Abstract

The processes governing the temporal and spatial patterns of isoprene and monoterpenes emitted by a rainforest in the central Amazon region of Brazil is investigated using a combination of field experiments and numerical simulations. Specifically, Large Eddy Simulations (LES) are used to resolve emissions of isoprene and monoterpenes, turbulent transport, and air chemistry. The coupled chemistry-transport LES included the effects of isoprene and monoterpenes reactivity due to reactions with hydroxyl radical and ozone. The LES results are used to compute vertically resolved budgets of isoprene and monoterpenes in the rainforest canopy in response to emissions, turbulent transport, surface deposition, and air chemistry. Results indicated that emission and dispersion dominated the isoprene budget as the gases were transported out of the canopy space. In a region limited by nitrogen oxides (with prevailing nitric oxide levels of < 0.5 parts per billion), the in-canopy chemical destruction removed approximately 10% of locally emitted monoterpenes. Hydroxyl radical production rates from the ozonolysis of monoterpenes amounted to $\approx 2 \times 10^6$ radicals cm⁻³ s⁻¹ and had similar magnitude to the light-dependent hydroxyl radical formation. One key conclusion was that the Amazonia rainforest abundantly emitted monoterpenes whose in-canopy ozonolysis yielded hydroxyl radicals in amounts similar to the magnitude of light-dependent formation. Reactions of monoterpenes and isoprene with hydroxyl radical and ozone were necessary for the maintenance of the Amazon rainforest canopy as a photochemically active environment suitable to generate oxidants and secondary organic aerosols.

1 1. Introduction

The Amazon rainforest represents the most expansive and contiguous region of the world 2 with the largest and the most diverse emissions of biogenic volatile organic compounds (BVOCs) 3 (Jardine et al., 2011, 2015a,b). Due to the suitable environmental conditions to promote productive 4 biosynthesis and emissions – namely high air temperature (> 20 $^{\circ}$ C) and sunlight – the rainforest 5 releases isoprenoid molecules year round (Arneth et al., 2011; Sindelarova et al., 2014). Plants in the 6 Amazon emit rich blends of BVOCs that are mostly comprised of isoprene (C_5H_8), monoterpenes 7 $(C_{10}H_{16})$, sesquiterpenes $(C_{15}H_{24})$, and oxygenated compounds such as methanol (CH_3OH) (Jardine 8 et al., 2011, 2015a). Because of strong sources, isoprene and monoterpenes can reach maximum 9 ambient mixing ratios of 20 and 2 parts per billion (ppb) on a volume basis, respectively, with some 10 seasonality in emissions due to foliage ontogeny (Alves et al., 2016; Wei et al., 2018; Yáñez-Serrano 11 et al., 2018). 12

In the tropical atmospheric boundary layer (ABL) overlying the rainforest, the observed large 13 hydroxyl radical (HO) reactivities arise from the abundant emissions of BVOCs (Edwards et al., 14 2013; Nölscher et al., 2016; Pfannerstill et al., 2021). In response to the pletora of emitted reactive 15 chemical species, the HO budget in the ABL is adjusted by BVOC levels (Liu et al., 2016, 2018). 16 This influence occurs because the principal sink of isoprene is its reaction with HO. The oxidation 17 of isoprene generates hydroperoxy aldehydes (HPALD) whose rapid photolysis results in a first-18 generation of hydroperoxyl radical (HO₂) and HO (Taraborrelli et al., 2012; Fuchs et al., 2013; 19 Rohrer et al., 2014; Bates and Jacob, 2019; Schwantes et al., 2020). In addition, ozonolysis of 20 monoterpenes (Atkinson et al., 1992; Aschmann et al., 2002; Herrmann et al., 2010) produces 21 relatively high yields of HO, thereby contributing to the oxidation capacity of the tropical ABL 22 (Lelieveld et al., 2008; Whalley et al., 2011). In general, the reactions of BVOCs with ozone (O_3) , 23 HO, and nitrate radical (NO_3) contribute to the formation of additional oxidants (e.g., organic 24 peroxide radicals) and secondary organic aerosols (SOAs) (Fuentes et al., 2000; Pöschl et al., 2000, 25 2010). Therefore, BVOCs can indirectly play critical roles in cloud formation processes (Pöschl 26 et al., 2010) and regional climate (Barr et al., 2003). Despite the recent progress in discerning 27 the chemical cycles of BVOCs, additional investigations are still required to determine (i) the 28 mechanisms governing their turbulent transport from the biosphere to the ABL and (ii) the ensuing 29 chemistry under the influences of varying levels of nitrogen oxides (NOx). 30

Turbulence is the primary agent transporting BVOCs and associated chemical processes oc-31 curring within and above the rainforest canopy. During the daytime, only the upper half of the 32 rainforest canopy is well mixed whereas its lower region is either partially or poorly mixed due 33 to the effective momentum sink in the forest crown (Fitzjarrald et al., 1990; Kruijt et al., 2000; 34 Gerken et al., 2017). For the most part, the rainforest canopy remains poorly mixed at night due 35 to buoyancy destruction of mechanically produced turbulence (Fitzjarrald and Moore, 1990; Santos 36 et al., 2016; Freire et al., 2017). Turbulence characteristics give rise to median canopy residence 37 times that can approach 30 minutes in the lower canopy layers under statically neutral conditions 38 (Gerken et al., 2017). Because such air parcel residence times are comparable to lifetimes of many 39 BVOCs (Fuences et al., 2000), appreciable amounts can undergo reactions before they are vented 40 out of the forest environment. Furthermore, the transport of BVOCs is impacted by sweeps and 41 ejections from coherent mixing-layer eddies (Raupach et al., 1996; Finnigan, 2000) whose penetra-42 tion depth into the canopy is limited by the dense Amazon plant canopy (Fitzjarrald et al., 1990; 43 Kruijt et al., 2000). The need to explore turbulent transport and chemistry in concert is further 44 highlighted as air parcels emanating from the canopy are enriched with plant-emitted hydrocarbons 45 as descending air motions transport O_3 and other atmospheric oxidants into the canopy airspace 46 (Fuentes et al., 2007; Gerken et al., 2016; Freire et al., 2017). 47

Large Eddy Simulations (LES) can provide realistic estimates of the links between the turbulence 48 features in both the plant canopy and the atmospheric boundary layer, and the chemistry of isoprene 49 and monoterpenes, which are ordinarily under resolved in most regional models. Early LES studies 50 involving plant canopies applied to passive scalars (Shaw and Schumann, 1992; Edburg et al., 2011) 51 and treated reactive gases (Patton et al., 2001) based on their exponential decays due to chemical 52 reactions. Recent LES investigations coupled condensed (Vilà-Guerau de Arellano et al., 2011; 53 Ouwersloot et al., 2013) and detailed (Su et al., 2016; Khan et al., 2021) photochemical mechanisms 54 with atmospheric turbulence to determine the oxidation of isoprene in convective boundary layers. 55 but did not include in-canopy chemical reactions. Patton et al. (2016) integrated canopy and 56 convective boundary-layer processes to link turbulence and scalars, emphasizing the potential to 57 extend the LES approach to include photochemical mechanisms necessary for studying detailed 58 chemical reactions of BVOCs in forest canopies. In addition, stochastic Lagrangian transport 59 models (Strong et al., 2004; Rinne et al., 2012) have been applied to determine the reactions 60

⁶¹ isoprene and monoterpenes with oxidants as first order decay in and above forest canopies.

