,800 \mathrm{mt})$ was estimated as the $10^{\text {th }}$ percentile of $\mathrm{F}_{\text {MSY }}$ (Figure J3). $\mathrm{F}_{\text {THRESHOLD }}=\mathrm{F}_{\text {MSY }}=0.37$ on biomass when biomass $=\mathrm{B}_{\text {MSY }}$. When total stock biomass is between $1 / 2 \mathrm{~B}_{\text {MSY }}(13,900 \mathrm{mt})$ and $\mathrm{B}_{\text {MSY }}$, a 10 -year rebuilding strategy applies. When total stock biomass is between $\mathrm{B}_{\text {THRESHOLD }}=1 / 4 \mathrm{~B}_{\text {MSY }}(7,000 \mathrm{mt})$ and $1 / 2 \mathrm{~B}_{\text {MSY }}$, a 5 -year rebuilding strategy applies. When biomass is below $1 / 4 \mathrm{~B}_{\text {MSY }}, \mathrm{F}_{\text {THRESHOLD }}=0$.

## K. Georges Bank/Gulf of Maine White Hake by K.A. Sosebee

### 1.0 Background

A VPA was last conducted for this stock in 1998 and reviewed at SAW 28 (NEFSC 1999). In 1999, projections were done to estimate mean biomass in 2000. Reported landings in 1998 were used to derive fishing mortality in 1998. Fully recruited fishing mortality (ages 4-8) in 1998 was estimated to be 1.09 , a decrease from 1.15 in 1997. Spawning stock biomass was estimated to have declined to $2,700 \mathrm{mt}$ in 1998, a decline from a recent high of $9,600 \mathrm{mt}$ in 1992. NEFSC spring and autumn research vessel bottom trawl survey indices had declined to near record low levels in 1998 and 1999.

### 2.0 2000 Assessment

## Fishery

United States commercial landings of white hake increased to 2,624 metric tons (mt) in 1999, an $11 \%$ increase from 1998 (Table K1; Figure K1). Canadian landings declined to 175 mt ( $23 \%$ decline). No discard estimates were derived for 1999.

## Input Data and Analyses

The present assessment represents a one-year update to the previous assessment (Northern Demersal Working Group 2000). Forecast software was used to estimate fishing mortality and biomass in 1999. Survivors from 1000 bootstrapped VPA outcomes from the 1997 assessment (NEFSC 1999) were used to start the projections. Reported landings were used to generate fishing mortality in 1998 and 1999. Survey data from the fall of 1998 and 1999 and the spring of 1999 and 2000 was aged using seasonal pooled age-length keys from 1982-1999. The age estimates for fall age-1 and spring age- 2 were then used to derive an estimate of recruitment for the 1997 and 1998 year classes using RCT3. The estimate and the standard error were used to generate 1000 recruitment estimates for age 1 in the projections for 1997. The estimate for 1998 was used in the first year of the projection.

### 3.0 Assessment Results

NEFSC research vessel bottom trawl survey abundance and biomass indices for white hake remained relatively low through autumn 1999 and spring 2000 (Table K2, Figure K2). The autumn 1999 indices declined slightly from the 1998 levels, while the spring 2000 indices increased from the 1998 levels because of an apparently strong 1998 year class (Figure K3). Recruitment of the 1997 year class was estimated to be 1.9 million fish, the second lowest value in the time series while the 1998 year class is estimated to be 9.0 million fish, the third highest value (Figure K5).

Fully recruited fishing mortality (ages 4-8) in 1999 is now estimated to be 0.90 (Figure K4), a slight decline from 1.09 in 1998, as reported in the previous assessment. Spawning stock biomass is estimated at $3,297 \mathrm{mt}$ in 1999, an increase from 2,717 mt in 1998 (Figure K5). The most recent high level of $\operatorname{SSB}(9,563 \mathrm{mt}$ ) occurred in 1992. Mean biomass increased to 6,887 in 1999 due to both the 1996 and 1998 year classes (Figure K5). Biomass weighted fishing mortality (ages $1+$ ) has declined from 0.8 in 1996 to 0.40 in 1999 (Figure K4). Accounting for precision in the current assessment, there is a $90 \%$ probability that fully recruited F in 1999 was greater than 0.6 , SSB in 1999 was less than $4,500 \mathrm{mt}$, and mean biomass was less than $9,000 \mathrm{mt}$.

### 4.0 Consistency of 1999 Projection Forecast with 2000 Assessment Results

Projections conducted during the 1999 assessment were performed assuming that F1999= F1998 $=1.09$ and estimated that mean biomass would be 5498 mt in 1999. The 2000 assessment using actual landings estimated an F of 0.9 with $80 \%$ probability that F was between 0.6 and 1.7 which includes the former value of 1.09 . With a lower value of fishing mortality and a higher level of recruitment in 1999, the mean biomass from the new projection was $6,887 \mathrm{mt}$ as compared to $5,498 \mathrm{mt}$. With $80 \%$ confidence limits of 3847 and 8964 , the values are still similar.

### 5.0 Control rule.

According to the SARC 28 overfishing control rule, when mean biomass is at $\mathrm{B}_{\text {msy }}(22,300 \mathrm{mt})$ or greater, the target fishing mortality is 0.12 and the threshold is 0.24 (Figure K6). When biomass is between $6,900 \mathrm{mt}$ and 22,300 the fishing mortality rate should allow recovery to $B_{\text {msy }}$ in 5years. At biomass levels below $6,900 \mathrm{mt}$, fishing mortality should be as close to zero as possible.

### 6.0 Sources of Uncertainty

- 1999 fishing mortality may be uncertain if landings are not complete and if the PR has changed.
- 1997 and 1998 year classes based on pooled age-length keys.
- The control rule is based on a rescaled estimate of $\mathrm{F}_{\text {msy }}$. The scaling may not show the actual rate of recovery.

From SARC 28:

- Discards are not incorporated into the VPA catch at age.
- Red hake may be mis-identified as white hake and vice versa.
- Missing ages in the survey age/length keys were interpolated.
- White hake may move seasonally into and out of the defined stock area.

## L. Scotian Shelf/Georges Bank/Gulf of Maine Pollock by R.K. Mayo

### 1.0 Background

Pollock, Pollachius virens (L.) Are assessed as a unit stock from the eastern Scotian Shelf (NAFO Division 4V) to Georges Bank and the Gulf of Maine (Subarea 5). This stock was last assessed over its range via VPA at SAW 16 in 1993 (Mayo and Figuerido 1993, NEFSC 1993a, 1993b). At that time, spawning stock biomass had been declining since the mid-1980s, and was expected to reach its long-term average ( $144,000 \mathrm{mt}$ ). Fishing mortality was estimated to be 0.72 in 1992, above F20\% (0.65) and well above Fmed (0.47). The stock was then considered to be fully exploited and at a medium biomass level.

