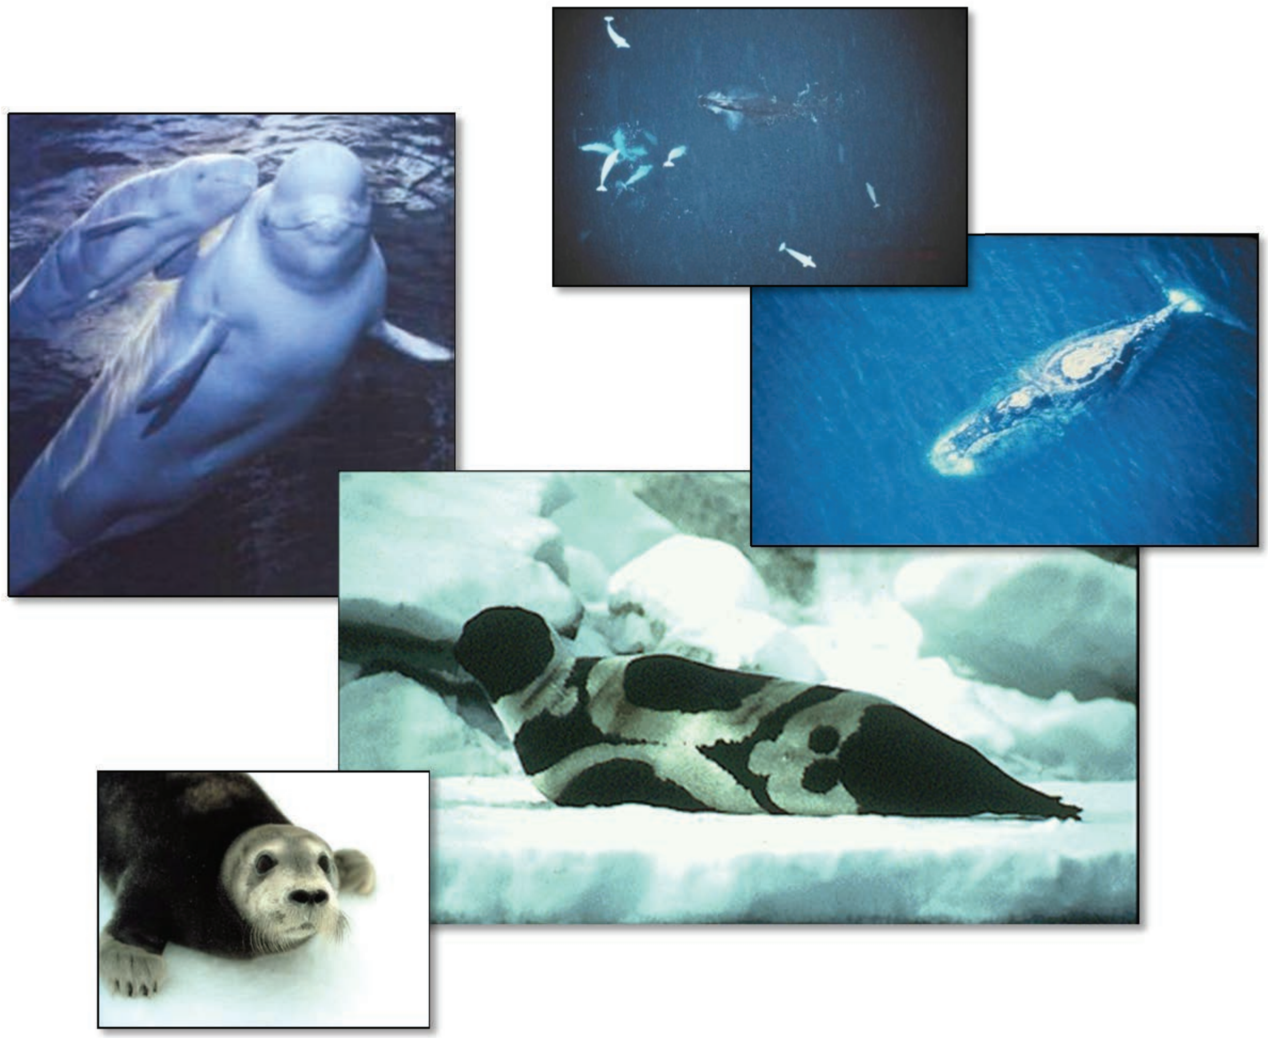
Effects of Oil and Gas Activities in the Arctic Ocean

Supplemental Draft Environmental Impact Statement



March 2013

Prepared by:
U.S. Department of Commerce
National Oceanic and Atmospheric Administration
National Marine Fisheries Service
Office of Protected Resources

EXECUTIVE SUMMARY

1.0 INTRODUCTION

The National Marine Fisheries Service (NMFS) and the Bureau of Ocean Energy Management (BOEM) have prepared this Environmental Impact Statement (EIS) to describe the effects of offshore oil and gas exploration activities in the U.S. Beaufort and Chukchi seas. This EIS analyzes a range of management alternatives to assist NMFS and BOEM in carrying out their statutory responsibilities to authorize or permit these activities.

The statutory responsibilities include BOEM's issuance of permits and authorizations under the Outer Continental Shelf Lands Act (OCS Lands Act) for seismic surveys and ancillary activities and NMFS' issuance of incidental take authorizations (ITAs) under Section 101(a)(5) of the Marine Mammal Protection Act (MMPA). A geological and geophysical (G&G) permit must be obtained from BOEM in order to conduct G&G exploration activities for oil, gas, and sulphur resources when operations occur on unleased lands or on lands leased to a third party.

NMFS issues ITAs for oil and gas exploration activities because it is likely that seismic and exploratory drilling activities may result in the disturbance of marine mammals through sound, discharge of pollutants, and/or the physical presence of vessels. Because of the potential for these activities to "take" marine mammals, oil and gas operators may choose to apply for an ITA.

1.1 Background

On April 6, 2007, NMFS and the U.S. Minerals Management Service (MMS [now BOEM]) published a Draft Programmatic EIS (DPEIS) that assessed the impacts of MMS' issuance of permits and authorizations for seismic surveys in the Beaufort and Chukchi seas off the coast of Alaska, and NMFS' issuance of ITAs to take marine mammals incidental to conducting those permitted activities. Since the DPEIS was published, new information that alters the scope, set of alternatives, and analyses in the DPEIS has become available. In addition, NMFS determined that an EIS must also address the potential effects of exploratory drilling, which were not addressed in the 2007 DPEIS. Therefore, MMS and NMFS filed a Notice of Withdrawal of the PDEIS on October 28, 2009 and announced their decision to prepare a new EIS to be called, *Effects of Oil and Gas Activities in the Arctic Ocean*, with BOEM as a cooperating agency.