Building on these earlier studies, this investigation was framed around three objectives. First, we 62 determined the processes governing temporal and spatial patterns of isoprene and monoterpenes in 63 response to emissions, turbulent transport, surface dry deposition, and chemical reactions. Second, 64 we estimated the fraction of locally emitted isoprene and monoterpenes destroyed in the rainforest 65 canopy due to surface deposition and chemical reactions occurring under the influences of observed 66 O_3 and nitric oxide (NO) levels. Third, given the substantial daytime concomitant emissions 67 of isoprene and monoterpenes in the rainforest, we ascertained the feedback generated between 68 ozonolysis of monoterpenes and chemical destruction of isoprene via its reaction with HO. To 69 achieve these objectives, we included in an updated LES the algorithm for the explicit treatment 70 of chemical reactions to resolve turbulent transport of mass, energy, and momentum in and above 71 a rainforest canopy. 72

73 2. Methodology

74 2.1. Study site description and field measurements

Field data used here were collected during April 2014 to January 2015 (Fuentes et al., 2016). 75 The study site is located approximately 60 km north-northwest of Manaus, Amazonas, Brazil. The 76 site consists of dense primary rainforest with a canopy height (h_c) of approximately 35 m. The leaf 77 area index (LAI) ranged from 5.7 to $7.3 \text{ m}^2 \text{ m}^{-2}$ (McWilliam et al., 1993; Marques Filho et al., 78 2005; Tota et al., 2012), depending on the location of measurements. Terrain consists of gentle 79 valleys and hills. A 50-m meteorological tower is located on an approximately 60-m high plateau. 80 Located in the middle of the forest, the tower served as the platform to mount nine triaxial sonic 81 anemometers (CSAT-3, Campbell Scientific Inc, Logan, UT) to measure the three wind components 82 (u, v, and w), their turbulent fluctuations, and the sonic temperature at 20 Hz. Measurement 83 heights were $z h_c^{-1} = 1.38, 1.15, 1.0, 0.90, 0.70, 0.63, 0.52, 0.39, and 0.20$. One additional sonic 84 anemometer was placed near the tower at $z h_c^{-1} = 0.04$. Mean air relative humidity and temperature 85 (HMP-155, Vaisala, Vantaa, Finland) were measured at the 32-m height. Ambient O_3 mixing 86 ratios (49i, Thermo Fisher Scientific, Waltham, MA) were measured at a frequency of 1 Hz. A 87 Proton Transfer Reaction Mass Spectrometer (PT-RMS, Ionicon Analytik, Innsbruck, Austria) 88 measured isoprene, aggregated monoterpene, and the sum of methyl-vinyl ketone and methacrolein 89

(MVK+MACR) mixing ratios. Both instruments shared a common gas sampling inlet equipped 90 with a rain-shield and placed at $z h_c^{-1} = 1.14$ and were housed in a temperature-controlled shed, 91 located 5 m from the tower. Air samples were drawn at a rate of $12 \,\mathrm{L\,min^{-1}}$ through a $1-\mu\,\mathrm{m}$ pore 92 size Teflon filter and through a 3/8-inch outer diameter Teflon tube that was shielded from sunlight. 93 Photosynthetically active radiation (PAR) was measured at $z h_c^{-1} = 1.46$, and air temperature was 94 recorded at $z h_c^{-1} = 1.46, 1.21, 0.8, 0.44, 0.15$. Ambient air pressure as well as turbulent fluxes of 95 sensible and latent heat $(z h_c^{-1} = 1.46)$ were averaged in 30-minute intervals. Additional details on 96 the study site, measurements, and postprocessing of data are provided elsewhere (Fuentes et al., 97 2016). 98

99 2.2. Large Eddy Simulation

A description of the governing equations and the main features of the LES are provided here and additional details are reported elsewhere (Chamecki et al., 2008, 2009; Pan et al., 2014). For incompressible flows ($\nabla \cdot \tilde{\mathbf{u}} = 0$), the filtered momentum and air mass conservation equations were solved to obtain the three dimensional wind field ($\tilde{\mathbf{u}}$):

$$\frac{\partial \tilde{\mathbf{u}}}{\partial t} + (\tilde{\mathbf{u}} \cdot \nabla) \, \tilde{\mathbf{u}} = -\frac{1}{\rho} \nabla \left(\tilde{p} + P \right) - \mathbf{g} \left(\frac{\tilde{\theta}_v - \langle \tilde{\theta}_v \rangle}{\langle \tilde{\theta}_v \rangle} \right) - \nabla \cdot \tau_{\text{sgs}} - \mathbf{d}. \tag{1}$$

Terms on the right hand side of Equation (1) represent the resolved pressure gradient force, buoyancy force, subgrid-scale (SGS) force, and the drag force exerted by the forest canopy (represented as a porous medium with negligible fractional solid volume). Hereafter, ρ is air density, \tilde{p} is resolved modified pressure (as it also includes the SGS turbulent kinetic energy), P is the mean pressure used to impose a mean pressure gradient to drive the flow, $\tilde{\theta}_v$ is virtual potential temperature, **g** is the gravitational acceleration, τ_{sgs} is the SGS stress tensor, and angle brackets indicate average over horizontal planes. Following Shaw and Schumann (1992), the canopy drag (**d**) was determined as

$$\mathbf{d} = C_d \ \left(\mathbf{P} \ a(z) \right) \cdot \left(|\tilde{\mathbf{u}}| \tilde{\mathbf{u}} \right), \tag{2}$$

where C_d is a constant drag coefficient (form drag), **P** is a diagonal tensor that projects the total leaf area density onto planes perpendicular to each of the three spatial dimensions (Pan et al., 2014), and a(z) is the plant area density assumed to be reasonably approximated by the leaf area density. This study assumed a random orientation of leaves ($P_x = P_y = P_z = 1/2$) and a horizontally homogeneous distribution of LAI for each layer with $C_d = 0.4$. The temporal change of virtual potential temperature $\tilde{\theta}_v$ was expressed as a filtered advection-diffusion equation

$$\frac{\partial \theta_v}{\partial t} + \nabla \cdot \left(\tilde{\mathbf{u}} \, \tilde{\theta}_v \right) = -\nabla \cdot \pi_{\theta_{\mathbf{v}}} + H,\tag{3}$$

where π_{θ_v} is the SGS buoyancy flux, and H is a source term representing the total buoyancy flux from the forest canopy to overlying air layers. Similarly, filtered advection-diffusion-reaction equations were solved for each gaseous chemical species, $\tilde{\chi_i}$

$$\frac{\partial \tilde{\chi}_i}{\partial t} + \nabla \cdot \left(\tilde{\mathbf{u}} \, \tilde{\chi}_i \right) = -\nabla \cdot \pi_{\chi_i} + C_i + E_i - D_i, \tag{4}$$

where π_{χ_i} is the SGS flux for the chemical species, C_i represents the gas net loss or gain due 100 to chemical reactions, and E_i and D_i represent gas emission and deposition, respectively. The 101 filtered equations were closed through SGS momentum fluxes that were determined using the scale 102 dependent Lagrangian dynamic Smagorinsky model (Bou-Zeid et al., 2004). Scalar SGS-fluxes 103 were estimated based on the SGS eddy viscosity and a constant SGS Schmidt number (Sc_{τ} = 0.8). 104 Equations (1) and (3) were discretized using a pseudo-spectral approach in the horizontal directions 105 and a second-order centered finite-difference scheme in the vertical. Equations for the gases were 106 discretized using the finite volume method with the third-order upwind advection scheme SMART 107 (Gaskell and Lau, 1988). The time integration of the LES was advanced through the second-order 108 Adam-Bashforth scheme (Peyret and Taylor, 2012). Lateral boundary conditions were periodic 109 for momentum and all scalars. The upper boundary condition was no-stress/no-flux while a wall 110 model based on Monin-Obukhov similarity (Foken, 2006) was used for the lower boundary condition 111 situated at the forest floor. 112