The state of this stock was most recently evaluated in 1998 via index assessment (Mayo 1998). At that time, it was noted that biomass indices for the Gulf of Maine-Georges Bank portion of the stock, derived from NEFSC autumn bottom trawl surveys, had increased during the mid1970s, declined sharply during the 1980s, and have remained relatively low since 1989. Indices derived from Canadian bottom trawl surveys, conducted on the Scotian Shelf, increased during the 1980s, but declined sharply during the early 1990s. The stock was then considered to be fully exploited, but at a low biomass level.

An assessment of this stock over the major portion of its range (NAFO Divisions 4VWX and Subdivision 5 Zc c) has been conducted by Canada since 1989. The most recent assessment was conducted in 1999 (Neilson et al. 1999), and it was noted that age $5+$ population biomass reached a maximum in 1985 and then declined steadily to a minimum in 1995. Biomass has increased since 1995 due to recruitment from the 1992 year class. Recent recruitment has been declining, and it was concluded that most indicators of stock status suggest that the resource remains depleted.

### 2.0 The Fishery

Nominal commercial catches from the Scotian Shelf, Gulf of Maine, and Georges Bank region increased from an annual average of $38,200 \mathrm{mt}$ during 1972-76 to $68,800 \mathrm{mt}$ in 1986 (Table L1, Figure L1). Canadian landings increased steadily from $24,700 \mathrm{mt}$ in 1977 to an annual average of 43,900 mt during 1985-87, while U.S. landings increased from an average of 9,700 mt during 1973-77 to more than 19,000 mt annually from 1985-1987, peaking at 24,500 mt in 1986. Landings by distant-water fleets declined from an annual average of 9,800 mt during 1970-73 to less than $1,100 \mathrm{mt}$ per year during 1981-88. Distant-water fleet landings increased to $3,300 \mathrm{mt}$ in 1991, but have since declined to negligible levels. Over time, most of the distant water fleet catch has been taken by the USSR/Russian fleet on the Scotian Shelf (Table L1).

Since 1984, the USA fishery has been restricted to areas of the Gulf of Maine and Georges Bank west of the line delimiting the USA and Canadian fishery zones. The Canadian fishery occurs primarily on the Scotian Shelf some additional landings from Georges Bank east of the line delimiting the USA and Canadian fishery zones. This fishery has shifted westward over time,
and the contribution to the total catch from larger, mobile gear vessels has steadily diminished since 1981.

By 1996, USA and Canadian landings had declined to $2,963 \mathrm{mt}$ and $9,145 \mathrm{mt}$, respectively, the lowest landings by either country in over 3 decades. Landings by distant water fleets fishing on the Scotian Shelf remained almost negligible. Since 1996, USA and Canadian landings have increased slightly but remain low relative to past levels.

### 3.0 Research Survey Indices

Indices of relative biomass (ln re-transformed), derived from NEFSC autumn research vessel bottom trawl surveys have varied considerably since 1963 (Table L2, Figure L1). Indices generally fluctuated between 2 and 5 kg per tow throughout most of the 1960s and 1970s, peaking at over $5-7 \mathrm{~kg}$ per tow during the mid-to-late 1970 s , reflecting recruitment of several moderate-to strong year classes from the early 1970s. Strong year classes were also produced in 1979 and 1980, after which recruitment began to diminish during the 1980s.

Biomass indices declined rapidly during the early 1980s, and continued to decline steadily through the early 1990s, remaining below 1 kg per tow and reaching a minimum in 1994. Since 1994, biomass indices from the Gulf of Maine-Georges Bank region have generally increased, reaching 1.5 kg per tow in 1999 (Table L2, Figure L1). On the Scotian Shelf, Canadian biomass indices, derived from commercial fishery catch rates, declined rapidly after 1985, following the recruitment of the 1979 year class. After increasing slightly from 1994 to 1996, catch rate indices have continued to decline.

### 4.0 Assessment Results

As evident from recent trends in landings and NEFSC autumn biomass indices, exploitation ratios, derived from landings/NEFSC autumn biomass index, peaked in the mid-to-late 1980s after which they have steadily declined (Table L3, Figure L2). Despite this, measures of stock biomass in the Gulf of Maine-Georges Bank region and on the Scotian Shelf remain extremely low relative to past levels.

### 5.0 Harvest Control Rule

The Harvest Control Rule proposed for this stock by the Overfishing Definition Review Panel is based upon Yield and SSB per Recruit analyses combined with an estimate of average recruitment. According to this control rule, a target F should be set at $75 \%$ of the Fmsy proxy ( $0.49=0.75 \mathrm{xF} 20 \%$ ) when spawning stock biomass is greater than $102,000 \mathrm{mt}$ and would decrease linearly to zero at $51,000 \mathrm{mt}$ ( $1 / 2$ of the SSBmsy proxy).

The index assessment presented above provides no basis with which to evaluate the present state of the stock relative to this control rule.

### 6.0 Sources of Uncertainty

- Survey indices for pollock exhibit considerable inter-annual variability
- Movement of pollock among the NAFO Divisions comprising the stock unit is likely to vary over time, contributing to the year effects noted in the surveys

## M. Gulf of Maine-Georges Bank Redfish by R.K. Mayo

### 1.0 Background

Redfish, Sebastes fasciatus Storer, are assessed as a unit stock in the Gulf of Maine and Georges Bank region (NAFO Subarea 5). This stock was last assessed via survey index at SAW 15 in 1992 (Mayo 1993, NEFSC 1993a, 1993b). At that time, the NEFSC autumn survey biomass index had been gradually increasing at a very slight rate since the mid-1980s, but the index remained well below levels seen in the 1960s and early 1970s. Since landings had also declined to record lows, it was concluded that the exploitation rate was probably quite low, but that the stock remained at a very low level. Recruitment was also found to be extremely poor in recent years and that the population was composed of very few contributing year classes.

The state of this stock was most recently evaluated in 2000 via index assessment (Mayo 2000). At this time, it was noted that biomass indices for Gulf of Maine-Georges Bank redfish, derived from NEFSC autumn bottom trawl surveys, had increased substantially beginning in 1996 and had reached levels approximately equal to those evident in the 1960s. Despite this extremely sharp increase, landings had not increased from the very low levels noted in the early 1990s. The gradual increase in the survey biomass index between 1990 and 1993 was consistent with incremental annual increases in the NEFSC survey abundance index (mean number per tow) observed during the early 1990s, and reflect accumulated recruitment and growth of one or more above-average year classes produced in the mid-1980s. However, the large increase in the survey biomass index in 1996 was supported almost exclusively by fish in the 18-23 cm range at a corresponding age of approximately 5-6 years. It was concluded, therefore, that production of these redfish is likely to have occurred during 1990 and 1991, with reproduction augmented by early-maturing spawners from the mid-1980s year classes. Thus, stock biomass appears to have increased during the mid-1990s through the combined effects of growth and survival of fish from a period of relatively successful reproduction in the early1990s. Further increases in biomass since 1996 have been supported by a wide range of sizes of fish in the population.

