Abstract. Container technology provides a pathway to facilitate easy access to unified modeling systems and opens opportunities for collaborative model development and interactive learning. In this paper, we present the implementation of software containers for the System for High-resolution prediction on Earth-to-Local Domains (SHiELD), a unified atmospheric model for weather-to-seasonal prediction. The containerized SHiELD is cross-platform and easy to install. Flexibility of the containerized SHiELD is demonstrated as it can be configured as a global, a global–nest, and a regional model. Bitwise reproducibility is achieved on various x86 systems tested in this study. Performance and scalability of the containerized SHiELD are evaluated and discussed.

1 Introduction

Unified modeling systems have shown advantages as a single framework supporting versatile applications across a wide range of spatial and temporal scales. Such a system helps accelerate model development as it provides an ideal platform for modelers and scientists to gather together and combine efforts to improve the model. The Unified Model of the UK Met Office, the most notable unified modeling system, adopted the unified modeling approach and demonstrated its strength in terms of integration and collaboration (Walters et al., 2011). In addition to facilitating collaboration, the system opens the possibility of developing one model with mul-

iple uses. Previous studies (e.g., Brown et al., 2012; Harris et al., 2020) have shown that it is possible to develop multiple applications at the same time for multiple purposes, such as conducting severe weather forecast and climate prediction simultaneously. Finally, the unified modeling system allows users to apply lessons learned from one application to another application. For example, Brown et al. (2012) showed that the error growth calculated based on short-range predictions can be used to evaluate the performance of climate predictions. Likewise, climatological signals deduced from the model provide valuable information for the development of physics parameterizations that can be used in short-range weather forecasts.

Lowering the barriers of entry into unified modeling systems will open many opportunities for the earth science community. To that end, the Unified Forecast System has been making consistent steps to make the system accessible and encourage discussion and collaborative research, one example being the Graduate Student Test (<https://ufsccommunity.org/science/gst/>, last access: 25 November 2021). As discussed, a unified infrastructure provides a bedrock for cooperation. Assuring easy access to the infrastructure will help achieve cooperation. In an educational setting, Hacker et al. (2017) have shown that better access to a mesoscale model benefits classroom learning. Better access to unified modeling systems can greatly improve the learning experience. For example, a highly configurable unified model can be used as a global model to demonstrate the concept of cli-

mate sensitivity, as a regional model to learn the impact of topography on the track of a hurricane, or as a tool to study multiscale interactions.

A software container provides a pathway to enhance the accessibility of geoscientific models. A software container, or simply container, is a software artifact that is designed to deploy applications with portability and performance. There are a few geoscientific models being implemented in software containers. Hacker et al. (2017) containerized the Weather Research and Forecasting model (WRF), a regional atmospheric model. Melton et al. (2020) containerized the Canadian Land Surface Scheme including Biogeochemical Cycles (CLASSIC). Jung et al. (2021) containerized the regional ocean-modeling system (ROMS). However, due to the fact that unified modeling systems are complicated and traditionally developed on specialized machines (e.g., high-performance computers), there appears to be no unified modeling system being containerized yet. This paper attempts to take advantage of container technology and make unified modeling systems approachable.

The purpose of this paper is to describe the implementation of software containers for the System for High-resolution prediction on Earth-to-Local Domains (SHiELD), a compact unified atmospheric model developed at the Geophysical Fluid Dynamics Laboratory (GFDL). Simulations of Hurricane Laura, with a regional and a global-nest configuration, are conducted on different computer systems to demonstrate the flexibility, portability, and easy use of the containerized SHiELD. Performance and scalability of the containerized SHiELD are examined and discussed. Future work and potential applications are discussed.

2 SHiELD in a container

2.1 SHiELD

The System for High-resolution prediction on Earth-to-Local Domains (SHiELD), a unified atmospheric model developed at the GFDL, has demonstrated its capability for versatile applications on a wide range of temporal and spatial scales, including severe weather nowcasting, hurricane forecasting, and subseasonal-to-seasonal prediction (Harris et al., 2020). SHiELD is powered by the finite-volume cubed-sphere dynamical core (FV3; Putman and Lin, 2007; Harris and Lin, 2013) and is equipped with a modified version of the Global Forecast System (GFS) physics suite developed by the Environmental Modeling Center of the National Centers for Environmental Prediction. As a unified modeling system, SHiELD has been used for forecast, research, and model development: all in a single framework (Harris et al., 2020). For example, SHiELD, featuring variable resolution, has demonstrated excellence in tropical cyclone forecasting (Hazelton et al., 2018). Another example is that SHiELD was used to develop a time-split microphysics parameterization for mul-

iple applications, such as convective-scale weather prediction and global-scale cloud radiative forcing research (Harris et al., 2020). Version 2021b of the SHiELD is used in this study and the model source code can be found in Cheng et al. (2021a).