113 2.2.1. Emissions of biogenic hydrocarbons

The Model of Emissions of Gases and Aerosols from Nature (MEGAN) version 2.1 (Guenther et al., 2012) was used to estimate emissions of isoprene and monoterpene as a function of leaf area density, temperature, and PAR in the canopy. Vertically resolved emissions ($E_i(z)$) for a given gas species (i) were estimated for each plant functional type using (Guenther et al., 2006):

$$E_i(z) = C_{ce} \epsilon_i \gamma_P(z) \gamma_T(z) \gamma_A \gamma_{SM} \gamma_{CO_2} a(z).$$
(5)

In Equation (5), C_{ce} is a canopy environment model dependent factor (here $C_{ce} = 0.17$ is adopted to adjust emissions to observed ambient gas levels (Kuhn et al., 2007; Karl et al., 2007)), ϵ_i is

a plant species specific emission factor. The $\gamma_P(z)$ and $\gamma_T(z)$ functions consider the influences of 120 PAR and temperature on emissions of isoprene and monoterpenes. As documented by previous field 121 studies (Rinne et al., 2002; Kuhn et al., 2002; Jardine et al., 2015a), in the Amazon emissions of 122 monoterpenes also depend on PAR levels. The activity factors of leaf age (γ_A) , soil moisture (γ_{SM}) , 123 and carbon dioxide inhibition on hydrocarbon emissions (γ_{CO_2}) were assumed to equate unity as 124 done by Alves et al. (2016). The vertically resolved temperature and PAR functions, $\gamma_T(z)$ and 125 $\gamma_P(z)$, modulating basal emissions were calculated following Equations (3–11) in Guenther et al. 126 (2012). A two-stream radiative transfer module (Sellers, 1985; Gu, 1999; Moon et al., 2020) was 127 used to estimate PAR for shaded and sunlit leaves. Fractions of sunlit leaves were determined 128 assuming exponential decreases in such foliage with cumulative leaf area as in Dai et al. (2004). 129 Basal emission of isoprene was based on $\epsilon_{Iso} = 7.0 \text{ mg m}^{-2} \text{ h}^{-1}$ and emissions of monoterpenes were 130 calculated as the sum of eight monoterpenes listed in the MEGAN formulation (Guenther et al., 131 2012) and identified in the studied forest canopy (Jardine et al., 2015a). Emission profiles (Figures 132 1) were calculated using Equation (5) every 30 minutes during the day and linearly interpolated 133 for times in between. To avoid the repeated execution of the canopy radiative transfer algorithm 134 within the LES, the BVOC emissions were computed offline and externally imposed on the LES. 135

136 2.2.2. Summary of reactions involving isoprene and monoterpenes

The third research objective was achieved by estimating the oxidation of isoprene and monoter-137 penes in and above the rainforest canopy, utilizing a condensed photochemical mechanism (Table 138 S1). Based on the initial gas concentrations, the mechanism calculates formation and destruc-139 tion of HO, NO₃, and O₃ due to photooxidation of BVOCs. The HO initiates the oxidation of 140 isoprene (ISOP) and monoterpenes (MON), resulting in the formation of peroxyl radicals $(RO_2,$ 141 TPO_2 , R9 and R28. As done in previous studies (Van Stratum et al., 2012), the reaction of ISOP 142 with O_3 is not included in the chemical mechanism due to the extremely low reaction coefficient 143 $(k_{O_{3.Iso}} = 1.30 \times 10^{-17} \, cm^3 \, molec^{-1} \, s^{-1}).$ Monoterpenes also react with NO₃ to form free radicals 144 (TPO₂), R30. The ozonolysis of monoterpenes generates HO, methyl vinyl keone (MVK), and 145 hydroperoxyl radicals (HO_2) , see R29 in Table S1. The RO₂ and TPO₂ are short-lived and in 146 the presence of NO can produce NO₂, HO₂, MVK, HO, and formaldehyde (CH₂O), R15 and R31. 147 Additional reactions involving MVK with HO generate HO₂ and CH₂O, R10, which can undergo 148 photolysis to generate HO₂, R6. Also, the reaction of CH₂O with HO produces HO₂, R16, which 149

subsequently combines with NO to generate HO plus NO_2 . In low-NO environments (i.e., [NO] <150 30 parts per trillion (ppt)), the HO_2 can react with O_3 to form HO whereas the reaction of HO_2 151 with NO dominates and produces HO and NO_2 in NO-laden air masses (Atkinson, 2000). The 152 photolysis of NO₂ generates NO and ground-triplet state atomic oxygen $(O(^{3}P))$, which readily 153 combines with O_2 to produce O_3 , R5. Therefore, this summary of reactions (R9 to R34) indicates 154 that one key role of BVOCs is to convert NO to NO_2 , which is the key precursor of O_3 . The 155 condensed photochemical mechanism (Table S1) is an enhanced version of the one described in 156 Heus et al. (2010) and tested for isoprene chemistry in numerical simulations applied above the 157 Amazon rainforest (Vilà-Guerau de Arellano et al., 2011). The isoprene mechanism is based on the 158 one reported by Geiger et al. (2003) and Ouwersloot et al. (2013). Monoterpenes are represented 159 as a single chemical species as implemented in the Model for Ozone and Related chemical Tracers 160 (MOZART) version 4 (Emmons et al., 2010) and used by Su et al. (2016). An implicit two-step 161 chemical solver is applied to estimate rates of reactions (Verwer, 1994; Verwer and Simpson, 1995). 162 Vilà-Guerau de Arellano et al. (2011) and Su et al. (2016) reported that equilibrium HO concen-163 trations in the current chemical mechanism are 30–50% higher than in the more complete chemical 164 mechanisms due to the unaccounted NO_x sinks in species such organic nitrates (RONO₂). 165