On December 30, 2011, NMFS published a Notice of Availability for the *Effects of Oil and Gas Activities in the Arctic Ocean Draft Environmental Impact Statement* in the *Federal Register* (76 FR 82275). The public was afforded 60 days to comment on that document. Consistent with comments on the Draft EIS, NMFS and BOEM determined that the Final EIS would benefit from the inclusion of an additional alternative for analysis that cover a broader range of potential levels of exploratory drilling, including scenarios in the Beaufort and Chukchi seas that are more reflective of the levels of activity that oil and gas companies have indicated may be pursued in the region within the coming years and that some of the alternatives should be slightly altered from the 2011 Draft EIS. The alternatives are based upon the agencies' analysis of additional information, including the comments and information submitted by stakeholders during the Draft EIS public comment period. For this reason, the agencies determined it appropriate to prepare this Supplemental Draft EIS and allow for an additional public comment period before releasing the Final EIS and Record of Decision (ROD). On January 30, 2013, NMFS published an NOI informing the public of its determination to prepare a Supplemental Draft EIS in the *Federal Register* (78 FR 6303).

NMFS made several substantive changes to this EIS since publication of the 2011 Draft EIS. Portions of the EIS where substantive changes have occurred include:

- Alternatives
    - Added a new alternative that contemplates a higher level of exploratory drilling activity overall than the previous high level of activity alternative (now contemplates a scenario with a maximum of four exploratory drilling programs in both the Beaufort and Chukchi seas each year).
    - Based on updated data, modified some of the time/area closures, which have been identified as areas in which activities could be limited in order to protect marine mammals during times when key life functions are being performed (e.g. feeding) and subsistence hunting areas from the effects of exploration activities.
- Mitigation Measures
    - Updated the structure and analysis of the mitigation measures contemplated for inclusion under the alternatives.
    - For each measure, outlined activities to which it applies (e.g. just 2D/3D seismic surveys or just exploratory drilling or all activities), the purpose of the measure, the science, support for reduction of impacts to marine mammals or subsistence availability of marine mammals, the likelihood of effectiveness, the history of implementation of the measure, practicability for applicant implementation, and recommendation for how, and if, to apply the measure in future MMPA ITAs.
- Baseline Information
    - Using data and literature noted by commenters during the previous public comment period, updated information in the affected environment sections to incorporate newer information (mostly for marine mammals and subsistence activities).
- Impact Analyses
    - Revised the impact criteria and analyses of potential impacts to marine mammals and subsistence resources to include additional factors that more closely align with analyses conducted under the MMPA.
    - Included information regarding potential changes to the acoustic criteria currently used by NOAA to determine the level at which injury of marine mammals and behavioral effects from seismic airguns occurs. Because the acoustic criteria will go out for public comment and undergo a peer review process, we can only include some basic information at this time and then refer the public to the acoustic criteria document for comment when it is made available. The schedules for the public review process and finalization of the two documents are similar.

While NMFS has made several changes to the document based on public comments received on the 2011 Draft EIS, an appendix addressing responses to all public comments on both the 2011 Draft EIS and this Supplemental Draft EIS will appear in the Final EIS.

1.2 Process

NMFS, as the lead federal agency, prepared this EIS to evaluate a broad range of reasonably foreseeable levels of exploration activities that may occur. BOEM and the North Slope Borough (NSB) (a local government entity of the State of Alaska) are serving as formal cooperating agencies; the Environmental Protection Agency (EPA) is serving as a consulting agency. NMFS also coordinated with the Alaska Eskimo Whaling Commission (AEWC) pursuant to our co-management agreement under the MMPA on the preparation of this EIS. NMFS invited the U.S. Fish and Wildlife Service (USFWS) to join the effort as a cooperating agency, but they declined the request.

NMFS has published this EIS to disclose the potential impacts associated with their issuance of ITAs, and invites all interested parties to comment. The EIS will allow NMFS and BOEM to comprehensively assess activities that may occur in a given season before receiving applications. This will allow them to issue permits and authorizations more quickly and efficiently.

A brief summary of the agencies' regulatory requirements follows:

1.2.1 MMPA Requirements

Sections 101(a)(5)(A) and (D) of the MMPA (16 United States Code [U.S.C.] § 1361 *et seq.*) direct the Secretary of Commerce to allow, upon request, the incidental, but not intentional taking of small numbers of marine mammals by U.S. citizens who engage in a specified activity (other than commercial fishing) within a specified geographical region, if certain findings are made and either regulations are issued or, if the taking is limited to harassment, a notice of proposed authorization is provided to the public for review. Authorization for incidental takings shall be granted if:

- NMFS finds that the taking will have a negligible impact on the species or stock(s);
- NMFS finds that the taking will not have an unmitigable adverse impact on the availability of the species or stock(s) for subsistence uses (where relevant); and
- the permissible methods of taking and requirements pertaining to the mitigation, monitoring, and reporting of such takings are set forth.

1.2.2 OCS Lands Act Requirements:

The OCS Lands Act, 43 U.S.C. § 1331 et seq. prescribes a four stage process for development of offshore federal oil and gas resources: (1) a 5-year oil and gas leasing program; (2) lease sales; (3) exploration pursuant to exploration plans; and (4) development and production plans. Environmental reviews are conducted for each of these stages. Government-to-Government consultation occurs in stages two through four, and there is opportunity for public comment in all four stages.

The OCS Lands Act directs BOEM and the Bureau of Safety and Environmental Enforcement (BSEE) to oversee the "expeditious and orderly development [of OCS resources] subject to environmental safeguards" (43 U.S.C. §§ 1332(3), (6), 1334(a)(7)). Critical to the potential development of OCS resources is the ability to gather geological and geophysical data on the resource potential of the OCS. BOEM, which has rights to all data collected under the OCS Lands Act and implementing regulations, needs the best available data to ensure that the federal government, i.e. the American people, receives fair market value for leased resources. The OCS Lands Act establishes U.S. Department of Interior authority, delegated to BOEM by regulation, to issue G&G permits or notice approvals for G&G, ancillary, and exploration activities, and approve exploratory drilling plans for these and related purposes. BOEM's regulations are at 30 CFR Part 551 and for G&G permits and ancillary activities and Exploration Plans are at 30 CFR Part 550.