2.2 Containerization

Containerization refers to packaging one or more applications (such as a unified atmospheric model) into a container in a portable manner. A container packages not only applications but all their dependencies, such as runtime environment and libraries, so the applications can run directly from one computing system to another. Unlike a virtual machine that emulates a whole computing system for use at the hardware layer, a container uses the kernel of the host machine and packages only the necessary components required to run applications. As a result, a container is lightweight and fast, compared to a virtual machine.

Advantages of the containerization of geoscience models are discussed in many papers (Hacker et al., 2017; Melton et al., 2020) and will be shown throughout this paper, including easy installation, high portability, and perfect reproducibility. We want to add one additional advantage that motivates innovation and spurs model development. It is not uncommon for developers to come up with innovative schemes that are not ready for publication but ready for technology transfer and/or public use. In this situation, developers may want to take advantage of container technology to package their innovations as a black box that users can use but cannot see through. Unlike source code sharing which reveals everything, software containers may be used to protect developers' intellectual properties without revealing their full content while being used to share software with others.

Technically speaking, a container does not directly package applications and dependencies. It is the container image, or simply image, that does the packaging. An image is an immutable file that contains pre-built applications and their dependencies needed to run the applications. An image is used by a container to construct a runtime environment and then run applications.

For the containerization of SHiELD, we use Docker (<https://www.docker.com/>, last access: 25 November 2021) as a primary tool and Singularity (<https://sylabs.io/>, last access: 25 November 2021) as a secondary one. Docker is a leading containerization platform that sets the industry standard for containers. However, Docker containerization requires superuser access, which is a concern for multi-user systems like supercomputers. As a result, most supercomputers do not allow Docker to be installed. Singularity, on the other hand, is designed to address the security concern. Singularity is originally designed for supercomputers (Kurtzer et al., 2017) and architected specifically for large-scale and performance-oriented applications. Both Docker and Singularity can be used for free. At the time of this writing (25 November 2021),

Docker is free for personal or academic use. Singularity provides a free community edition under a Berkeley Software Distribution (BSD) license. Other containerization platforms (e.g., Podman, <https://podman.io/>, last access: 25 November 2021) may also be used to containerize SHiELD.

The procedure of containerizing SHiELD is described as follows. First, we create a Docker image with SHiELD and its dependencies. In the spirit of open collaboration, the SHiELD image does not contain any proprietary software. SHiELD and all its dependencies are open-source. SHiELD is built using open-source compilers: GNU Compiler Collection (GCC) and GFortran. Second, we create a SHiELD container by containerizing the SHiELD image on any supported system. As of November 2021, Docker supports three major operating systems (OSs): Windows, macOS, and Linux. The SHiELD image can also be used in cloud computing. Major cloud computing platforms (e.g., Amazon Web Services and Microsoft Azure) can directly deploy Docker containers. On supercomputers where Docker is generally not available, the SHiELD image can be easily converted to a Singularity container image and seamlessly executed. One thing to note is that the container made by either Singularity or Docker gives identical results, which will be discussed in the next section.

3 Running containerized SHiELD as a regional and a global–nest model

For the purpose of demonstration and experimentation, we conducted 24 h simulations of Hurricane Laura initialized from 12:00 UTC on 26 August 2020. Two different domain configurations, as illustrated in Fig. 1, are used to demonstrate the flexibility of SHiELD, showing that it can be used for a variety of applications at different spatial and temporal scales. The first configuration is a regional domain centered over the Gulf Coast of the United States. The domain size is 108×108 grid cells with a grid-cell width of approximately 35.5 km. Initial conditions and a time series of boundary conditions for the regional configuration are generated from the US operational Global Forecast System (GFS) analysis.