166 2.3. Numerical simulation setup

The modeling domain was $3584 \times 1792 \times 1120 \,\mathrm{m}^3$ and was discretized by $164 \times 82 \times 320$ grid 167 points in the streamwise, crosswise, and vertical direction, respectively. The vertical resolution was 168 set as $\Delta z = 3.5 \,\mathrm{m}$, which yielded ten layers in the canopy. The horizontal model resolution was 169 $\Delta x = \Delta y = 21.85$ m, which corresponded to an aspect ratio of $\Delta x / \Delta z = 2\pi$. The simulation time 170 step was 0.04 s and the chemical mechanism was called every 8 simulation steps. The Coriolis effect 171 was neglected due to the field site's proximity to the Equator. The LAI was set to 6.0 using the 172 vertical leaf area distribution measurements (Tota et al., 2012). Simulations were forced by imposing 173 time dependent mean pressure gradient and heat sources designed to match observed conditions. 174 Simulations from 6:00 h (sunrise) to 12:00 h (all times are given in local time) on 21 September 2014 175 are included in this manuscript. After sunrise, the pressure gradient driving the flow increased so 176 that diurnal cycle of the friction velocity (u_*) at the canopy top closely matched observed values. 177 The mean pressure gradient was determined from the mean force balance $dP/dx = \rho u_*^2/Z_i$ (Z_i is the 178 depth of the convective boundary layer). Due to the time lag required for the flow field to respond 179

to changes in the pressure gradient forcing, the time evolution of the forcing had to be adjusted 180 (see Supplement for details). Vertically-resolved kinematic heat fluxes $(\overline{w'\theta'_n})$ from eddy covariance 181 measurements were temporally smoothed (using a linear fit) and vertically interpolated to the 182 numerical grid levels to produce buoyancy fluxes, $B_{\rm smooth}(z,t)$. In the lower half of the canopy 183 $(z/h_c < 0.5)$ fluxes were set to zero as observed daytime fluxes were negligible. The heat source, 184 H, in Equation (3) was specified as $H(z,t) = B_{\text{smooth}}(z,t)/dz$. Similarly to H, the in-canopy water 185 vapor source was specified assuming a constant Bowen ratio in the vertical as determined from 186 above-canopy measurements (Fuentes et al., 2016). 187

Upper air sounding data taken at a site 20 km away from the tower were used to initialize the 188 LES. The θ_v profile was constant for the first 50 m above ground and then θ_v increased by the 189 gradient of $\partial \theta_v / \partial z = 0.024 \,\mathrm{K \,m^{-1}}$ between 50 and 150 m and $\partial \theta_v / \partial z = 0.016 \,\mathrm{K \,m^{-1}}$ above 150 190 m. The initial surface temperature was set to 299 K and the specific humidity profile was set to 191 $17.0 \,\mathrm{g\,kg^{-1}}$ below $150 \,\mathrm{m}$ and $13.0 \,\mathrm{g\,kg^{-1}}$ above $150 \,\mathrm{m}$. Ozone levels were initialized at 8 ppb at 192 the surface and then linearly increased by 0.056 ppb m^{-1} until they reached a constant level above 193 450 m. Concentrations of chemical species were initialized as constant values within the entire 194 domain (a value of zero was chosen unless indicated in Table 1). Due to the unpolluted conditions 195 at the study site, NO₂ was set to 0.1 ppb with 0.1 ppb of NO near the surface. The soil NO source 196 of 5×10^{-4} ppb m s⁻¹ was considered (Vilà-Guerau de Arellano et al., 2011). Ozone deposition to 197 the canopy was modeled following Wolfe and Thornton (2011). Isoprene deposition to the ground 198 surface was considered through a deposition velocity, $V_{dep} = 2.7 \,\mathrm{mm \, s^{-1}}$ (Gordon et al., 2014). At 199 the ground, zero flux of monoterpenes was assumed. Three numerical simulations were performed. 200 The first simulation (hereafter labeled as *Iso*) included emissions and chemistry of isoprene only 201 (R1 - R27, Table S1). The *Iso* scenario was done to separate the influences of isoprene sinks 202 associated with HO production from ozonelysis of monoterpnes. There are monoculture forested 203 ecosystems that only emit isoprene (Fuentes et al., 1999). The second simulation combined isoprene 204 and monoterpenes (Mon), R28 – R34. In this simulation, monoterpenes were represented by a 205 single chemical species whose reactivity $(k_{O_{3,Mono}} = 1.82 \times 10^{-16} \, cm^3 \, molec^{-1} \, s^{-1})$ was calculated 206 as the weighted geometric mean of the composition of monoterpenes observed at the study site 207 (Jardine et al., 2015a). The third simulation (Pin) assumed that the emitted monoterpenes had the 208 reactivity of α -pinene $(k_{O_{3,Pin}} = 8.09 \times 10^{-17} \, cm^3 \, molec^{-1} \, s^{-1})$ as assumed in other atmospheric 209

chemistry models (Emmons et al., 2010). Finally, for the purposes of assessing the importance of chemistry versus transport of monoterpenes, non-reactive tracers were also included in the simulations. These were referred to as passive monoterpenes (Mon_{Pas}), but their emission and deposition were estimated in the same manner as the reactive chemical species.

214 2.4. Fluxes and budgets of isoprene and monoterpenes

The LES results were analyzed for the canopy region $(0 \le z \le h_c)$. Average gas mixing ratios within the canopy volume were obtained from Equation (4) by calculating averages over horizontal planes (temporal averages were also obtained over periods of 10 minutes). Resulting averages were vertically integrated to derive the change of gas mixing ratio with time $(\frac{d\langle \tilde{\chi_j} \rangle_{\text{Can}}}{dt})$, given by

$$\frac{d\langle \tilde{\chi}_j \rangle_{\text{Can}}}{dt} = \frac{1}{h_c} \left[-F_j(h_c) + E_{j,\text{Can}} - D_{j,\text{Can}} + C_{j,\text{Can}} \right].$$
(6)

Here $\langle \tilde{\chi}_j \rangle_{\text{Can}} \equiv h_c^{-1} \int_0^{h_c} \langle \tilde{\chi}_j \rangle_{xy} dz$ is the mean gas mixing ratio inside the canopy, $\langle \tilde{\chi}_j \rangle_{xy}$ is the horizontally-averaged mixing ratio, $F_j(h_c)$ is the total gas flux at the top of the canopy (including contributions from resolved and SGS fluxes). The hydrocarbon flux at the surface was assumed to be zero. The isoprene surface deposition was prescribed as $V_{\text{dep}} = 2.7 \,\text{mm s}^{-1}$ (Gordon et al., 2014; Nguyen et al., 2015) and the deposition of monoterpenes was set to zero.

220 3. Results and Discussion

221 3.1. Canopy emissions of isoprene and monoterpenes

During the rainy season in the central Amazon, prevailing atmospheric conditions from sunrise to 222 local noontime kept recurring day after day. Afternoons became predominantly cloudy and rainfall 223 events mostly occurred during 14:00 to 16:00 local h (Fuentes et al., 2016; Vilà-Guerau de Arellano 224 et al., 2020). Because the principal goal of this study was to estimate the in-canopy oxidation 225 rates of isoprene and monoterpenes, the numerical model simulations focused on a representative 226 day (14 September 2014) during the start of the rainy season. Sunny conditions dominated the 227 period of the numerical simulations, with maximum incoming solar irradiance reaching nearly 1200 228 W m $^{-2}$ around 11:00 h. Clouds appeared around 11:00 h and reduced the incoming sunlight levels 220 during the last hour of simulations (Figure 1a). Air temperature varied from 23 (at 6:30 h) to 32 230 ^oC (at 12:00 h) while wind speed remained below 3.5 m s⁻¹ (Figure 1b, c). Computed emissions 231 of isoprene and monoterpenes increased after sunrise and reached values of 8.0 and 1.5 mg m^{-2} 232

 h^{-1} at 12:00 h (Figure 1d), respectively. Emission rates (Figure 1d) were in good agreement 233 with previously reported canopy-scale fluxes in the central Amazonia region (Rinne et al., 2002; 234 Kuhn et al., 2007). Isoprene emission density profiles changed rapidly with canopy depth (Figure 235 1e), reaching maximum values of 0.4 mg m⁻³ h⁻¹ around 12:00 h at z $h_c^{-1} = 0.6$ where the 236 greatest amount of active biomass was present and most PAR interception occurred. As emissions 237 of monoterpenes were independent of PAR, the bulk of emissions originated from deeper in the 238 forest canopy (z $h_c^{-1} > 0.4$), with maximum emission density values of 0.075 mg m⁻³ h⁻¹ (Figure 239 1f). 240