### 2.0 The Fishery

During the early development phase of the Gulf of Maine redfish fishery, USA landings increased rapidly to a peak level of about $56,000 \mathrm{mt}$ in 1942 followed by a steep decline through the early 1950s (Table M1). Nominal catches then declined at a more gradual rate to less than $10,000 \mathrm{mt}$ during the 1960s. During the 1970s, USA landings increased again, peaking at 16,000 mt in 1971 and again at $15,000 \mathrm{mt}$ in 1979. During the 1970 s , additional catches by Canadian and distant water fleets increased the total redfish catch to a maximum of about 17,000 to 20,000 mt per year from 1970 through 1973; catches of redfish by these fleets declined to negligible levels after 1976.

Landings of redfish declined steadily throughout the 1980s, remaining below $1,000 \mathrm{mt}$ per year since1989, and at less than 500 mt per year since 1994. Total redfish landings in 1999 were 353 mt compared to 320 mt in 1998.

### 3.0 Research Survey Indices

Indices of relative biomass, derived from NEFSC autumn research vessel bottom trawl surveys, although variable, exhibited a rather steady decline between 1963 and 1982 (Table M2, Figure M1). On average, the biomass index appears to have declined by about $90 \%$ over a 20 year period. During this time, only 2 year classes of any significance were produced, 1971 and 1978. Between 1983 and 1993, the biomass index approximately doubled, reflecting the relatively low rate of removals by the fishery and the very slow growth rate of the species. No substantial year classes were detected by the research vessel surveys in the inshore survey strata traditionally used to monitor recruitment until autumn 1995 when a substantial number of fish in the 15-19 cm range were noted, suggesting the possibility of above average reproduction in 1990 and/or 1991. This was followed by a very large increase in the index in the offshore strata in the autumn of 1996, followed by a large decrease in autumn 1997. The autumn biomass index rose sharply in 1996 and has fluctuated between 20 and 30 kg per tow since then, a magnitude comparable to the period between 1963 and the mid-1970s.

During the earlier periods, however, redfish were generally first detected in the inshore strata at relatively small sizes ( $\sim 10 \mathrm{~cm}$ or less, age 1 or 2 ), only to appear in the offshore strata after about 5 or six years (Mayo, 1993). During the 1990s recruitment event, the year class was not detected until fish were close to 20 cm , or about ages 4 or 5 , and the numbers appeared to be present in both inshore and offshore strata. In addition, the autumn biomass index increased 4-5 fold between the early 1990s and the mid-1990s, a rate that is inconsistent with the dynamics of this species. The spring index, however, suggests only a very modest change in biomass since the mid-1990s.

Given the continued extremely low landings of redfish relative to the recent increase in the autumn survey biomass index, the exploitation ratio is now extremely low compared to the 1960s and 1970s (Table M3; Figure M2). However, in contrast to this earlier period, where a substantial proportion of the stock persisted in the $30-40 \mathrm{~cm}$ range (Mayo, 1993), during the 1990s, almost all of the redfish are less than 25 cm , and almost none are greater than 30 cm . This suggests that, given the present demographics of the stock, only a small fraction of the biomass would be considered exploitable.

### 4.0 Harvest Control Rule

The Harvest Control Rule proposed for this stock by the Overfishing Definition Review Panel is derived from an estimate of Bmsy $(121,000)$ based on the ratio of an MSY estimate $(14,000 \mathrm{mt})$ derived from a Generalized Production Model (Mayo 1980) to a proxy estimate of Fmsy (F20\% $=0.116$; Mayo, 1993). Annual biomass estimates which relate to Bmsy were then derived by expanding NEFSC autumn bottom trawl survey biomass indices to total biomass using swept area calculations.

Given that these two approaches are inconsistent, it would seem prudent that the basis for evaluating the current status of redfish relative to the biomass reference points and the harvest
control rule should be re-examined. Thus, the index assessment presented above provides no basis with which to evaluate the present state of the stock relative to this control rule.

### 5.0 Sources of Uncertainty

- The sharp increase in the survey biomass index in 1996 is inconsistent with the life history characteristics of this species.
- Given the pelagic diurnal movement and general distribution of redfish, swept area estimates of stock biomass derived from bottom trawl survey data will tend to underestimate absolute stock size.

## N. Ocean Pout by S.E. Wigley

### 1.0 Background

Ocean pout, Macrozoarces americanus, are assessed as a unit stock from Cape Cod Bay south to Delaware. An index assessment for this species was last reviewed at SAW 11 in 1990 (NEFSC 1990). The most recent update of stock status determined the ocean pout population was overfished and overfishing was occurring in 1999 (Wigley 2000). Ocean pout are included in the New England Fishery Management Council' s Multispecies Fishery Management Plan under the "nonregulated multispecies" category.

### 2.0 The Fishery

From 1964 to 1974, an industrial fishery developed for ocean pout, and nominal catches by the U.S. fleet averaged 4,700 mt. Distant-water fleets began harvesting ocean pout in large quantities in 1966, and total nominal catches peaked at $27,000 \mathrm{mt}$ in 1969. Foreign catches declined substantially afterward, and none have been reported since 1974 (Table N1, Figure N1). United States landings declined to an average of 600 mt annually during 1975 to 1983. Catches increased in 1984 and 1985 to $1,300 \mathrm{mt}$ and $1,500 \mathrm{mt}$ respectively, due to the development of a small directed fishery in Cape Cod Bay supplying the fresh fillet market. Landings have declined more or less continually since 1987, in spite of continued market demand. In recent years, landings from the southern New England/Mid-Atlantic area have continued to dominate the catch, reversing landing patterns observed in 1986-1987, when the Cape Cod Bay fishery was dominant. The shift in landings is attributed to the changes in management (gear/mesh) regulations. Total landings in 1999 were only 18 mt , a near record low in the time series (Table N1, Figure N1).