The second configuration is a global domain embedding a locally refined nest domain centered over the Gulf Coast of the United States. The global domain is a cubed sphere with 96×96 grid cells on each of the six tiles, which yields an average grid-cell width of approximately 100 km. The nest domain shares identical size and position with the regional domain. This global–nest configuration requires only initial conditions from the GFS analysis and enables two-way interaction between the global and the nest domains. The details of the two-way nesting method can be found in Harris and Lin (2013).

Both configurations use identical 63 Lagrangian vertical levels, the same as those used in GFS version 15. The vertical resolution is finest at the bottom level and gradually expands with height, as shown in Fig. 2. As for time step, both re-

gional and global–nest runs use the same time step (450 s) for physical parameterization. The regional run uses an acoustic time step of 75 s. For the global–nest run, the acoustic time step is 150 and 75 s in the global and the nest grid, respectively. The resolution, time steps, and physical parameterizations of the regional and the global–nest run are summarized in Table 1.

The containerized SHiELD has been tested on a variety of different x86 systems. Here we choose three machines – a laptop, a desktop, and a supercomputer – to demonstrate the portability, reproducibility, and performance of the containerized SHiELD. The three machines are chosen for their different OSs on different hardware, which are built for different purposes, as listed in Table 2. They should be representative of computers used in most situations, including research, operation, and education.

All machines use the same Docker image to execute the containerized SHiELD for both regional and global–nest simulations. For the supercomputer, the Docker image is converted to a Singularity image for containerization, as described in Sect. 2.2. All machines use the same initial conditions and model configurations (and boundary conditions if the simulation is a regional run) to run a 24 h simulation of Hurricane Laura. In both the regional and the global–nest case, all three machines finish the simulations successfully and give bitwise identical output even though they use different OSs and hardware. The containerized SHiELD has demonstrated its high portability and perfect reproducibility on any computing system that supports containerizing Docker images.

4 Result and discussion

4.1 Hurricane Laura hindcast

Hurricane Laura was the first major hurricane (Category 4) that made landfall in the record-breaking 2020 Atlantic hurricane season. Originating from a large tropical wave off the west African coast on 16 August, Laura became a tropical depression on 20 August and made landfall in the US state of Louisiana early on 27 August after a period of rapid intensification.

Figure 3 shows the simulated outgoing longwave radiation with both the regional and the global–nest configuration of SHiELD, together with a satellite image of Laura for simple verification. At 12 h into the integration, both simulations capture the location and general structure of Laura well, even at a grid spacing of ~ 36 km. Laura is moving north toward the coastline. From the spiral rainbands, the size and the shape of the simulated Laura agree very well with the observation. Both configurations give realistic simulations, demonstrating SHiELD as a truly unified modeling system. Although requiring higher computational resources, one advantage of the global–nest run is that it allows two-way in-