The thermodynamic conditions of the convective ABL exerted control on the vertical distribu-241 tion of isoprene and monoterpenes. The LES-chemistry coupled model provided high-resolution 242 temporal Z_i variations. Under the assumed atmospheric thermodynamic conditions, simulated Z_i 243 rapidly changed over the course of the morning hours and Z_i values ranged from 200 m at 8:00 h 244 to approximately 760 m at 12:00 h (Figure 2 a). Simulated Z_i values at 11:00 h and 14:00 h were 245 comparable to mixed layer depths of 491 ± 133 m and 813 ± 128 m, respectively, observed 24 246 km away from the study site during the wet season (Fisch et al., 2004). Additional details on the 247 atmospheric boundary layer thermodynamic evolution as well as turbulence statistics are provided 248 in the the Supplement (Figures S1-S4). Meanwhile, canopy emissions of isoprene and monoterpenes 249 contributed to rapid increases in mixing ratios of the gases in the convective boundary layer. Most 250 of the emitted hydrocarbons remained in the convective boundary layer, with mixing ratios close 251 to zero ppb in the entrainment zone above the mixed layer (Figures 2b, c). Isoprene mixing ratios 252 in the ABL exhibited a high sensitivity to variations in Z_i (Wei et al., 2018), so that even small 253 perturbations in the dynamics of the convective boundary layer considerably impacted the vertical 254 distribution and mixing ratios of isoprene and monoterpenes. While nearly constant θ_v prevailed 255 in the well mixed boundary layer above the canopy (Figure 2a), isoprene (Iso, Figure 2b) and 256 monoterpene (Mon, Figure 2c) levels revealed strong vertical gradients in response to the source 257 strength of the gases in the canopy, and the ensuing turbulent transport and air chemistry. The 258 cases of *Iso* and *Mon* exhibited greatest gas gradients near the forest canopy and the magnitude 259 of gradients increased with height in the upper ABL in response to the gas transport to the free 260 atmosphere and the downward transfer of air parcels nearly devoid of isoprene and monoterpenes 261 from aloft to the top of the mixed layer. Within the mixed layer, the *Iso* and *Mon* cases showed 262

relatively invariant gas mixing ratios with altitude due to the effective atmospheric turbulent transport. The appreciable differences estimated between the vertical distribution of Mon and Mon_{Pas} (Figure 2d) near the forest canopy resulted due to the higher reactivity associated with the Moncase.

Simulated ambient levels of isoprene, monoterpenes, and O_3 were contrasted with observations 267 to ascertain the fidelity of LES outputs. At the canopy top (h_c) , during 6:00 to 9:00 h temporal 268 patterns of simulated isoprene (Figure 3a) closely matched observations. Thereafter, estimated 269 levels of isoprene progressively diverged from observations and reached maximum discrepancies 270 around 12:00 h, leading to approximately 30% higher isoprene mixing ratios than observations. 271 Modeled monoterperpene mixing ratios overestimated the observations (Figure 3b). Differences 272 between simulated and observed monotepene levels steadily increased as simulations proceeded, 273 reaching nearly 35% higher monoterpenes mixing ratios than observations (Figures 3b). Previous 274 studies (Alves et al., 2016) also found greater estimated monoterpene mixing ratios than observa-275 tions, with higher mixing ratios of total monoterpenes estimated during daytime in response to the 276 light-dependent emissions (Rinne et al., 2002; Kuhn et al., 2002; Jardine et al., 2015a), and the 277 likely inadequate representation the actual light-dependent behavior of monoterpene emissions in 278 low light conditions in the morning hours. As demonstrated in previous studies (Kuhn et al., 2007; 279 Alves et al., 2016), emissions of isoprene and monoterpenes were likely overestimated in response 280 to variations in the basal emissions throughout the canopy environment. Also, mixing ratios of iso-281 prene and monoterpenes were sensitive to variations in the values of Z_i ((Wei et al., 2018) so that 282 underestimation of simulated mixing-layer heights in the LES may be responsible for the overesti-283 mation of above canopy isoprene and monoterpene mixing ration. Simulated temporal variations 284 of O_3 mixing ratio at the canopy top closely matched observations (Figure 3c), with LES results 285 underpredicting O_3 by an average of 5%. At $zh_c^{-1} = 1.14$, the O_3 levels varied from 12 to 24 ppb 286 over the course of the simulation period (Figure 3c). Once the influences of chemical reactions 287 were integrated for the full canopy, the Iso, Mon, and Pin scenarios produced similar patterns in 288 ambient gas levels at the canopy top (Figure 3). 289

290 3.2. Processes controlling canopy budgets of isoprene and monoterpenes

Emissions and turbulent transport dominated the processes controlling the isoprene budget in the rainforest canopy. At midday, isoprene emissions contributed to 80 ppbv h^{-1} whereas turbulent

transport carried 75 ppbv h^{-1} out of the canopy. On average, surface deposition and air chemistry 293 accounted for 1-2% and < 5% of the total isoprene budget destroyed in the canopy (Figure 4a), 294 respectively. The condensed photochemical mechanism (Table S1) employed to investigate chemical 295 reactions in the canopy did not consider the influences of HO recycling associated with isoprene 296 oxidation (Taraborrelli et al., 2012; Fuchs et al., 2013). The small chemical loss resulted because 297 most of the isoprene was emitted in the forest crown (Figure 1e) where air turbulence became 298 strongest and median air parcel residence times varied from seconds to ten minutes (Gerken et al., 299 2017). Such time scales were much shorter than the isoprene lifetime of about 1.0 hour due to the HO 300 reaction. In addition, limited isoprene emissions occurred in the lower region of the forest canopy 301 (Figure 1e) where actinic irradiance (Moon et al., 2020) and oxidant levels (Freire et al., 2017) 302 ordinarily remained low to drive isoprene chemical reactions. Similar patterns in the budget terms 303 prevailed for monoterpenes, with emissions and turbulent transport contributing with 8.5 and 7.5 304 ppbv h^{-1} (Figure 4b), respectively. For the *Mon* case, in-canopy oxidation removed approximately 305 5-10% of emitted monoterpenes. In contrast, for the *Pin* scenario, reactions destroyed 3-5% of 306 emitted gases due to the lower reactivity (for α -pinene) assumed in the photochemical mechanism 307 (see Figure S5 of the Supplement). Compared to isoprene, the greater chemical loss occurred 308 because emissions of monoterpenes prevailed throughout the canopy (Figure 1f) where air parcels 309 remained long enough to allow chemical reactions to occur and generate HO, thereby producing 310 a positive feedback loop to augment chemical reactions involving HO in the full canopy volume. 311 Previous studies (Makar et al., 1999; Stroud et al., 2005; Fuentes et al., 2007) reported similar 312 results for monoterpenes in temperate forests. Hence, one conclusion is that chemical processing 313 in tropical, dense forests consumes appreciable amounts of monotertpenes (Figure 4b) and needs 314 to be considered in numerical models designed to determine BVOC budgets. 315