BOEM regulations (30 CFR Part 551) specifically state that G&G activities cannot:

- interfere with or endanger operations under any lease or right-of-way, easement, right-of-use, Notice, or permit issued or maintained under the OCS Lands Act;
- cause harm or damage to life (including fish and other aquatic life), property, or to the marine, coastal, or human environment;
- cause harm or damage to any mineral resource (in areas leased or not leased);
- cause pollution;
- create hazardous or unsafe conditions;
- disturb archaeological resources; or

- unreasonably interfere with or cause harm to other uses of the area.

Pursuant to 30 CFR Part 551.4, a G&G permit must be obtained from BOEM to conduct G&G exploration for oil, gas, and sulphur resources when operations occur on unleased lands or on lands leased to a third party. Ancillary activities are regulated under 30 CFR Part 550.207 through 550.210, which also states that a notice must be submitted before conducting such activities pursuant to a lease issued or maintained under the OCS Lands Act.

1.3 Project Overview

The proposed actions of two federal agencies considered in this EIS are:

- The issuance of ITAs under Section 101(a)(5) of the MMPA, by NMFS, for the incidental taking of marine mammals during G&G permitted activities, ancillary activities, and exploratory drilling activities in the U.S. Beaufort and Chukchi seas, Alaska, and
- The authorization of G&G permits and ancillary activities in the U.S. Beaufort and Chukchi seas, Alaska, by BOEM under the OCS Lands Act.

These federal actions are related, but distinct, actions.

This EIS will also evaluate the potential effects to the environment of authorizing takes of marine mammals incidental to such activities occurring in either federal or State of Alaska waters. Activities that could occur in state waters include on-ice and open water seismic surveys, high-resolution site clearance/shallow hazards surveys, and exploratory drilling. The oil and gas exploration activities that are addressed and evaluated in this EIS are grouped into the following three categories:

- <u>Deep penetration geophysical surveys</u> – (e.g. seismic surveys, including open-water, towed streamer 2-dimensional [2D] or 3-dimensional [3D] surveys, in-ice towed streamer 2D surveys, on-ice 2D or 3D surveys or Ocean-Bottom- Receiver [cable or node; OBC] surveys; gravity and gradiometry surveys; and controlled source electromagnetic surveys [CSEM]). These surveys are conducted to identify prospective blocks for bidding in lease sales and to optimize drilling sites on leases acquired in sales.
- <u>Shallow hazards surveys</u> – (also called high-resolution or site clearance surveys). These activities use either acoustic sources to provide imagery of the sub-seafloor to a depth of less than 1,500 meters (0.9 miles), or use sediment sampling devices to identify hazards.
- <u>Exploratory drilling</u> – Any drilling conducted by a lessee to search for commercial quantities of oil, gas, or sulfur is authorized under 30 CFR Parts 250 and 550, regulated by BSEE and BOEM respectively.

The project area (Figure 1.1) covers an area of approximately 200,331 square miles within the Alaskan portion of the Beaufort and Chukchi seas. It includes State of Alaska and OCS waters adjacent to the North Slope of Alaska and transit areas of the Chukchi Sea north of the Bering Straits.

1.4 Project Purpose and Need

1.4.1 Purpose

Energy use in the U.S. is expected to continue to increase from present levels through 2040 and beyond (EIA 2012). For example, the U.S. consumption of crude oil and petroleum products has been projected to increase from about 19.1 million barrels (Mbbl) per day in 2010 to about 21.9 Mbbl per day in 2035 (EIA 2011). Oil and gas reserves in the OCS represent significant sources that currently help meet U.S. energy demands and are expected to continue to do so in the future. The benefits of producing oil and natural gas from the OCS include not only helping to meet this national energy need but also generating money for public use. In this context, the purpose for issuing permits for seismic surveying activities under the OCS Lands Act and issuing authorizations to "take" marine mammals under the MMPA are discussed below.

The federal actions considered in this EIS are the issuance of G&G permits and ancillary activity notice approvals by BOEM for the Beaufort and Chukchi seas and the issuance of ITAs under the MMPA for G&G surveys, ancillary activities, and exploratory drilling activities in the Beaufort and Chukchi seas by NMFS. ITAs could be issued for these activities in either federal or State of Alaska waters. Given the widespread presence of several species of marine mammals in the Beaufort and Chukchi seas and the nature of oil and gas exploration activities, it is likely that some amount of seismic and exploratory drilling activities may result in the disturbance of marine mammals through sound, discharge of pollutants, and/or the physical presence of vessels. Because of the potential for these activities to "take" marine mammals, oil and gas operators may choose to apply for an ITA.

Sections 101(a)(5)(A) and (D) of the MMPA direct NMFS to allow, upon request, the incidental, but not intentional, taking of small numbers of marine mammals of a species or population stock by U.S. citizens who engage in a specified activity (other than commercial fishing) within a specified geographical region if certain findings are made and either regulations are issued or, if the taking is limited to harassment, a notice of proposed authorization is provided to the public for review. Authorization for incidental taking shall be granted if NMFS finds that the taking will have a negligible impact on the affected species or stock(s) and will not have an unmitigable adverse impact on the availability of the species or stock(s) for taking for subsistence uses. NMFS must also prescribe: the permissible methods of taking pursuant to the activity; other means of effecting the "least practicable adverse impact" on the affected species or stock and its habitat and on the availability of such species or stock for subsistence uses; and requirements pertaining to the monitoring and reporting of such taking.

1.4.2 Need

Authorizing "Take" under the MMPA: NMFS expects to receive applications to take marine mammals incidental to oil and gas industry exploration activities (i.e. G&G and ancillary surveys and exploratory drilling) pursuant to Sections 101(a)(5)(A) and (D) of the MMPA. This EIS is intended to assist NMFS in its MMPA decision-making process related to projected requests for ITAs by providing a comprehensive understanding of deep penetration geophysical surveys, shallow hazards surveys, and exploratory drilling in the U.S Beaufort and Chukchi seas for future years and may be revised as necessary. NMFS intends to use this EIS as the required NEPA analysis to support the issuance of ITAs for Arctic oil and gas exploration activities. It is the intent of NMFS that the scope of this EIS covers as many actions as possible. However, if necessary, NMFS may need to conduct additional NEPA analysis to support future Arctic MMPA oil and gas permit decisions if such activities fall outside the scope of this EIS. This applies to actions taken under Sections 101(a)(5)(A) and (D) (i.e. issuance of LOAs and IHAs) Please see Chapter 5 (Sections 5.1.2 and 5.1.3) for additional discussions on NEPA compliance related to this EIS.