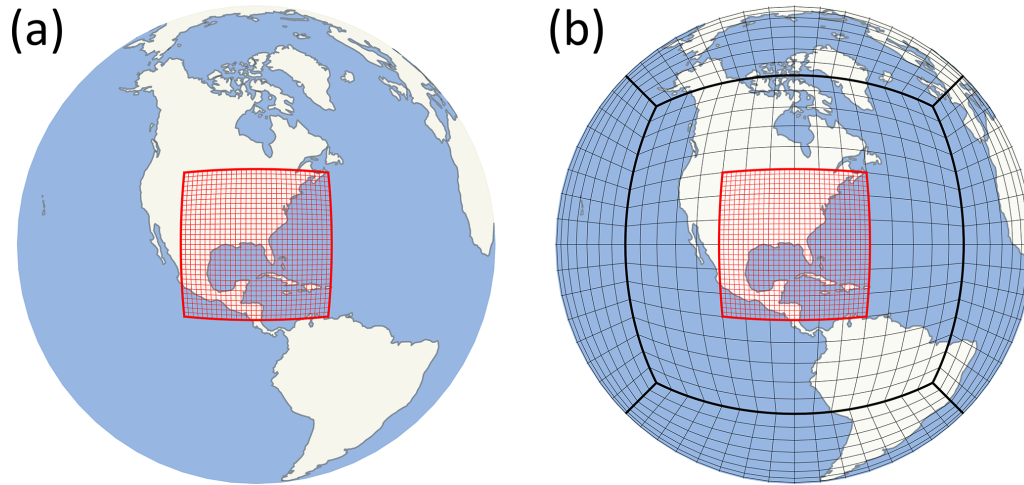

Figure 1. Two grid configurations. (a) A 37.5 km regional grid (red mesh). (b) A 100 km global grid (black mesh) with a nest grid (red mesh) that is refined by a factor of 3; the position and the grid size of the nest grid are the same as those of the regional grid. Each grid box represents 12×12 actual grid boxes. Heavy black lines are the cubed-sphere edges and heavy red lines are the boundaries of the regional/nest domain.

Table 1. Model configurations of the regional and the global–nest run. For the global–nest run, resolution and acoustic time step are shown in the format of global/nest.

Configuration	Regional run	Global–nest run
Resolution	37.5 km	100/37.5 km
Acoustic time step	75 s	150/75 s
Physics time step	450 s	
Microphysics	In-line GFDL microphysics (Harris et al., 2020)	
PBL scheme	Yonsei University scheme (Hong, 2010)	
Convection scheme	Scale-aware simplified Arakawa–Schubert (Han et al., 2017)	
Ocean surface	Mixed-layer ocean (Pollard et al., 1973)	

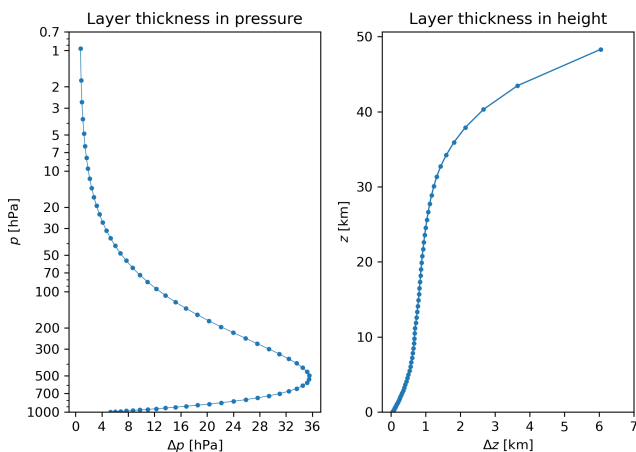

Figure 2. Vertical levels used in simulations. Layer thickness in pressure Δp /height Δz as a function of pressure p /height z for a US standard atmosphere with a surface pressure of 1000 hPa.

teraction between the nest domain and the large-scale circulation in the global domain. Another advantage is that the global–nest run does not need a time series of boundary conditions, which could potentially introduce significant errors for a regional model, as discussed in Warner et al. (1997). Comparison of the results suggests that this two-way interaction contributes to slightly faster movement of the storm and brings it closer to the observation. Why Laura moves faster in the global–nest run is beyond the scope of this work. At a relatively coarse resolution for a hurricane simulation, this computationally inexpensive case study serves to illustrate the capability of the containerized SHIELD.

4.2 Performance and scalability

Table 3 shows the wall-clock timings of the containerized SHIELD for the Hurricane Laura simulations on the three machines listed in Table 2 with the laptop as the baseline. In the regional case, each machine runs a 24 h simulation using two message passing interface (MPI) processes. The results reflect the per-core performance on each system with

Table 2. The operating system (OS), the central processing unit (CPU), and the total number of cores on the three representative machines.

Machine	OS	CPU	Total cores
Laptop	Windows 10	Intel Core i7-8550U	4
Desktop	Windows 10	AMD Ryzen 9 3950X	16
Supercomputer	CentOS 7.6	Intel Xeon Gold 6148	72 000