Ozone and HO dominated the oxidation of monoterpenes whereas HO controlled the isoprene chemistry in the forest canopy. Based on the individual terms of the mass budget relationship (6), turbulent transport and surface deposition accounted for 38% and 35% of the O₃ budget (Figure 4c), respectively. These results agreed with earlier findings (Freire et al., 2017). On average, the O₃ sink due to chemical reactions in the canopy represented 5% of the canopy budget. The small chemical O₃ sink (Figure 4c) resulted largely in response to the low NO levels (< 0.5 ppb) and relatively slow rate of O₃ reaction with isoprene ($k_{O_{3,Iso}} = 1.30 \times 10^{-17} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$), which was the dominant

hydrocarbon in the forest canopy (Fuentes et al., 2016). The O₃ plus NO reaction only consumed 323 0.5 ppb h^{-1} whereas reactions with monoterpenes removed O_3 molecules at the rate of 0.4 ppb h^{-1} 324 (Figure 4d). Trace NO₂ levels (< 0.1 ppb) prevailed in the forest canopy. As a result, the sink 325 for O_3 due to reaction with NO₂ reached nearly 0 ppb h⁻¹ (Figure 4d). Sesquiterpenes were not 326 considered in the photochemical mechanism, but such gases could represent a significant sink for O_3 327 within the canopy due to their rapid ozonelysis (Jardine et al., 2011, 2015a) whose reactivity value 328 could be as high as $k_{O_{3,Caryo}} = 1.16 \times 10^{-14} \,\mathrm{cm^3 \, molec^{-1} \, s^{-1}}$ for the β -caryophyllene (C₁₅H₂₄) 329 molecule. 330

In the case of HO, chemical reaction rates nearly balanced the net turbulent (upward and down-331 ward) transport, each budget term amounting to absolute values of approximately 350 radicals $\rm cm^{-3} \, s^{-1}$. 332 As expected, the storage term remained close to zero radicals $cm^{-3}s^{-1}$ in response to the rapid 333 formation and destruction of HO (Figure 4e). Individual reactions revealed the salient HO sinks 334 and sources (contributions of select individual reactions were estimated indirectly from the reac-335 tion constants and modeled concentrations). For example, the reaction rate of monoterpenes with 336 HO (R28) produced 1.8×10^6 radicals cm⁻³ s⁻¹ whereas the reaction rate of isoprene with HO 337 (R9) consumed 3.0×10^6 radicals cm⁻³ s⁻¹ (Figure 4 f). The HO source from the ozonolysis 338 of monoterpenes in the rainforest closely agreed with previous estimates of 10^6 radicals cm⁻³ s⁻¹ 339 (Gerken et al., 2016). The HO formation or consumption rates occurred while averaged mixing 340 ratios of monoterpenes and isoprene reached 1 and 10 ppb, respectively, with prevailing NO levels 341 of < 0.5 ppb in the forest canopy. The abundance of isoprene dominated the HO sink in the upper 342 canopy. Due to the high reactivity of monoterpenes with O₃, the HO source from the reaction of 343 monoterpenes with O_3 (R29) greatly exceeded the HO sink from the reaction of monoterpenes with 344 HO (R28). In the forest canopy, O₃ and monoterpenes had much greater mixing ratios than HO 345 levels and also had greater lifetimes. Therefore, the magnitude of the estimated HO source became 346 less affected by competing reactions than the HO sink from isoprene reactions. This finding high-347 lights the crucial role of monoterpenes in maintaining a photochemically active forest environment 348 through the generation of HO. 349

350 3.3. Vertical variability of HO source and sinks in the forest canopy

Source and sink of HO resulting from the oxidation of isoprene and monoterpenes exhibited strong vertical variations in the forest canopy. The LES results showed that HO concentrations

associated with isoprene reaction (R9) increased (i.e., became more negative) with time of day 353 and decreased with canopy depth (Figure 5 a). Maximum HO consumption occurred around 354 12:00 h when the destruction rate reached -4.0×10^6 radicals cm⁻³s⁻¹ in the upper (z/h_c > 355 0.85) canopy. At the canopy depth of $z/h_c = 0.25$, the HO destruction rate was 50% lower 356 than the values determined in the forest crown in response to the reduced actinic irradiance flux 357 due to canopy shading, which reduced photochemical production of HO (R1 + R2), and limited 358 isoprene emissions. In contrast, the HO formation rate resulting from oxidation of monoterpenes 359 (Mon, Pin) increased with time of day and canopy depth (Figure 5 b). Despite the comparatively 360 low ambient O_3 levels in Amazonia ($\overline{O_3}$) ~ 10 ppb) during the wet season (Dias-Junior et al., 361 2017), the ozonelysis of monoterpenes (R29) yielded maximum HO formation rates ranging from 362 $+2.0 \times 10^6$ radicals cm⁻³ s⁻¹ in the lower canopy to $+1.3 \times 10^6$ radicals cm⁻³ s⁻¹ in the forest 363 crown around 12:00 h. Compared to the *Pin* scenario, the *Mon* case contributed to greater HO 364 yield (see the Supplement) due to the higher O_3 reactivity for the assumed average monoterpene 365 $(k_{\rm O_{3,Mono}} = 1.82 \times 10^{-16} \text{ versus } k_{\rm O_{3,Pin}} = 8.09 \times 10^{-17} \, {\rm cm^3 \, molec^{-1} \, s^{-1}}).$ The HO formation 366 rates (Figures 5 a, b) were computed while the range of NO levels prevailed < 0.5 ppb. However, 367 as confirmed by previous studies (Rohrer et al., 2014; Vilà-Guerau de Arellano et al., 2011; Wei 368 et al., 2018), HO yields strongly depend on NOx concentrations. As revealed by the fraction of 369 HO production from oxidation of monoterpenes (R28, R29) to HO consumption by isoprene (R9), 370 sources and sinks of HO remained closely in balance at canopy depths $z/h_c < 0.25$ (Figure 5 c). 371 In addition, the absolute ratio of HO destruction rate (involving the isoprene reaction) to the 372 simulated HO concentration ($|Sink_{HO_{Iso}}|/[HO]$), which was a measured of HO reactivity in the 373 canopy, exhibited minor variations with canopy depth. The LES-derived HO reactivity values for 374 isoprene varied from 10 s⁻¹ at 08:00 h to 40 s⁻¹ at 12:00 h. The computed reactivity values 375 were similar to the daytime quantities of $10-30 \text{ s}^{-1}$ observed in an Amazonian rainforest during 376 the dry season (Nölscher et al., 2016). Overall, the oxidation of monoterpenes in the lower forest 377 canopy $(z/h_c < 0.25)$ generated enough HO to balance the HO needed to drive the isoprene 378 reaction (Figure 5). Because the Amazon rainforest emits a plethora of reactive sesquiterpenes 379 (not considered in this study) and monoterpenes (Jardine et al., 2015a), the HO production from 380 oxidation of emitted hydrocarbons can be greater than the values (Figures 5) reported in this study. 381 Additionally, HO yields from ozonelysis of monoterpenes and sesquiterpenes can be expected to 382

greatly vary in response to increases in NOx levels associated with biomass burning and/or regional air pollution (Wei et al., 2019). In the central Amazon, sesquiterpenes (such as β -caryophyllene, α -humulene, α -copaene) can reach mixing ratios of 0.5 ppb in the crown of the rainforest (Jardine et al., 2011).