Authorizing Offshore Oil & Gas Activities: BOEM expects to receive applications to conduct exploration surveys, ancillary activities, and exploration drilling pursuant to the OCS Lands Act. To fulfill statutory mandates for proposed exploratory drilling projects, BOEM requires lessees to submit industry-obtained seismic survey data, high-resolution shallow hazards data, and well information with an Exploration Plan. BOEM and BSEE use the information to: (a) ensure safe operations, which refers to detection of shallow gas pockets, faults, channel boundaries or other geological or man-made features that could be hazards to drilling; (b) support environmental impact analyses; (c) protect resources through avoidance measures, such as prohibiting anchor locations within a boulder patch area or a potential archeological site; and (d) perform other statutory responsibilities.

1.5 Public Input Process

1.5.1 Scoping

The scoping period for the *Effects of Oil and Gas Activities in the Arctic Ocean EIS* began on February 8, 2010 and ended April 9, 2010. Public scoping meetings were held during February and March 2010 in the communities of Kotzebue, Point Hope, Point Lay, Wainwright, Barrow, Nuiqsut, Kaktovik, and Anchorage. Scoping comments were received verbally and in writing through discussion, testimony, fax, regular mail, and electronic mail.

Of the issues identified during scoping, those that were most commonly raised included:

- Concerns regarding the NEPA process;
- Impacts to marine mammals and habitats;
- Risks of oil spills;
- Climate change;
- Protection of subsistence resources and the Iñupiat culture and way of life;
- Availability of research and monitoring data for decision-making;
- Monitoring requirements; and
- Suggestions for, or implementation of, mitigation measures.

For more detail on the issues raised during the scoping process, please refer to Appendix C in the 2011 Draft EIS.

Executive Order 13175 (*Consultation and Coordination with Indian Tribal Governments*), states that the U.S. Government will "*work with Indian tribes on a government-to-government basis to address issues concerning Indian Tribal self-government, trust resources, and Indian Tribal treaty and other rights.*" For government-to-government consultation during the scoping process for this EIS, Tribal governments in each community, with the exception of Anchorage, were notified of the EIS process and invited to participate. The Tribal Organizations that received invitations to participate are listed below. Native Village of Point Hope declined to participate because they received less than one month of prior notification.

- Native Village of Nuiqsut
- Iñupiat Community of the Arctic Slope
- Native Village of Point Hope
- Native Village of Point Lay
- Native Village of Barrow
- Native Village of Wainwright
- Native Village of Kotzebue

1.5.1 Draft EIS Public Comment Process

The public comment process for the 2011 Draft EIS began on December 30, 2011. After granting a 15-day extension, the comment period ended on February 28, 2012. Public meetings were held in the communities of Barrow, Wainwright, Kotzebue, Kivalina, Point Hope, and Anchorage. Public comments were received verbally and in writing through discussion, testimony, fax, regular mail, and electronic mail.

Of the issues raised during the 2011 Draft EIS public comment process, many were similar to those mentioned above as raised during the scoping process. Those that were most commonly raised include:

- Concerns related to public participation and review process;
- Compliance with NEPA, the MMPA, and other applicable statutes;
- Inadequacy with the range of alternatives;

- Improper dismissal of alternatives;
- Inadequacy of description and analysis of certain physical, biological, and social resources and failure to include newer data; and
- Insufficient analysis and information related to the effectiveness and implementation of mitigation measures.

NMFS will include an appendix in the Final EIS that contains a summary of comments and responses received on the 2011 Draft EIS and this Supplemental Draft EIS.

2.0 ALTERNATIVES

A total of 11 alternatives were initially considered for this Supplemental Draft EIS, with the No Action Alternative and five action alternatives carried forward for analysis. The alternatives dismissed and not considered for analysis include: permanent closures of areas, caps on levels of activity and/or noise, duplicative surveys, zero discharge, and a level of exploratory drilling programs commensurate with the number of lease holders in the Beaufort and Chukchi seas. Some aspects of the dismissed alternatives have been incorporated into the five remaining action alternatives and/or mitigation measures to be considered for analysis.

NMFS and BOEM identified alternatives by:

- Evaluating alternative concepts suggested during the scoping period (such as using alternative technologies to airguns for seismic surveys).
- Reviewing potential alternatives in the context of NMFS and BOEM's regulatory requirements.
- Assessing potential levels of seismic exploration and exploratory drilling activities, and a suite of Standard Mitigation Measures.
- Identifying a range of potential Additional Mitigation Measures that need further analysis and may be applied to alternatives pursuant to the MMPA ITA process and the BOEM OCS Lands Act permitting process.

Alternatives were developed based on NMFS' desire to proactively analyze both the effects of multiple exploration activities and effectiveness of mitigation measures, and to anticipate regulatory compliance needs over the timeframe of this EIS.

Past ITAs have been issued for individual G&G surveys, ancillary activities, and exploratory drilling projects in the Beaufort and Chukchi seas in the form of Incidental Harassment Authorizations (IHAs) for periods of no more than one year at a time. This EIS analyzes the effects from multiple oil and gas industry exploration activities, the potential effects of authorizing takes from concurrent activities, and whether the standard mitigation and monitoring measures stipulated in the past are appropriate for current and reasonably foreseeable oil and gas activities. The analysis also includes additional mitigation measures suggested by the public or other agencies.

Based upon past lease sales, G&G permits, ancillary activity notices, exploration drilling exploration activities, and requests for ITAs, NMFS and BOEM have determined a reasonable range and level of activities for which permits and authorizations may be requested in the foreseeable future. While the level of activity proposed may vary from one year to the next, the action alternatives represent a reasonable range of exploration activities for which permits and authorizations may be requested.

In this EIS, NMFS and BOEM present and assess a reasonable range of G&G, ancillary, and exploratory drilling activities expected to occur, as well as a reasonable range of mitigation measures, in order to accurately assess the potential consequences of issuing ITAs under the MMPA and permits under the OCS Lands Act.

The six alternatives evaluated are:

- **Alternative 1:** No Action
- **Alternative 2:** Authorization for Level 1 Exploration Activity
- **Alternative 3:** Authorization for Level 2 Exploration Activity
- **Alternative 4:** Authorization for Level 3 Exploration Activity
- **Alternative 5:** Authorization for Level 3 Exploration Activity with Additional Required Time/Area Closures
- **Alternative 6:** Authorization for Level 3 Exploration Activity with Use of Alternative Technologies

Table ES-1 outlines the differences in the alternatives between the 2011 Draft EIS and this Supplemental Draft EIS, as well as outlining the differences between the alternatives themselves.

The potential level of activity described by each alternative is based on recent federal and state lease planning and recent industry plans for both seismic surveys and exploratory drilling programs in the Beaufort and Chukchi seas.