### 3.0 Research Survey Indices

Commercial landings and the NEFSC spring research vessel survey biomass index followed similar trends during 1968 to 1975 (encompassing peak levels of foreign fishing and the domestic industrial fishery); both declined from very high values in 1968-1969 to lows of 300 mt and 1.3 kg per tow, respectively, in 1975. Between 1975 and 1985, survey indices increased to record high levels, peaking in 1981 and 1985. Since 1985, survey catch per tow indices have generally declined, and are presently less than the long-term survey average ( 3.9 kg per tow); the 2000 spring survey index was 2.0 kg per tow (Table N2, Figure N1). While the NEFSC winter survey and the Massachusetts Division of Marine Fisheries inshore research vessel surveys both confirm the declining trend observed in the NEFSC spring survey, length frequency data from all three surveys do not reveal a truncation in the size range.

Exploitation ratios have declined sharply from a peak in 1973 to low levels in the early 1980s then increased slightly in the late-1980s, after which they declined to record low levels (Table N3, Figure N2).

### 4.0 Assessment Results

The index assessment presented above reveals that landings, survey and exploitation ratios trends have remained stable indicating that no substantial change in stock status has occurred since the last assessment.

### 5.0 Harvest Control Rule

The Overfishing Definition Review Panel (Applegate et al. 1998) proposed a harvest control rule for ocean pout based upon research vessel survey biomass trends and the exploitation history. MSY was chosen to be $1,500 \mathrm{mt}$ and the B-msy proxy was determined as the median survey index from 1980-1991 ( $4.9 \mathrm{~kg} / \mathrm{tow}$ ). Given these proxies, the threshold F-msy is 0.31 (1.5/4.9). The minimum biomass threshold is $1 / 2$ of the B-msy proxy ( $2.4 \mathrm{~kg} /$ tow ). The control rule states that a target F should be set at $60 \%$ of the $\mathrm{F}-\mathrm{msy}$ proxy $(\mathrm{F}-\mathrm{msy}=0.19)$ when the spring survey index is greater than $4.9 \mathrm{~kg} / \mathrm{tow}$, and would decrease linearly to zero at $2.4 \mathrm{~kg} / \mathrm{tow}$.

To evaluate stock conditions, a three year average of NEFSC spring survey indices and an exploitation ratio (1999 catch/ average of 1997,1998,1999 spring survey biomass indices) are used as proxies for biomass and fishing mortality, respectively. In 1999, the three year average survey index ( $1.97 \mathrm{~kg} /$ tow) indicates that biomass is below the minimum biomass threshold (2.4 $\mathrm{kg} / \mathrm{tow}$ ) and the exploitation ratio ( 0.009 ) indicates F is well below the F threshold (Figure N 3 ).

### 6.0 Sources of Uncertainty

- Due to the lack of commercial length samples (one sample of 17 fish since 1996), the size composition of the commercial landings could not be characterized.
- Discards have not been estimated, only landings were used to derive exploitation ratios instead of total catch. Therefore, exploitation ratios may be underestimated.

## O. Gulf of Maine -Georges Bank Windowpane Flounder by Lisa Hendrickson

### 1.0 Background

No stock structure information is available. Therefore, a provisional arrangement has been adopted that recognizes two stock areas based on apparent differences in growth, sexual maturity, and abundance trends between windowpane flounder from Georges Bank and from Southern New England. The proportions of total landings contributed by the Gulf of Maine and Mid-Atlantic areas are low (less than 7\%), so data from these areas are combined with those from Georges Bank and Southern New England, respectively.

The northern windowpane flounder stock, which includes the Gulf of Maine and Georges Bank regions, has never been assessed through the SAW/SARC process. The following assessment is an update of the information contained in the Status of the Fishery Resources off the Northeastern United States, 2000 (Hendrickson 2000).

### 2.0 2000 Assessment Update

## The Fishery

Since 1975, when landings of this species were first recorded, the majority of the total landings have been harvested from the Gulf of Maine-Georges Bank stock. Following a 1991 record high of $2,900 \mathrm{mt}$, landings declined to $300 \mathrm{mt} \mathrm{in} \mathrm{1994}$. and reached a record low of 46 mt in 1999 (Table O1; Figure O1). High landings during the early 1990s probably reflect an expansion of the fishery to offshore areas, as well as the targeting of windowpane flounder as an alternative to depleted groundfish stocks.

## Research Survey Indices

Stratified mean weight ( kg ) per tow and mean number per tow of windowpane flounder from the NEFSC autumn (October 1963-1999) bottom trawl surveys are presented in Table 2 for the Gulf of Maine-Georges Bank stock. These biomass indices are also shown in relation to the stock landings in Figure 1. Survey biomass indices are highly variable, but in general, show an increasing trend since 1991. The large increase in the 1998 survey index is primarily attributable to a large catch of windowpane at one station.

### 3.0 Harvest Control Rule

The MSY-based control rule for GOM-GB windowpane flounder adopted in Amendment 9 was derived from survey-based proxies of biomass and exploitation. The control rule defines a maximum sustainable yield for the stock of $1,000 \mathrm{mt}$. The threshold F is defined as an FMSY proxy (FMSY $=1.11$ ) when the NEFSC autumn survey index is greater than $0.94 \mathrm{~kg} /$ tow (minimum biomass threshold equal to a BMSY proxy) and declines linearly to zero at $50 \%$ of
the BMSY proxy ( $=0.47 \mathrm{~kg} /$ tow $)$. The target exploitation index is defined as $60 \%$ of the F MSY proxy $(=0.67)$ when the autumn survey index is greater than $0.94 \mathrm{~kg} /$ tow and declines linearly to zero at $0.47 \mathrm{~kg} /$ tow (Figure O2).

Exploitation indices (catch/NEFSC autumn survey biomass index) during 1975-1999 are presented, in Table O3 and Figure O3, in relation to the harvest control rule FMSY proxy (=1.11). The 1997-1999 autumn survey mean biomass index equals $0.94 \mathrm{~kg} /$ tow and the 19971999 mean exploitation index (catch/NEFSC autumn survey biomass index) equals 0.42.

### 4.0 Sources of Uncertainty

- Stock structure is uncertain.
- Discarding is not quantified and may a significant fraction of the catch given recent roundfish retention restrictions.
- Vessel trip reports have been used to prorate the landings since 1995, and a fraction of the landings from Southern New England may have been reported as Georges Bank landings or vice versa.

## P. Southern New England/Mid-Atlantic Windowpane Flounder by Lisa Hendrickson

### 1.0 Background

No stock structure information is available. Therefore, a provisional arrangement has been adopted that recognizes two stock areas based on apparent differences in growth, sexual maturity, and abundance trends in fish from Georges Bank and from Southern New England. The proportions of total landings contributed by the Gulf of Maine and Mid-Atlantic areas are low (less than 7\%), so data from these areas are combined with those from Georges Bank and Southern New England, respectively.