387 4. Summary and conclusions

Based on the three posed research questions, several conclusions were derived. First, emissions, 388 turbulent transport, surface deposition, and chemical reactions governed temporal and spatial 389 patterns of isoprene and monoterpenes in and above the rainforest. Despite sufficient active biomass 390 distributed throughout the canopy volume, approximately 85% of isoprene emissions came from 391 the upper (z/h_c > 0.40) canopy. Maximum isoprene emission density reached 400 $\mu g m^{-3} h^{-1}$ at 392 $z/h_c\,\approx\,0.60$ around noontime. In part, the greater emissions in the forest crown occurred because 393 the high leaf area density in the upper canopy intercepted most of the incoming photosynthetically 394 active radiation needed to promote isoprene emissions. In contrast, emissions of monoterpenes 395 occurred throughout the forest canopy in response to the suitable conditions (e.g., temperature) to 396 drive emissions. The greatest emission density of monoterpenes was 75 $\mu g m^{-3} h^{-1}$ at z/h_c ≈ 0.60 397 around noontime. The unusually high emission densities gave rise to maximum ambient levels 398 of isoprene and monoterpenes of 8 and 0.8 ppb, respectively, at $z/h_c = 1.14$. Mixing ratios of 399 isoprene and monoterpenes remained effectively dispersed in the mixed layer but rapidly decreased 400 with altitude in the upper region of the convective boundary layer, attaining mixing ratio values 401 close to zero ppb just above the entrainment zone. 402

Second, chemical reactions and surface deposition destroyed some isoprene and monoterpenes 403 in the forest canopy. Under the influences of observed ozone (< 25 ppb) and nitric oxide (< 0.5 ppb) 404 levels, isoprene destruction due to the chemical reactions amounted to < 5% of the canopy emis-405 sions. The reaction with the hydroxyl radical dominated the chemical sink of isoprene in the canopy. 406 The small chemical loss resulted because most of the emitted isoprene occurred in the upper canopy 407 where air parcel residence times were substantially shorter than the isoprene lifetime. In addition, 408 while substantial isoprene levels persisted in the forest canopy, the low ozone (directly) and nitric 409 oxide (indirectly) levels limited the isoprene chemical sink. In the case of monoterpenes, chemical 410 reactions destroyed approximately 10% of the total canopy emissions. The ozonelysis of monoter-411

⁴¹² penes became the dominant chemical sink in the canopy. Because emissions of monoterpenes took ⁴¹³ place throughout the canopy and air parcels in the lower canopy had longer residence times, the ⁴¹⁴ molecules had greater likelihood to partake in chemical reactions before the gases were exported ⁴¹⁵ out of the forest canopy.

Third, concomitant and copious emissions of isoprene and monoterpenes within the tropical 416 forest canopy mixed and interacted with ozone and hydroxyl radical to create a unique chemical 417 environment. While both ozone and hydroxyl radical contributed to the oxidation of isoprene and 418 monoterpenes, their role for in-canopy air chemistry was fundamentally different. Ozone was prin-419 cipally carried from aloft into the canopy through turbulent transport whereas hydroxyl radical was 420 continuously produced, destroyed, and recycled in the rainforest canopy. Decreasing actinic fluxes 421 due to shading in the dense canopy reduced light-dependent hydroxyl radical formation rates in 422 the lower air canopy layers. At the same time, the ozonelysis became the most important chemical 423 sink of monoterpenes and contributed to the formation of hydroxyl radical whose yield reached 424 $\approx 2 \times 10^6$ radicals cm⁻³ s⁻¹. Therefore, in dense forest canopies with co-located emissions of iso-425 prene and monoterpenes, the oxidation of hydrocarbon molecules can produce sufficient hydroxyl 426 radical levels to maintain a photochemically active environment. The degree of photochemical ac-427 tivity in the canopy would substantially depend on the levels of both ozone and nitrogen oxides, 428 and reactivity of emitted hydrocarbon molecules. 429

431 Acknowledgments

The authors thank G. Katul for comments and suggestions. The U.S. Department of Energy sup-432 ported the field studies as part of the GoAmazon 2014/5 project (grant SC0011075). Fundação de 433 Amparo à Pesquisa do Estado de São Paulo (FAPESP) and Fundação de Amparo à Pesquisa do 434 Estado do Amazonas (FAPEAM) funded the Brazilian component of the field studies. The Large 435 scale Biosphere-Atmosphere Experiment in Amazonia (LBA) provided logistic support and made 436 the flux tower and housing unit available to complete the field studies. We thank the support from 437 the LBA central office that operated at INPA. We acknowledge logistical support from the ARM 438 Climate Research Facility. JDF acknowledges support from the National Oceanic and Atmospheric 439 Administration, Educational Partnership Program, U.S. Department of Commerce, under Agree-440 ment No. NA16SEC4810006-NCAS-M and the National Science Foundation (Award 2000403). The 441 data needed for reproducing the figures are available from the authors upon request. We thank an 442

⁴⁴³ anonymous reviewer who provided excellent comments to improve the original manuscript.

722

Figure 1. a) Incoming solar radiation, b) air temperature, c) wind speed, d) integrated emissions of isoprene and monoterpenes, e) isoprene emission density, and f) monoterpene emission density from 6:00 h to 12:00 h (yellow to dark red) on 14 September 2014. Shaded circles represent select times when data are plotted.

727

Figure 2. Horizontally averaged profiles of instantaneous a) virtual potential temperature (θ_v) in degrees Kelvin (K) and mixing ratios in ppb of b) isoprene, c) monoterpenes (*Mon*), and d) passive monoterpenes (*Mon*) at 8:00 (black), 10:00 (blue), and 12:00 h (red) on 14 September 2014.

Figure 3. Simulated and observed gas mixing ratios in ppb at $zh_c^{-1} = 1.14$ of a) isoprene (the Iso case indicates only isoprene chemistry, Mon means that the chemistry of monoterpenes was added to the isoprene chemistry, Pin means the chemistry of α -pinene was added to the isoprene chemistry), b) monoterpenes (Mon indicates that the chemistry of monoterpes was combined with isoprene chemistry, Pin means the chemistry of α -pinene was added to the isoprene chemistry), and c) ozone for cases Iso, Mon, and Pin on 14 September 2014. Shaded circles represent select times when data are plotted.