For analysis in this EIS, one "program" entails however many surveys or exploration wells a particular company is planning for that season. Each "program" would use only one source vessel (or two source vessels working in tandem, e.g. OBC surveys) or drilling unit (i.e. drillship, jackup rig, SDC, etc.) to conduct the program and would not survey multiple sites or drill multiple wells concurrently. Survey vessels and drilling units are generally self-contained, with the crew living aboard the vessel. For surveys in the Beaufort Sea, support operations would likely occur out of West Dock or Oliktok Dock near Prudhoe Bay. Chukchi Sea surveys could be supported either from Wainwright or Nome. Helicopters stationed at either Barrow (for operations in either the Beaufort Sea or Chukchi Sea) or Deadhorse (for operations in the Beaufort Sea) would provide emergency or search-and-rescue support, as needed.

Site clearance and shallow hazards survey programs are contemplated in each action alternative and typically also include ice gouge and strudel scour surveys and are often referred to as marine survey programs by oil and gas industry operators. The ice gouge and strudel scour surveys do not involve the use of airguns but do involve the use of smaller, higher-frequency sound sources, such as multibeam echosounders and sub-bottom profilers. The area of a site clearance and shallow hazards survey, which is tied to a lease plan, is typically determined by the number of potential, future drill sites in the area. Table 2.4 outlines the typical types of sound sources used in these programs.

Table ES-1 Differences in the Alternatives between the December 2011 Draft EIS and this Supplemental Draft EIS

Alternative	2011 Draft EIS	2013 Supplemental Draft EIS
Alternative 1 (No Action)	NMFS would not issue ITAs under the MMPA, and BOEM would not issue permits and notices under the OCS Lands Act.	Same as in 2011 Draft EIS
Alternative 2	Considered up to: • Four 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to three 2D/3D seismic or CSEM surveys in the Chukchi Sea, with up to one of that total number in each done in-ice if necessary. • Three site clearance and high resolution shallow hazards survey programs in each sea per year • One on-ice seismic survey in the Beaufort Sea per year • One exploratory drilling program in each sea per year Considered inclusion of required standard mitigation measures and additional mitigation measures.	Same as in 2011 Draft EIS
Alternative 3	Considered up to: • Six 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to five 2D/3D seismic or CSEM surveys in the Chukchi Sea, with up to one of that total number in each done in-ice if necessary. • Five site clearance and high resolution shallow hazards survey programs in each sea per year • One on-ice seismic survey in the Beaufort Sea per year • Two exploratory drilling programs in each sea per year Considered inclusion of required standard mitigation measures and additional mitigation measures.	Same as in 2011 Draft EIS
Alternative 4	Considered up to: • Six 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to five 2D/3D seismic or CSEM surveys in the Chukchi Sea, with up to one of that total number in each done in-ice if necessary. • Five site clearance and high resolution shallow	This alternative differs from Alternative 4 from the 2011 Draft EIS in the following ways: • Considers up to four exploratory drilling programs in each sea per year

	hazards survey programs in each sea per year • One on-ice seismic survey in the Beaufort Sea per year • Two exploratory drilling programs in each sea per year Considered inclusion of required standard mitigation measures and additional mitigation measures. Considered inclusion of required time/area closures for specific areas important to biological productivity, life history functions for specific species of concern, and subsistence activities. Areas considered were: • Camden Bay; • Barrow Canyon and the Western Beaufort Sea; • Shelf Break of the Beaufort Sea; • Hanna Shoal; and • Kasegaluk Lagoon/Ledyard Bay Critical Habitat Unit.	• It does not consider inclusion of any required time/area closures. Everything else about the alternative remains the same.
Alternative 5	Considered up to: • Six 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to five 2D/3D seismic or CSEM surveys in the Chukchi Sea, with up to one of that total number in each done in-ice if necessary. • Five site clearance and high resolution shallow hazards survey programs in each sea per year • One on-ice seismic survey in the Beaufort Sea per year • Two exploratory drilling programs in each sea per year Considered inclusion of required standard mitigation measures and additional mitigation measures. Considered including specific additional measures that focus on the use of alternative technologies that have the potential to augment or replace traditional airgun-based seismic exploration activities.	Alternative 5 in this EIS is similar to Alternative 4 from the 2011 Draft EIS with some slight changes: • Increase in the maximum level of exploratory drilling programs from up to two per sea per year to up to four per sea per year • Inclusion of required time/area closures. However, there are changes. The following are the required time/area closures considered in this EIS: o Kaktovik o Barrow Canyon and the Western Beaufort Sea o Shelf Break of the Beaufort Sea o Hanna Shoal o Kasegaluk Lagoon

		o Ledyard Bay
Alternative 6	There was no Alternative 6 in this version of the EIS.	Alternative 6 in this EIS is similar to Alternative 5 from the 2011 Draft EIS. The only change is the maximum amount of exploratory drilling activities that could potentially occur under this alternative increases from up to two per sea per year to up to four per sea per year.

2.1 Alternative 1 – No Action

NEPA's implementing regulations require that the No Action Alternative be evaluated. Under the No Action Alternative, NMFS would not issue any ITAs under the MMPA for seismic surveys or exploratory drilling in the Beaufort and Chukchi seas, and BOEM would not issue G&G permits or authorize ancillary activities in the Beaufort and Chukchi seas. If companies proceeded to operate in this area without MMPA authorizations, any takes of marine mammals would occur in violation of the MMPA.

2.2 Alternative 2 – Authorization for Level 1 Exploration Activity

Alternative 2 is defined as the following:

2.2.1 Level of Activity

- Up to **four** 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to **three** 2D/3D seismic or CSEM surveys in the Chukchi Sea per year, with up to **one** of that total number of surveys in each sea including ice breaking if necessary.
- Up to **three** site clearance and high resolution shallow hazards survey programs in the Beaufort Sea and up to **three** site clearance and high resolution shallow hazards survey programs in the Chukchi Sea per year.
- **One** on-ice seismic survey in the Beaufort Sea per year.
- **One** exploratory drilling program in the Beaufort Sea and **one** exploratory drilling program in the Chukchi Sea per year.