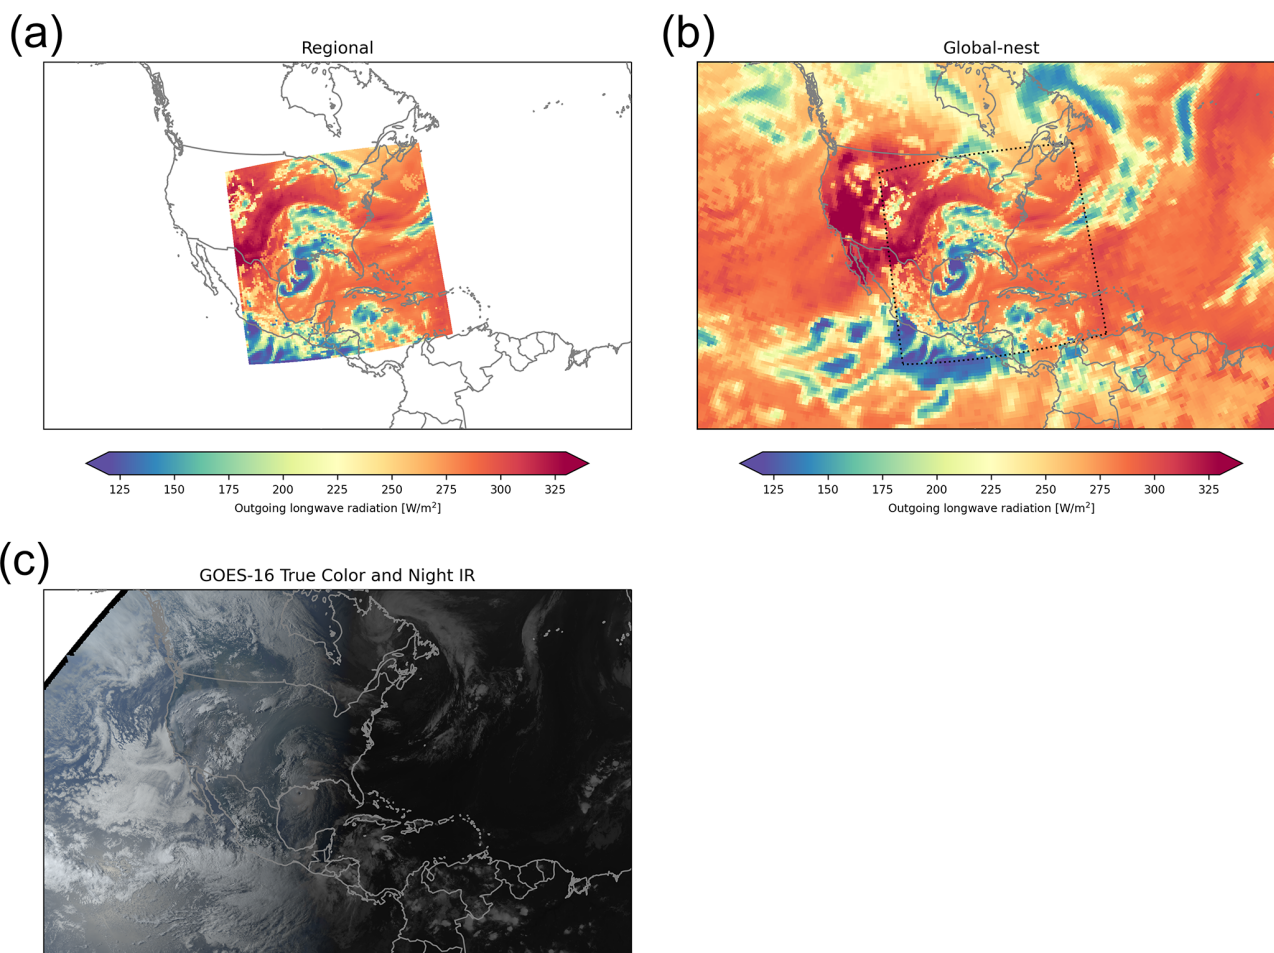

Figure 3. Hurricane Laura simulations versus satellite imagery. Panel (a) and (b) show outgoing longwave radiation simulated by SHIELD as a region and a global-nest model, respectively. Both are a snapshot at 00:00 UTC on 27 August 2020, 12 h into the simulation. The dotted box represents the boundaries of the nest domain. Panel (c) shows the Geostationary Operational Environmental Satellite-16 true color and night infrared imagery 10 min after 00:00 UTC on 27 August 2020.

the desktop being the fastest, followed by the supercomputer and the laptop. In the global-nest case, each machine runs a 24 h simulation using eight MPI processes, six more than used in the regional case. The result shows the same ranking: (1) desktop, (2) supercomputer, and (3) laptop. However, this time the laptop runs over 100 % more slowly than the other two systems. This considerable slowdown is because the eight MPI processes are oversubscribing only four cores (see Table 1). For the desktop and the supercomputer, both systems have more cores than required and therefore perform at comparable speeds, as it was with the regional case.