739

Figure 4. Computed budgets of gases at the canopy top. a) Terms in the canopy budget for a) 740 isoprene and b) monoterpenes (Mon case). Budget terms include air chemistry (R_{Can}) , flux across 741 canopy top (F(h_c)), change in gas storage (d< χ >/dt), canopy emission (E_{Can}), and surface de-742 position (D_{Can}) , which was calculated as the residual of the other terms. Positive values indicate 743 accumulation in the control volume. c) Terms (air chemistry, transport, storage, and surface depo-744 sition) of the ozone canopy budget. d) Rates of ozone destruction due to reactions with nitric oxide 745 (NO), nitrogen dioxide (NO₂), and mmonoterpenes (Mon). e) Terms (air chemistry, transport, and 746 storage) of the hydroxyl radical budget. f) Rates of hydroxyl radical destruction or formation due 747 to reactions with isoprene, monoterpenes, and ozonolysis of monoterpenes on 14 September 2014. 748 Shaded circles represent select times when data are plotted. 749

Figure 5. a) Vertical variation of hydroxyl radical sink due to reaction with isoprene (Sink_{HO,Isop}) and b) source of hydroxyl radical due to rozonolysis of monoterpenes (Source_{HO,Mon}). c) Comparison of source and sink strength of hydroxyl radical as a function of canopy depth. d) The absolute ratio of hydroxyl radical sink due to reaction with isoprene to average ambient hydroxyl radical concentration as a function of canopy depth for 08:00, 10:00, and 12:00 hours on 14 September 2014. Shaded circles represent select heights where data are plotted.

| Variable | Height | Value | Unit |
|------------------------------|---------------------------------------|--|----------------------|
| $	heta_v$ | $z \le 50$ | 299.1 | Κ |
| $\Delta \theta_v / \Delta z$ | $50\mathrm{m} < z \leq 150\mathrm{m}$ | 0.024 | ${ m Km^{-1}}$ |
| $\Delta \theta_v / \Delta z$ | $z>150{\rm m}$ | 0.016 | ${ m Km^{-1}}$ |
| q | $z \le 150$ | 17.0 | ${ m gkg^{-1}}$ |
| | z > 150 | 13.0 | ${ m gkg^{-1}}$ |
| O_3 | $z \leq 450\mathrm{m}$ | $8 + 0.056 \mathrm{ppb}\mathrm{m}^{-1}z$ | ppb |
| | $z > 450\mathrm{m}$ | 33.1 | ppb |
| NO | $z \leq 150\mathrm{m}$ | 0.1 | ppb |
| NO_2 | | 0.1 | ppb |
| CH_4 | | 1724.0 | ppb |

Table 1: Data used to initialize the vertical profiles in the LES domain

758 Supplement

- The purpose of this supplement is to provide the details of the photochemical mechanism (see Table
- ⁷⁶¹ S1) included in the updated LES and include additional figures showing the LES results for air
- ⁷⁶² turbulence and kinematic heat fluxes in and above the forest canopy.

Table S1: Chemical reaction scheme used in the LES with reactions and their respective rate constants

 \overline{a} First order reaction rates are in s⁻¹, second order reaction rates are in cm³molec⁻¹s⁻¹.

 χ is the solar zenith angle and T [K] is the absolute temperature from the LES.

 b Brackets indicate that the reaction scheme does not change the concentration of the species

^c The first reaction rate is for an average monoterpene, while the second rate is for α -pinene only.

763 Kinematic heat fluxes

764

Observed kinematic heat fluxes at the study site were used to specify the canopy heat source in the 765 simulation. Small differences between modeled and observed fluxes originated from smoothing and 766 interpolation in the forcing data (Figure S1). The kinematic fluxes increased until about 10:30 h. 767 with a marked decay at 11:00 h when clouds reduced the incoming sunlight (Figure S1a). Above 768 the forest canopy and within the roughness sublayer, for the most part the kinematic fluxes re-769 mained invariant with height (Figure S1b). Above the rainforest roughness sublaver, the kinematic 770 heat fluxes linearly decreased with altitude as typically observed in the convective boundary layer, 771 reaching negative values some distance within the entrainment zone (Figure S1c). 772

773

774 Atmospheric turbulence

775

Atmospheric turbulence statistics, derived from the LES outputs, were contrasted with observed 776 quantities for 21 September 2014 (Figure S2) to verify the fidelity of simulations in determining 777 vertical velocity (w) and momentum transfer (u'w') as a function of height (z) normalized to canopy 778 depth (z h_c^{-1}). Results (Figure S2) demonstrated that the numerical model realistically represented 779 the air turbulence characteristics in and above the forest canopy. On average, the numerical sim-780 ulations of the normalized mean velocity as a function of height $(\overline{u}(z))$ to the mean wind speed at 781 $h_c, \frac{\overline{u}(z)}{u(h_c)}$, closely matched the observations in and above the forest canopy (Figure S2a). In the 782 case of the standard deviation of the zonal wind speed (σ_u) normalized to the friction velocity (u_*) , 783 $\frac{\sigma_u(z)}{u_*}$, the LES results agreed reasonably well in the canopy but above the forest the numerical 784 model underestimated the $\frac{\sigma_u(z)}{u_*}$ values (Figure S2b). Similar results were observed for vertical 785 velocity variance $\frac{\sigma_w(z)}{u_*}$ (Figure S2e). This discrepancy likely resulted from the assumption of flat 786 topography or from the grid resolution adopted (or a combination of both). Simulations including 787 topography under neutral stability conditions using a finer grid were in better agreement with ob-788 servations from the same field campaign (Chen et al., 2019). The LES results and measured values 789 of the skewness of the u, (Sk_u) , showed qualitative good agreement in shape and depth, albeit with 790 a reduced magnitude (Figure S2c). The results could be used as an indicator of the penetration 791 depth of coherent sweeps and ejections. The penetration depth of sweeps and ejections occurred in 792

the upper half of the canopy. Results appeared to be in agreement with previous findings (Kruijt et al.,2000). Results for the momentum flux $\overline{u'w'}$ (Figure S2d) exhibited better agreement with observations and provided confidence that turbulent transport in the LES was realistically simulated and warranted reliable subsequent analyses of trace gas transport and chemistry in and above the forest canopy. There was also qualitative agreement between measurements and LES results for the skewness of vertical velocity (Sk_w), as both have a tendency for positive values above the canopy and for negative values below canopy height (Figure Sf).

⁸⁰¹ Thermodynamics of the atmospheric boundary layer

802

After sunrise, canopy heating contributed to the growth of the convective boundary layer that 803 reached a depth of 760 m around 12::00 hours (Figures S3a, b). After 7:00 h, the growth rate of the 804 convective boundary remained approximately constant and started to slow after kinematic fluxes 805 decreased after 11:00 h. Entertainment of drier air into the convective atmospheric boundary layer, 806 initially decreased the specific humidity until the value stabilizes resulting from increased evapotran-807 spiration (Figure S3c,d). The development of depth of the convective boundary layer and turbulent 808 transport of kinematic heat appeared realistic (Figure S3a, b). There were no direct observations of 809 temperature profiles at the study site to discern the depth of the mixed layer. Earlier studies (Fisch 810 et al., 2004) observed boundary layer depths of 491 \pm 133 m and 813 \pm 128 m for 11:00 h and 811 14:00 h, respectively, over a rainforest site 24 km away from the study site during the wet season. 812 The maximum boundary layer depth of 1002 ± 195 was observed around 17:00 h (Fisch et al., 2004). 813 814