2.2.2 Mitigation

- Including *required* Standard Mitigation Measures (described in Section 2.7) that are part of every action alternative.
- Including a full analysis of a wide range of Additional Mitigation Measures (described in Section 2.8) that *could potentially* be required through the MMPA process and could vary by alternative (i.e. some might be different based on level and/or type of activity in a given year)

2.2.3 Assumptions

Seismic work in the Arctic has traditionally been conducted in ice-free months (July through November); although this analysis addresses the possibility of one survey utilizing an icebreaker and potentially continuing through mid-December. Seismic surveys are also conducted on-ice in areas where there is bottom fast ice in the winter. These surveys generally occur from January through May. Each survey takes between 30 and 90 days, depending on ice conditions, weather, equipment operations, size of area to be surveyed, timing of subsistence hunts, etc. Because of the limited time period of open water, it is likely that concurrent surveys would be conducted in the same general time frame and may overlap in time, but will not overlap in space (i.e. with a minimum separation distance of approximately 24 km [15 mi] between each independent survey operation) for reasons regarding data integrity. It is assumed for analytical purposes that at least one of the authorized 2D/3D seismic surveys in the Beaufort Sea and one in the Chukchi Sea would utilize an ice breaker.

Exploratory activities (including deep penetration seismic, site clearance and high resolution shallow hazards, and exploratory drilling) in the next five years will be concentrated in areas of recently purchased leases. This does not mean that there will not be exploratory activities in other areas of the U.S. Arctic Ocean, especially if BOEM's next Five Year Lease Plan schedule includes sales in the Arctic OCS. In the U.S. Beaufort Sea, the two primary areas of interest for exploration are nearshore in Camden Bay and Harrison Bay. In the U.S. Chukchi Sea, the areas of interest are all well offshore in the lease areas, particularly around drill sites from the late 1980s, including Shell's Burger, Crackerjack, and Shoebill sites; ConocoPhillips' Klondike site; and Statoil's leases in the northeast part of the Lease Sale 193 area.

2.3 Alternative 3 – Authorization for Level 2 Exploration Activity

Alternative 3 is defined as the following:

2.3.1 Level of Activity

- Up to **six** 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to **five** 2D/3D seismic or CSEM surveys in the Chukchi Sea per year, with up to **one** of that total number of surveys in each sea including ice breaking if necessary.
- Up to **five** site clearance and high resolution shallow hazards survey programs in the Beaufort Sea and up to **five** site clearance and high resolution shallow hazards survey programs in the Chukchi Sea per year.
- **One** on-ice seismic survey in the Beaufort Sea per year.
- Up to **two** exploratory drilling programs in the Beaufort Sea and up to **two** exploratory drilling programs in the Chukchi Sea per year.

2.3.2 Mitigation

- Including *required* Standard Mitigation Measures (described in Section 2.7) that are part of every action alternative.
- Including a full analysis of a wide range of Additional Mitigation Measures (described in Section 2.8) that *could potentially* be required through the MMPA process and could vary by alternative (i.e. some might be different based on level and/or type of activity in a given year).

Assumptions for the analysis of Alternative 3 would be the same as those listed for Alternative 2.

2.4 Alternative 4 – Authorization for Level 3 Exploration Activity

Alternative 4 is defined as the following:

2.4.1 Level of Activity

- Up to **six** 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to **five** 2D/3D seismic or CSEM surveys in the Chukchi Sea per year, with up to **one** of that total number of surveys in each sea including ice breaking if necessary.
- Up to **five** site clearance and high resolution shallow hazards survey programs in the Beaufort Sea and up to **five** site clearance and high resolution shallow hazards survey programs in the Chukchi Sea per year.
- **One** on-ice seismic survey in the Beaufort Sea per year.
- Up to **four** exploratory drilling programs in the Beaufort Sea and up to **four** exploratory drilling programs in the Chukchi Sea per year.

2.4.2 Mitigation

- Including *required* Standard Mitigation Measures (described in Section 2.7) that are part of every action alternative.
- Including a full analysis of a wide range of Additional Mitigation Measures (described in Section 2.8) that *could potentially* be required through the MMPA process and could vary by alternative (i.e. some might be different based on level and/or type of activity in a given year).

Assumptions for the analysis of Alternative 4 would be the same as those listed for Alternative 2.

2.5 Alternative 5 – Authorization for Level 3 Exploration Activity <u>With Additional Required Time/Area Closures</u>

Alternative 5 is defined as the following:

2.4.1 Level of Activity

- Same level of activity as Alternative 4.

2.4.2 Mitigation

- Including *required* Standard Mitigation Measures (described in Section 2.7) that are part of every action alternative.
- Including *required* time/area closures for specific areas important to biological productivity, life history functions for specific species of concern, and subsistence activities. Activities would not be permitted to occur in any of the areas listed here during the specific time/area closure periods identified. Additionally, buffer zones around these time/area closures could potentially be included. Buffer zones would require that activities emitting pulsed sounds would need to operate far enough away from these closure areas so that sounds at 160 dB re 1 μPa rms do not propagate into the area or that activities emitting continuous sounds would need to operate far enough away from these closure areas so that sounds at 120 dB re 1 μPa rms do not propagate into the area.
    - <u>Kaktovik and Cross Island</u> – An area of importance for fall subsistence bowhead whale hunting
        - Bowhead whale subsistence hunting: late August – mid-September

  - Except for emergencies or human/navigation safety, oil and gas exploration operations shall not occur off Kaktovik or Cross Island or the designated buffer zones from August 25 to the close of the fall bowhead whale hunt in Kaktovik and on Cross Island.

- Barrow Canyon, the Western Beaufort Sea, and the Shelf Break of the Beaufort Sea – An area of high biological productivity; a feeding area for bowhead and beluga whales; fall subsistence bowhead whale hunting area.
  - Bowhead whales: September – October
  - Beluga whales: mid-July – late September
  - Except for emergencies or human/navigation safety, oil and gas exploration operations shall not occur within the Barrow Canyon area or the designated buffer zones from August 25 to the close of the fall bowhead whale hunt in Barrow.
- Hanna Shoal[1] – An area of high biological productivity (benthic organisms); a feeding area for various marine mammals (walrus and bearded seals).
  - Walrus: July – August (USGS 2011)
  - Bearded Seals: September – October (Clarke et al. 2011a)
  - Except for emergencies or human/navigation safety, oil and gas exploration operations shall not occur within the Hanna Shoal area or the designated buffer zones from July 1 – August 30.
- Kasegaluk Lagoon – An important habitat for beluga whales (feeding, molting, calving) and spotted seals; subsistence beluga whale hunting area.
  - Beluga whales: June – mid-July
  - Subsistence (Kasegaluk Lagoon beluga whale hunting): mid-June – mid-July
  - Spotted seals: August – October
  - Except for emergencies or human/navigation safety, oil and gas exploration operations shall not occur within Kasegaluk Lagoon or the designated buffer zones from June 1 – July 15.
- Ledyard Bay – An important habitat for spectacled eiders and the northern edge of important habitat for gray whales
  - Except for emergencies, human/navigation safety, or deployment of scientific devices, oil and gas exploration operations shall not occur within the Ledyard Bay Critical Habitat Unit or the designated buffer zones between July 1 and November 15.
  - To the maximum extent practicable, aircraft supporting seismic operations shall avoid operating below 1,500 ft (457 m) over the Unit between July 1 and November 15.