We have shown that the containerized SHIELD delivers reasonable performance that reflects the power of the hardware, regardless of the type of OS on the host machine. The next question to answer is how well the containerized SHIELD scales.

For scalability purposes, the 24 h global-nest case discussed previously will be executed with differing numbers of cores on the supercomputer and compared against SHIELD running natively (i.e., without containerization). Figure 4 shows the wall-clock timings for runs from 8 to 64 cores. Both the container and the native SHIELD give reason-

Table 3. Wall time of the regional and the global–nest run for a 24 h simulation of Hurricane Laura on different machines. The regional run uses two MPI (message passing interface) processes and the global–nest run uses eight MPI processes. Docker is used on all machines except for the supercomputer, where Singularity is used.

Machine	Regional run		Global–nest run	
	Wall time [s]	Cost relative to Laptop	Wall time [s]	Cost relative to Laptop
Laptop	739.80	1.00	1889.66	1.00
Desktop	526.80	0.71	778.81	0.41
Supercomputer	598.98	0.81	808.05	0.43

able scalability. Interestingly, the containerized SHiELD runs about 10 % faster than the native one at the same number of cores when using equal to or less than 32 cores. It is unclear why the containerized SHiELD outperforms the native one in some situations in spite of the overhead introduced by the software container, despite the overhead being tiny. It could be due to the difference in the runtime environment between the Docker image and the supercomputer, which makes the executable in the Docker image more efficient. Regardless, this result shows that the use of a software container does not appreciably impact application performance, which is consistent with the findings of Felter et al. (2015), where the Docker container introduces “negligible overhead for CPU and memory performance”.

When using 64 cores, the situation is the opposite: the native SHiELD outperforms the containerized version. Since each node on the supercomputer has 40 cores, this result could imply that the scalability of the container degrades across nodes. However, this is not the only explanation as the global–nest configurations can suffer from inherent load imbalance. The global and nest domains run concurrently, rather than sequentially. The concurrent approach greatly improves computational efficiency, as discussed in Harris and Lin (2013), but it is not always possible to exactly synchronize the time per integration step on the global and nest domains to avoid waits for one side or the other at the two-way update communication points. The current configuration uses a ratio of 3 to 1 to assign the number of MPI processes to the global and the nest domains. This configuration may not be optimal for the load balancing and therefore may not be suitable for scalability tests. Also, the problem size of the global–nest run may be too small to reveal the true scalability SHiELD can deliver.

4.3 Scalability issue

To better evaluate the scalability of containerized SHiELD, 12 h global simulations at 13 km horizontal resolution were conducted. Unlike a global–nest run, the scalability test for a global run is straightforward in terms of MPI configurations. The global domain (cubed-sphere grid) is engineered to achieve excellent scalability, as demonstrated during the dynamical core evaluation of the Next-Generation

Figure 4. Performance and scalability of the containerized SHiELD (with Singularity), compared to those of the native SHiELD. Results are from 24 h global–nest simulations.

Global Prediction System (https://www.weather.gov/sti/stimodeling_nggps_implementation_atmdynamics, last access: 25 November 2021). The global run conducted here uses configurations similar to those used by the flagship 13 km SHiELD, the details of which can be found in Harris et al. (2020) or Zhou et al. (2019). Figure 5a shows the data for runs from 96 to 3072 cores. The native SHiELD gives good scalability, with speed roughly doubling as the number of cores used doubles. The containerized SHiELD, on the other hand, cannot scale beyond 768 cores, due to a large degradation in the MPI communication (Fig. 5b). When the number of cores used is equal to or less than 768 cores, the containerized SHiELD outperforms the native one, which is consistent with the result seen in the global–nest case (Fig. 4). However, the performance gap decreases with increasing number of cores. This is due to a disproportionate increase in the MPI communication burden. As shown in Fig. 5b, the MPI communication efficiency degrades with increasing numbers of

cores for both containerized and native SHiELD. However, the degradation grows more quickly with the container. In the container case, the degradation becomes even worse when the simulation uses more than 768 cores. This result, combined with the results previously presented for the global–nest run, suggests the containerized SHiELD does scale reasonably well up to a modest number of cores, but the extreme scalability is significantly worse than that of the native SHiELD with an eventual plateau in performance. The modest core number seems proportional to the size of the problem, but an exact relationship is still unclear.