The southern windowpane flounder stock, which includes the southern New England and MidAtlantic Bight regions, has never been assessed through the SAW/SARC process. The following assessment is an update of the information contained in the Status of the Fishery Resources off the Northeastern United States, 2000 (Hendrickson 2000).

### 2.0 2000 Assessment Update

## The Fishery

Commercial landings from this stock exceeded those from the Gulf of Maine-Georges Bank stock during 1980-1984, and reached a record high of 2,100 mt in 1985 (Table P1; Figure P1). Landings declined rapidly between 1988 and 1995, from 2,100 mt to a record low of 100 mt in 1995. Landings in 1998 and 1999 were 123 mt and 116 mt , respectively.

## Research Survey Indices

Stratified mean weight ( kg ) per tow and mean number per tow of SNE-MAB windowpane flounder from the NEFSC autumn (October 1963-1999) bottom trawl surveys are presented in Table P2. NEFSC autumn survey biomass indices are also shown in relation to the landings for this stock in Figure P1. Both landings and survey biomass indices appear to have stabilized since 1995 at the lowest level on record.

### 3.0 Harvest Control Rule

The MSY-based control rule for SNE-MAB windowpane flounder adopted in Amendment 9 was derived from survey-based proxies of biomass and exploitation. The control rule defines a maximum sustainable yield for the stock of 900 mt . The threshold F is defined as an FMSY proxy ( $=2.24$ ) when the NEFSC autumn survey index is greater than $0.41 \mathrm{~kg} /$ tow (minimum biomass threshold equal to a BMSY proxy) and declines linearly to zero at $25 \%$ of the BMSY proxy ( $=0.10 \mathrm{~kg} /$ tow $)$. The target exploitation index is defined as the 80 th percentile of the FMSY bootstrap estimates (=1.60) (Figure P2).

Exploitation indices (catch/NEFSC autumn survey biomass index) during 1975-1999 are presented, in Table P3 and Figure P3, in relation to the harvest control rule FMSY proxy (=2.24). The 1997-1999 mean exploitation index equals 0.84 and the mean of the 1997-1999 autumn mean weight per tow index equals 0.14 (Figure P2).

### 4.0 Sources of Uncertainty

- Stock structure is uncertain.
- Discarding is not quantified and may a significant fraction of the catch given recent groundfish retention restrictions.
- Vessel trip reports have been used to prorate the landings, since 1995, and a fraction of the landings from Southern New England may have been reported as Georges Bank landings or vice versa.

## Q. Mid-Atlantic Yellowtail Flounder by S.X. Cadrin

### 1.0 Background

The stock has been at relatively low abundance in recent years (Overholtz and Cadrin 1999, Cadrin 2000). This report updates catch through 1999 and survey indices through 2000.

### 2.0 2000 Assessment

### 2.1 1999 Landings

Historical landings were revised according to weighout records. Recent landings (1994-1999) were prorated as described in the Georges Bank assessment (Cadrin et al. 1998; Table Q1; Figure Q1). Landings from Mid-Atlantic yellowtail increased by 118\% from 1998 to 1999.

### 2.3 1999-2000 Survey Indices

Survey abundance and biomass indices are reported in Table Q1. Estimates are from valid tows in the Mid-Atlantic area (offshore strata 1, 2, 69, 70, 73, 74), standardized according to net, vessel, and door changes (Cadrin et al. 1998). All survey indices of total biomass slightly decreased in 2000 (Figure Q2).

### 3.0 Assessment Results

The average fall biomass index for the last three years (1997-1999 average $=0.26 \mathrm{~kg} / \mathrm{tow}$ ) is $2 \%$ of the $\mathrm{B}_{\text {MSY }}$ proxy ( $1963-1972$ median $=11.69 \mathrm{~kg} /$ tow ) and well below the biomass threshold $\left(\mathrm{B}_{\mathrm{MSY}} / 2=5.85 \mathrm{~kg} /\right.$ tow; Figure Q3). The average exploitation index (landings/fall survey biomass index) for the last three years (2.01) is $724 \%$ of the $\mathrm{F}_{\text {MSY }}$ proxy ( 0.28 ), derived as the MSY proxy (1964-1969 average annual landings, 3300 mt ) divided by the $\mathrm{B}_{\text {MSY }}$ proxy.

### 4.0 Harvest Control Rule

The SFA control rule specifies a biomass threshold of $50 \% \mathrm{~B}_{\mathrm{MSY}}$, a maximum F threshold of $\mathrm{F}_{\text {MSY }}$, and exploitation index (landings/fall survey biomass index) as the metric for fishing mortality. When biomass is less than $B_{\text {MSY }}$, threshold $F$ decreases linearly to zero at $1 / 4 \mathrm{~B}_{\mathrm{MSY}}$. When biomass is below $1 / 4 \mathrm{Bmsy}$, threshold $\mathrm{F}=0$. Target F is $60 \%$ of $\mathrm{F}_{\text {MSY }}$ when biomass exceeds $\mathrm{B}_{\mathrm{MSY}}$, and decreases linearly to zero at $1 / 4 \mathrm{~B}_{\mathrm{MSY}}$.

The amendment \#9 $\mathrm{B}_{\text {MSY }}$ proxy is based on 1963-1972 survey indices. However, strata 69-74 were not sampled until 1967. Therefore the 1963-1972 series is inconsistent. A revised $\mathrm{B}_{\text {MSY }}$ proxy based on the 1967-1972 median biomass index would be slightly greater ( $12.91 \mathrm{~kg} / \mathrm{tow}$ ).

### 5.0 Sources of Uncertainty

- Estimates of prorated landings and discard ratios are based on preliminary logbook data and are subject to change.
- The Mid-Atlantic yellowtail resource may not be self-sustaining and may be an extension of the southern New England stock.

## R. Gulf of Maine Haddock by R.W. Brown

### 1.0 Background

The Gulf of Maine haddock stock was last assessed at SAW/SARC 2 in 1986 (NMFS-NEFSC 1986). At the time of the 1986 assessment, landings had declined from $7,600 \mathrm{mt}$ in 1983 to $3,000 \mathrm{mt}$ in 1985. Although no formal analysis of fishing mortality was attempted, fishing mortality was assumed to be relatively high. The fishery in the mid 1980s was being supported by spill over of large year classes from Georges Bank, and research vessel surveys indicated that recruitment in the Gulf of Maine was extremely poor. The Gulf of Maine haddock stock was not updated during the 1999 assessment process for groundfish stocks (NDWG 2000).

Although the last formal SAW/SARC assessment was in 1986, the Status of Stocks section for this stock has been updated on numerous occasions. In the most recent update (Brown 2000), both landings and research survey indices had declined sharply between the mid 1980s and the mid 1990s. Some increases in both landings and survey indices were observed in the late 1990s; however, the stock was determined to be in an overfished condition and that overfishing has been occurring with reference to the Amendment 9 MSY-based harvest control rule.