---

[1] Gray whales have been removed as a reason for designating Hanna Shoal as a time/area closure location. While gray whales were consistently seen feeding in that area in September and October in the late 1980s and early 1990s (Clarke and Moore 2002), gray whale sightings in Hanna Shoal have been very infrequent since aerial surveys recommenced in 2008, and the area probably should not be considered a current gray whale feeding area (Clarke et al. in prep.).

- Including a full analysis of a wide range of Additional Mitigation Measures (described in Section 2.8) that *could potentially* be required through the MMPA process and could vary by alternative (i.e. some might be different based on level and/or type of activity in a given year). The time/area closures that are described in this section that are optional for Alternatives 2, 3, 4 and 6 would not be optional but rather required under Alternative 5.

Assumptions for the analysis of Alternative 5 would be the same as those listed for Alternative 2.

2.6 Alternative 6 – Authorization for Level 3 Exploration Activity With Use of Alternative Technologies

Alternative 6 is defined as the following:

2.6.1 Level of Activity

- Same level of activity as Alternative 4.

2.6.2 Mitigation

- Including *required* Standard Mitigation Measures (described in Section 2.7) that are part of every action alternative.
- Including a full analysis of a wide range of Additional Mitigation Measures (described in Section 2.8) that *could potentially* be required through the MMPA process and could vary by alternative (i.e. some might be different based on level and/or type of activity in a given year), potentially including new mitigations developed to apply to new technologies.
- Including specific additional measures that focus on the use of alternative technologies that have the potential to augment or replace traditional airgun-based seismic exploration activities.

Assumptions for the analysis of Alternative 6 would be the same as those listed for Alternative 2.

2.7 Standard Required Mitigation Measures

The mitigation measures (and the identified mitigation monitoring needed to support them) listed below will be included as a requirement under every ITA issued for the type of activity identified. Full descriptions of these measures are contained in Appendix A.

a) Detection-based measures intended to reduce near-source acoustic exposures and impacts on marine mammals within a given distance of the source

2D/3D Seismic Surveys, Including In-ice Seismic; Site Clearance and High Resolution Shallow Hazards Surveys

- Establishment and execution of 180 dB shutdown/power down radius for cetaceans and 190 dB shutdown/power down radius for ice seals, respectively.
- Specified ramp-up procedures for airgun arrays.
- Protected Species Observers (PSOs; formerly referred to as Marine Mammal Observers [MMOs]) required on all seismic source vessels and icebreakers, as well as on dedicated monitoring vessels.

On-ice Seismic Surveys

- All activities must be conducted at least 152 m (500 ft) from any observed ringed seal lair.
- No energy source may be placed over a ringed seal lair.

Exploratory Drilling Activities

- PSOs required on all drill ships and ice management vessels.

b) Non-detection-based measures intended to more broadly lessen the severity of acoustic impacts on marine mammals or reduce overall numbers taken by acoustic source

This measure would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- Specified flight altitudes for all support aircraft except for take-off, landing, and emergency situations.

c) Measures intended to reduce/lessen non-acoustic impacts on marine mammals

These measures would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice surveys, CSEM surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- Specified procedures for changing vessel speed and/or direction to avoid collisions with marine mammals.

d) Measures intended to ensure no unmitigable adverse impact to subsistence uses

These measures would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice surveys, CSEM surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- Shutdown of activities occurring in specific areas of the Beaufort Sea corresponding to the start and conclusion of the fall bowhead whale hunts in Nuiqsut (Cross Island) and Kaktovik beginning on August 25.
- Establishment and utilization of Communication Centers in subsistence communities when oil and gas exploration activities and marine mammal subsistence hunts will occur at the same time to address potential interference with marine mammal hunts on a real-time basis throughout the season.
- Required flight altitudes and paths for all support aircraft in areas where subsistence occurs, except during take-off, landing, and emergency situations.

2.8 Additional Mitigation Measures

The mitigation measures (and mitigation monitoring needed to support them) listed below are evaluated in Chapter 4, which could lead to some of these measures becoming Standard Mitigation Measures in the Final EIS. In the future, these Additional Mitigation Measures will be evaluated in the context of each specifically described activity to determine whether they should be required by NMFS in a specific ITA or by BOEM in a specific G&G permit or ancillary activity notice approval to make the necessary findings under the MMPA or the OCS Lands Act. In short, these measures may, or may not, be incorporated in future permits and authorizations, depending on the specific activity and the analysis conducted pursuant to the MMPA and the OCS Lands Act.

a) Detection-based measures intended to reduce near-array acoustic exposures and impacts on marine mammals within a given distance of the source

2D/3D Seismic and In-ice Surveys; Site Clearance and High Resolution Shallow Hazards Surveys; Exploratory Drilling Activities

- Prior to conducting the authorized survey, the seismic array operator shall conduct sound source verification tests for their airgun array configurations in the area in which the survey is proposed to occur.
- All PSOs shall be provided with and use appropriate night-vision devices (e.g. Forward Looking Infrared [FLIR] imaging devices, 360° thermal imaging devices), Big Eyes, and reticulated and/or laser range finding binoculars in order to detect marine mammals within the exclusion zones.
- Operators shall limit seismic airgun operations in situations of low visibility when the entire safety radius cannot be observed (e.g., nighttime or bad weather).
- Seismic operators shall use passive (or active) acoustic monitoring systems, in addition to visual monitoring, to detect marine mammals approaching or within the exclusion zone and trigger the shutdown of airguns.
- Enhancement of monitoring protocols and mitigation shutdown zones to minimize impacts in specific biologic situations (e.g. expansion of shutdown zone to 120 dB or 160 dB when cow/calf groups and feeding or resting aggregations are detected, respectively).

b) Non-detection-based measures intended to more broadly lessen the severity of acoustic impacts on marine mammals or reduce overall numbers taken by acoustic source

These measures would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- Temporal/spatial limitations to minimize impacts in particular important habitats, including Kaktovik and Cross Island, Barrow Canyon/Western Beaufort Sea, Hanna Shoal, the shelf break of the Beaufort Sea, Kasegaluk Lagoon, and Ledyard Bay Critical Habitat Unit.
- Restriction of number of surveys (of same level of detail) that can be conducted in the same area in a given amount of time (i.e. to avoid needless collection of identical data).