It is not uncommon for a model to scale well in one environment but scale poorly in another environment even though the model is free of bugs. In addition to the model itself, the performance of MPI communication also depends on external hardware and/or software, as can be seen in the literature. Montes et al. (2020) compared the performance of a climate model on a cloud computing service with that on a computing infrastructure on premises. The cloud computing gave a better performance than the on-premises machine for a small number of MPI tasks. However, the on-premises machine performed better beyond approximately 100 MPI tasks. Zhuang et al. (2020) showed the impact of network software on the performance of the Goddard Earth Observing System chemical transport model (GEOS-Chem). The authors compared the performance of two different communication protocols – Elastic Fabric Adapter (EFA) vs. Transmission Control Protocol (TCP) – on the same hardware. They found that EFA and TCP performed comparably when less than 577 cores were used in the model. Beyond 577 cores, the EFA continued to scale, while the TCP failed to scale.

Note that the “bind model” provided by Singularity can be used to solve the scalability issue (<https://sylabs.io/guides/3.7/user-guide/multi.html>, last access: 25 November 2021), as can also be seen in Fig. 5. The bind model uses the MPI implementation on the host to build and run a container, which makes the container fully compatible with the high-performance interconnects on the host. However, the outstanding scalability achieved by the bind model comes with two caveats. First, the configuration of the bind model is likely more complicated than the native SHiELD installation, as users are required to install all the libraries needed by the pre-built SHiELD image, with the correct version and dependencies, on the host and to bind them to the container explicitly. This complicated installation process deviates from the idea that container technology simplifies the deployment of applications. Second, reproducibility is not guaranteed with the bind model since the runtime environment of the bind model is dependent on the host and is not isolated as in the case of the original containerization of SHiELD. For large-scale applications in which scalability is more important than portability, reproducibility, or convenience, we recommend either the bind model or a native installation of SHiELD from source.

5 Conclusion and future work

We have shown that software containers are a promising tool to enhance the accessibility of unified modeling systems, which opens possibilities for research, education, and operation. We documented the implementation of software containers for SHiELD, a compact unified modeling system developed at GFDL. To assure wide access and encourage collaboration, the containerization of SHiELD was made without any proprietary software. Furthermore, the containerization described in this study should be directly applicable to all unified modeling systems other than the one used here. We believe that making unified modeling systems approachable will greatly accelerate model development.

The containerized SHiELD has demonstrated its high portability without compromise on functionality. It is fully functional as the native one and can be easily deployed onto any computing system, as long as the system supports containerization of Docker images. Simulations of Hurricane Laura with a regional and a global–nest configuration were conducted on a variety of different x86 systems to show the flexibility of the containerized SHiELD. In either configuration, bit-for-bit reproducibility is achieved regardless of differences in computing systems. The high portability and perfect reproducibility brought by software containers enable reproducible research and analysis.

We demonstrated that the SHiELD container can be deployed on supercomputers across nodes using Singularity. The container scales well up to a certain number of cores, depending on the size of the simulations. Beyond that certain number of cores, the MPI communication burden grows quickly and degrades scalability drastically. The scalability issue of the container can be solved by utilizing the bind model of Singularity. However, the bind model is nearly as difficult to configure as the native SHiELD and does not guarantee reproducible results. Either a native SHiELD installation or the SHiELD containerized with the bind model is recommended if scalability is critical and portability is less important.

The containerized SHiELD is designed to be community-oriented. We will continue to bring new features to the SHiELD container using developments made within the experimental SHiELD. Efforts are being made to improve physics–dynamics coupling by taking advantage of the conservation laws upon which the FV3 dynamical core is built. New capabilities (for example, multiple and telescoping nest domains) are also being developed or planned. Meanwhile, we are working on enabling idealized experiments, such as the Held–Suarez test (Held and Suarez, 1994) and supercell simulations. We believe that these new capabilities will be useful for research or classroom learning.

Code and data availability. The containerized SHiELD developed in this study is available at <https://doi.org/10.5281/zenodo.5090895>