### 2.0 Fishery Catches and Research Survey Indices

## Historical Landings

Following recruitment of the 1975 and 1978 year classes, landings of haddock in the Gulf of Maine exceeded 6,000 mt from 1980 to 1984. Landings declined steadily from 1982 and the mid 1990s, and reached a historic low of 112 mt in 1994. Landings have increased steadily since 1994 reaching $1,000 \mathrm{mt}$ in 1998.

## 1999 Fishery

U.S. trip limit regulations for haddock continued to be liberalized in 1999, and regulations in 1999 were significantly in more liberal in 1999 compared to the 1998 calendar year. The trip limit from January 1 to April 1999 was 3,000 pounds/day up to a maximum of 30,000 pounds/trip, 2,000 pounds/day up to a maximum of 20,000 pounds/trip from May 1 to November 4,1999 , and 5,000 pounds/trip up to a maximum of 50,000 pounds/trip from November 5 to December 31, 1999. However, landings of Gulf of Maine haddock declined from 1,018 mt in 1998 to 668 mt in 1999 (Table 1, Figure 1). Management measures designed to reduce mortality on Gulf of Maine cod may have reduced access to the Gulf of Maine haddock resource in 1999.

## Fishery Independent Information

Abundance (stratified mean number/tow) and biomass (stratified mean weight/tow) survey indices are available for the U.S. Spring (1968 to 2000) and Autumn (1963 to 1999) surveys. Spring survey biomass and abundance indices declined from high levels in the late 1970s to record low levels by 1990 (Table R2; Figure R2). The spring surveys in 1987, 1989, 1990 and 1991 approached the level where the survey had difficulty detecting the presence of haddock in

Gulf of Maine strata. Survey indices in the 1990s have remained at chronic low levels, with the exception of 1997, 1999, and 2000 surveys (Table R2; Figure R2). The 1999 and 2000 abundance indices were the highest observed since 1981, and the biomass index in 2000 was the highest observed since 1985. Most of the tows indicating larger abundance occurred in areas bordering the Georges Bank stock boundary, rather than in areas where the stock was traditionally concentrated.
U.S. autumn survey abundance and biomass indices declined from very high levels in the mid 1960s to low levels in the early 1970s. The indices increased during the late 1970's and early 1980s in response to recruitment of the 1975 and 1978 year classes, and subsequently declined steady to historic low levels in 1991. The autumn surveys in 1990 and 1991 approached the level where the survey had difficulty detecting the presence of haddock in Gulf of Maine strata. Abundance and biomass indices increased moderately in the mid 1990s and sharply beginning in 1996. The 1999 autumn survey abundance index ( 6.73 haddock/tow) and biomass index (4.91 $\mathrm{kg} /$ tow) were the highest observed since 1980 and 1985, respectively. However, these indices are less than $50 \%$ of levels observed during the mid 1960s.

Trends in exploitation indices ( 3 year moving average of catch ( 000 s mt ) divided by the U.S. autumn survey biomass index [kg/tow]) indicate that relative exploitation was relatively low during the 1960 s, rose sharply during the early 1980s and again during the early 1990s (Figure R3). The exploitation index dropped sharply beginning in 1994 and has remained at moderate levels since.

Survey indices at age for both the U.S. spring and autumn surveys indicate the presence of strong year classes through the assessment period. Both surveys exhibit large abundance indices for the 1963, 1975, and 1978 year classes (Figures R4 and R5). Survey indices during the 1980s indicate very low levels of recruitment. During the 1990s, survey indices at age reflect an increase in recruitment and some broadening of age structure. Survey indices corresponding to the 1998 year class are the largest observed since the early 1980s.

### 3.0 Harvest Control Rule Evaluation

The MSY-based harvest control rule for Gulf of Maine haddock is outlined as follows:

> A maximum sustainable yield of 2,700 mt can be produced when relative stock biomass is $8.25 \mathrm{~kg} /$ tow $\left(B_{M S Y}\right.$ proxy) and the relative exploitation index (catch/autumn biomass index) is 0.29 (f MSY proxy). The maximum fishing mortality rate should be less than $f_{M S Y}$ when stock biomass exceeds $B_{M S Y}$ and less than the fishing mortality that would allow rebuilding in five years when biomass is below $B_{M S Y \text {. Since the intrinsic rate of }}^{\text {population growth }(r=0.20 \text { ) is less than other stocks where a } 10 \text { year rebuilding schedule }}$ was recommended, it is recommended that the minimum biomass threshold should be the biomass that can be rebuilt to $B_{M S Y}$ in five years with no fishing $(F=0.00$ ). This biomass level is slightly greater than $1 / 2 B_{M S Y}$ (average autumn survey biomass index of 4.38 kg tow).

The harvest control is shown graphically in Figure R6. Based on 1997 to 1999 autumn survey results, the current biomass proxy ( $3.41 \mathrm{~kg} /$ tow $)$ is less than $\mathrm{B}_{\text {threshold }}(4.38 \mathrm{~kg} / \mathrm{tow})$, and the F proxy $(0.247)$ is greater than $1999 \mathrm{~F}_{\text {Target }}$ proxy of 0.00 .

### 4.0 Conclusions

In recent years, exploitation indices have declined from previously high levels, and there has been a moderate increase in landings that appears to be associated with higher levels of abundance. U.S. spring and autumn survey indices provide evidence of increases in abundance and biomass within the stock area. Survey abundance at age indices provide evidence for broadening of the size and age structure of the population. Recent survey indices for younger ages provide evidence of significantly improved recruitment, especially indices corresponding to the 1998 year class. Despite indications of increased abundance and recruitment, biomass remains well below $\mathrm{B}_{\text {MSY }}$.

### 5.0 Sources of Uncertainty

- There is insufficient length and age sampling of U.S. commercial landings to reliably estimate catch at age for this stock.
- The magnitude of discarding due to bycatch and in response to U.S. management regulations is uncertain.

## S. Atlantic Halibut by Jon Brodziak

### 1.0 Background

The Atlantic halibut (Hippoglossus hippoglossus) is distributed from Labrador to southern New England in the northwest Atlantic (Bigelow and Schroeder 1953). The Atlantic halibut stock within Gulf of Maine and Georges Bank waters (NAFO Subarea 5) has been exploited since the 1830s. This resource is currently depleted and is not expected to rebuild in the near future (NEFMC 1998). This working paper updates fishery and survey information to evaluate stock status.

### 2.0 Fishery

Records of Atlantic halibut landings from the Gulf of Maine and Georges Bank begin in 1893 (Table S1). Substantial landings occurred prior to this, however, as the halibut fishery declined in the late 1800s (Hennemuth and Rockwell 1987). Landings have decreased since the 1890s as components of the resource have been sequentially depleted. Annual landings averaged 662 mt during 1893-1940 and declined to an average of 144 mt during 1941-1976. Since 1977, landings have averaged $95 \mathrm{mt} \cdot \mathrm{yr}^{-1}$. Reported landings in 1999 were 20 mt . Of these, 12 mt were landed by domestic fishermen ( $60 \%$ ) with the remainder landed by Canadian fishermen (Division 5Zc).

### 3.0 Survey Indices

The Northeast Fisheries Science Center spring and autumn bottom trawl surveys provide measures of the relative abundance of Atlantic halibut within the Gulf of Maine and Georges Bank (Offshore survey strata 13-30 and 36-40, Table S2). Both indices have high inter-annual variability since relatively few halibut are captured during these surveys; in some years, no halibut are caught. The survey indices suggest that relative abundance increased during the 1970s to early 1980s and subsequently declined in the 1990s. It is unknown whether abundance trends in the Gulf of Maine and Georges Bank have been influenced by changes in the seasonal distribution and availability of Atlantic halibut, however.

### 4.0 Status Update

Based on updated spring and autumn survey data, Atlantic halibut biomass within the Gulf of Maine and Georges Bank remains very low. Swept-area biomass indices in spring 2000 and autumn 1999 were both less than 100 mt (Figure S1). Thus, even if survey catchability was as low as $25 \%$, current stock biomass, as indexed by the 5 -year moving average of swept-area biomass, would be below the biomass threshold of $2,700 \mathrm{mt}$ (Figure S2). Although no estimates of fishing mortality are available, exploitation rate indices (annual landings/5-year moving average of survey index) suggest that exploitation rates have probably been stable since the 1970s, and may have declined during the 1990s (Figure S3). Thus, the Atlantic halibut stock in the Gulf of Maine and Georges Bank remains depleted and exploitation rates do not appear to have increased since the 1970s.

### 5.0 Harvest Control Rule

In the 1998 report on overfishing definitions and its Supplement (NEFMC 1998), the overfishing review panel recommended proxies for the stock biomass ( $\mathrm{B}_{\text {MSY }}$ ) and fishing mortality rate ( $\mathrm{F}_{\text {MSY }}$ ) that would produce the largest long-term potential yield. Based on yield-per-recruit and biomass-per-recruit calculations, the panel concluded that $\mathrm{B}_{\text {MSY }}$ was roughly $5,400 \mathrm{mt}$ and that $\mathrm{F}_{\text {MSY }}$ was about 0.06 per year with an associated long-term potential yield of 300 mt per year. Accordingly, the panel recommended that the biomass threshold ( $\mathrm{B}_{\text {THRESHOLD }}$ ) be set to $1 / 2$ of $\mathrm{B}_{\text {MSY }}$ so that $\mathrm{B}_{\text {THRESHoLD }}=2,700 \mathrm{mt}$ and that the target fishing mortality rate ( $\mathrm{F}_{\text {TARGET }}$ ) be set to $60 \%$ of $\mathrm{F}_{\text {MSY }}$ so that $\mathrm{F}_{\text {TARGET }}=0.04$ per year. The panel also recommended that an appropriate harvest control rule would be to keep fishing mortality as close to zero as practicable until the Gulf of Maine and Georges Bank stock was rebuilt. To evaluate the harvest control rule, the review panel compared swept-area biomass estimates from the NEFSC spring and autumn surveys with the threshold. The panel concluded that the stock was depleted because, on average, the sweptarea biomass index was far below $\mathrm{B}_{\text {THRESHoLD }}$ given an implicit assumption that survey catchability was probably on the order of $25-50 \%$.

### 6.0 Sources of Uncertainty

Fishery-dependent information on the size and age composition of Atlantic halibut landings is very limited. The magnitude of discards and unreported landings is uncertain. Fishery-dependent data needs to be collected to accurately quantify the impacts of harvests.

Life history information is limited for this species. In particular, research on growth is needed for age-structured population assessment.

Stock structure of Atlantic halibut within the Gulf of Maine and Georges Bank is uncertain. Wise and Jensen (1959) documented movements of tagged Atlantic halibut between Georges Bank and Browns Bank, but it is difficult to draw any definite conclusions about movement rates from their study.

The current harvest control rule, as proposed by the review panel, should be expressed in terms of relative biomass indices (weight in kg per tow) so that uncertainties about survey catchability do not affect the interpretation of biomass status.

The portion of the Atlantic halibut population within Gulf of Maine and Georges Bank waters is a transboundary stock. Conservation measures for both USA and Canadian fisheries may be needed to rebuild this stock.

1. Spring surveys during 1973-1981 were conducted using a modified 'Yankee 41' trawl; in all other years spring surveys were conducted using a 'Yankee 36 ' trawl.
No adjustment have been made to survey catches for these differences.

Figure S1. Trends in swept-area biomass indices (mt) of Atlantic halibut from NEFSC spring and autumn bottom trawl surveys.

Figure S2. Trends in Atlantic halibut landings from the Gulf of Maine and Georges Bank in comparison to 5 -year moving

Figure S3. Trends in exploitation rate indices for Atlantic halibut from the Gulf of Maine and Georges Bank based on 5 -year moving averages of NEFSC spring and autumn survey indices, 1967-1999

## Section 3. Working Group Comments and Recommendations

The Joint Working Group noted that the quality of the data used for assessment purposes continues to deteriorate. The most serious concerns are:

- Continued reliance on provisional landings estimates by stock which are derived by prorating total landings to stock based primarily on unaudited VTR data.
- Continued deterioration of biological sampling of commercial landings in the ports.
- Continued poor spatial and seasonal coverage of most major gear sectors in the NEFSC Sea Sampling program and the effect on discard estimation accuracy.

The Joint Working Group developed the following generic and stock-specific recommendations:

## 1) Generic Recommendations

The most over-riding concern of the Joint Working Group was the continued deterioration of biological sampling of the commercial landings in the ports in 1999. Poor sampling intensity and seasonal coverage in 1999 required an unprecedented degree of pooling of samples across calendar quarters for many stocks, including Georges Bank cod, Georges Bank haddock, Georges Bank yellowtail flounder, Gulf of Maine cod, Southern New England yellowtail flounder and Cape Cod yellowtail flounder. Other stocks, including American plaice, witch flounder, Georges Bank winter flounder and Southern New England/Mid-Atlantic winter flounder, would have been included in the above list had VPAs been attempted this year.

This is an undesirable outcome and may have biased the estimation of catch numbers at age for use in VPA. In the case of Southern New England yellowtail flounder, poor sampling was the primary factor leading to the rejection of the VPA by the Working Group. In other cases, poor biological sampling contributed substantially to the uncertainty of the assessment results.

Therefore, the Working Group recommends that biological sampling criteria including overall sampling levels and seasonal coverage as specified in annual requests be strictly met.

Regulatory discarding has become an increasingly important component of fishing mortality for several stocks. Accurate estimates of discards depends on the availability of independent observations of kept and discarded components of the catch, obtained primarily from at-sea observer data. However, observer coverage in the groundfish fisheries is sparse, except for the sink gillnet gear sector, due to protected species priorities. Therefore, it has been necessary to rely on Vessel Trip Reports filed by individual vessel operators to estimate discard rates. It is unknown whether these reports are completed in a comprehensive and accurate manner.

Therefore, the Working Group recommends that sea sampling coverage of major gear sectors involved in the Northeast groundfish fisheries be increased to a level which will allow estimation of discard rates for major gear types with sufficient seasonal and spatial resolution. The Working Group suggests that a minimum of 5 sea sample trips be completed within each 2-digit area per quarter for each major gear type (e.g., large mesh otter trawl, small mesh otter trawl, gill net, dredge, etc.).

The Working Group noted a number of inconsistencies in the specification of the Harvest Control Rules across stocks. For example, for index level assessments, where mortality and biomass proxies are derived from research vessel survey biomass indices, approaches used to determine recent conditions vary among stocks (e.g., 3-year averages of exploitation ratio or biomass index). In other cases, reference points are based on absolute biomass and F , while the assessment of current stock conditions is derived from survey indices raised by swept area calculations, or Bmsy and Fmsy incorporate ages which are not part of the exploitable stock.

Therefore, the Working Group recommends that the Harvest Control Rules be re-examined with a goal of achieving a more consistent derivation of reference points and specification of the Control Rule among stocks which are assessed in a similar manner.

## 2) Stock-specific Recommendations

a) Recommendations for Georges Bank cod, as listed in 2000 TRAC Proceedings.

- Determine the effects of the following on NMFS survey indices:

1) exclusion of survey data from areas south of Georges Bank and
2) removal of unusually large catches

- Examine the appropriateness of assuming a flat-topped partial recruitment pattern for recent years.
- Review maturity ogives for 5 Z and 5 Zjm cod and reconcile differences if possible.
b) Recommendations for Georges Bank haddock, as outlined in 2000 TRAC Proceedings:
- Examine options for transformations of survey data to reduce the influence of large tows.
- Explore the use of inverse weighted by the variance of tuning indices relative to VPA formulations.
- Study the reproductive biology and factors affecting changes in maturation schedules.
- Develop consistent methods for inclusion of discards in the construction of the catch-atage matrix.
c) Recommendations for Georges Bank Yellowtail flounder
- USA catches should be characterized by age/length keys dis-aggregated by sex if feasible
- The TAWG and the TRAC should further evaluate biological reference points with particular reference to MSY, including other methods of estimating MSY
- Other biological attributes of the stock should be included in future assessments to help characterize stock status
d) Recommendations for Gulf of Maine cod
- Examine sea sampling and other available data to determine the size composition of 1999 discards,
- Examine spatial aspects of 1999 discard rates with respect to perceived differences in density of cod between inshore and offshore regions of the Gulf of Maine,
- Examine VTR data to evaluate the level of fishing effort applied to Gulf of Maine cod in 1998 and 1999, and
- Examine the VTR data for the presence of outliers with respect to discard rates.
e) Recommendations for witch flounder:
- Examine inconsistency between VPA biomass and survey biomass trends in recent years.

# Publications and Reports of the Northeast Fisheries Science Center 

The mission of NOAA's National Marine Fisheries Service (NMFS) is "stewardship of living marine resources for the benefit of the nation through their science-based conservation and management and promotion of the health of their environment." As the research arm of the NMFS's Northeast Region, the Northeast Fisheries Science Center (NEFSC) supports the NMFS mission by "planning, developing, and managing multidisciplinary programs of basic and applied research to: 1) better understand the living marine resources (including marine mammals) of the Northwest Atlantic, and the environmental quality essential for their existence and continued productivity; and 2) describe and provide to management, industry, and the public, options for the utilization and conservation of living marine resources and maintenance of environmental quality which are consistent with national and regional goals and needs, and with international commitments." Results of NEFSC research are largely reported in primary scientific media (e.g., anonymously-peer-reviewed scientific journals). However, to assist itself in providing data, information, and advice to its constituents, the NEFSC occasionally releases its results in its own media. Those media are in four categories:

NOAA Technical Memorandum NMFS-NE -- This series is issued irregularly. The series typically includes: data reports of long-term or large area studies; synthesis reports for major resources or habitats; annual reports of assessment or monitoring programs; documentary reports of oceanographic conditions or phenomena; manuals describing field and lab techniques; literature surveys of major resource or habitat topics; findings of task forces or working groups; summary reports of scientific or technical workshops; and indexed and/or annotated bibliographies. All issues receive internal scientific review and most issues receive technical and copy editing.

Northeast Fisheries Science Center Reference Document -- This series is issued irregularly. The series typically includes: data reports on field and lab observations or experiments; progress reports on continuing experiments, monitoring, and assessments; background papers for scientific or technical workshops; and simple bibliographies. Issues receive internal scientific review, but no technical or copy editing.

Fishermen's Report -- This information report is a quick-turnaround report on the distribution and relative abundance of commercial fisheries resources as derived from each of the NEFSC's periodic research vessel surveys of the Northeast's continental shelf. There is no scientific review, nor any technical or copy editing, of this report.

The Shark Tagger -- This newsletter is an annual summary of tagging and recapture data on large pelagic sharks as derived from the NMFS's Cooperative Shark Tagging Program; it also presents information on the biology (movement, growth, reproduction, etc.) of these sharks as subsequently derived from the tagging and recapture data. There is internal scientific review, but no technical or copy editing, of this newsletter.

OBTAINING A COPY: To obtain a copy of a NOAA Technical Memorandum NMFS-NE or a Northeast Fisheries Science Center Reference Document, or to subscribe to the Fishermen's Report or the The Shark Tagger, either contact the NEFSC Editorial Office (166 Water St., Woods Hole, MA 02543-1026; 508-495-2228) or consult the NEFSC webpage on "Reports and Publications" (http: //www.nefsc.nmfs.gov/nefsc/publications/).

ANY USE OF TRADE OR BRAND NAMES IN ANY NEFSC PUBLICATION OR REPORT DOES NOT IMPLY ENDORSEMENT.