2D/3D Seismic, including in-ice surveys ONLY

- Separate seismic surveys are prohibited from operating within 145 km (90 mi) of one another.

c) Measures intended to reduce/lessen non-acoustic impacts on marine mammals

These measures would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice seismic, CSEM surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- Vessel and aircraft avoidance of concentrations of groups of ice seals by 0.8 km (0.5 mi).
- Specified shipping or transit routes to avoid important habitat in areas where marine mammals may occur in high densities.

Exploratory Drilling Activities ONLY

- Requirements to ensure reduced, limited, or zero discharge of any or all of the specific discharge streams identified with potential impacts to marine mammals or marine mammal prey or habitat.

- Operators are required to recycle drilling muds.

On-ice Seismic Surveys

- Use trained seal-lair sniffing dogs for areas with water deeper than 3 m (9.8 ft) depth contour to locate seal structures under snow in the work area and camp site before initiation of activities.
- Use trained seal-lair sniffing dogs to survey the ice road and establish a route where no seal structures are present.

d) Measures intended to ensure no unmitigable adverse impact to subsistence uses

These measures would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice surveys, CSEM surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- No transit of exploration vessels into the Chukchi Sea prior to July 15 or until the beluga hunt is completed at Point Lay.
- Vessels transiting east of Bullen Point to the Canadian border should remain at least 8 km (5 mi) offshore during transit along the coast, provided ice and sea conditions allow.
- Shutdown of exploration activities in the Beaufort Sea for the Nuiqsut (Cross Island) and Kaktovik bowhead whale hunts based on real-time reporting of whale presence and hunting activity rather than a fixed date.
- Shutdown of exploration activities in the Beaufort Sea for the Barrow bowhead whale hunts from Pitt Point on the east side of Smith Bay to a location about half way between Barrow and Peard Bay from September 15 to the close of the fall bowhead whale hunt in Barrow.
- Shutdown of exploration activities in the Chukchi Sea for the Barrow (the area circumscribed from the mouth of Tuapaktushak Creek due north to the coastal zone boundary, to Cape Halkett due east to the coastal zone boundary) and Wainwright (the area circumscribed from Point Franklin due south to the coastal zone boundary, to the Kuk River mouth due west to the coastal zone boundary) bowhead whale hunts based on real-time reporting of whale presence and hunting activity rather than a fixed date.
- Shutdown of exploration activities in the Chukchi Sea for the Point Hope and Point Lay bowhead whale hunts based on real-time reporting of whale presence and hunting activity rather than a fixed date.
- Transit restrictions into the Chukchi Sea modified to allow offshore travel under certain conditions (e.g. 32 km [20 mi] from the coast) if beluga whale, fall bowhead whale (Barrow and Wainwright), and other marine mammal hunts would not be affected.

Exploratory Drilling Activities ONLY

- For exploratory drilling operations in the Beaufort Sea west of Cross Island, no drilling equipment or related vessels used for at-sea oil and gas operations shall be moved onsite at any location outside the barrier islands west of Cross Island until the close of the bowhead whale hunt in Barrow.

3.0 AFFECTED ENVIRONMENT AND ENVIRONMENTAL CONSEQUENCES

Chapter 3 of the EIS describes the current condition of the physical, biological, and social environment in the EIS project area to serve as a baseline to compare the potential positive or negative impacts of the alternatives. Chapter 4 of the EIS analyzes the potential impacts of each alternative on physical, biological, and social resources. Impact levels were determined in consideration of the following four criteria:

<u>Intensity (Magnitude)</u>

Low:	A change in a resource condition is perceptible, but it does not noticeably alter the resource's function in the ecosystem or cultural context.
Medium:	A change in a resource condition is measurable or observable, and an alteration to the resource's function in the ecosystem or cultural context is detectable.
High:	A change in a resource condition is measurable or observable, and an alteration to the resource's function in the ecosystem or cultural context is clearly and consistently observable.

<u>Duration</u>

Temporary:	Impacts would be intermittent, infrequent, and typically last less than a month.
Interim:	Impacts would be frequent or extend for longer time periods (an entire project season).
Long-term:	Impacts would cause a permanent change in the resource that would perpetuate even if the actions that caused the impacts were to cease.

<u>Extent</u>

Local:	Impacts would be limited geographically; impacts would not extend to a broad region or a broad sector of the population.
Regional:	Impacts would extend beyond a local area, potentially affecting resources or populations throughout the EIS project area.
State-wide:	Impacts would potentially affect resources or populations beyond the region or EIS project area.

<u>Context</u>

Common:	The affected resource is considered usual or ordinary in the locality or region; it is not depleted in the locality and is not protected by legislation. The portion of the resource affected does not fill a distinctive ecosystem role within the locality or the region.
Important:	The affected resource is protected by legislation (other than the ESA). The portion of the resource affected fills a distinctive ecosystem role (such as an important subsistence resource) within the locality or the region.
Unique:	The affected resource is listed as threatened or endangered (or proposed for listing) under the ESA or is depleted either within the locality or the region. The portion of the resource affected fills a distinctive ecosystem role within the locality or the region.

Separate impact criteria tables were developed and used to guide the analysis of impacts for each of the resources discussed under the physical, biological, and social environments. The impact criteria tables use terms and thresholds that are quantified for some components and qualitative for other components. The terms used in the qualitative thresholds are relative, necessarily requiring the analyst to make a judgment about where a particular effect falls in the continuum from "negligible" to "major".

Summary impact levels were then determined using the following guidance.

- Negligible[2]: Impacts are generally extremely low in intensity (often they cannot be measured or observed), are temporary, localized, and do not affect unique resources.
- Minor: Impacts tend to be low in intensity, of short duration, and limited extent, although common resources may experience more intense, longer-term impacts.
- Moderate: Impacts can be of any intensity or duration, although common resources may be affected by higher intensity, longer-term, or broader extent impacts while important and/or unique resources may be affected by medium or low intensity, shorter-duration, local or regional impacts.
- Major: Impacts are generally medium or high intensity, long-term or permanent in duration, a regional or state-wide extent, and affect important or unique resources.

The following summary (Sections 3.1 to 3.3 of this Executive Summary) addresses only those resources that may experience greater than minor impacts, were identified during scoping as being of concern, or that highlight differences among the alternatives. Table ES-2 provides a summary of impacts to all resources for Alternative 1 through Alternative 6.

Because most of the alternative technologies associated with Alternative 6 have not yet been built and/or tested, it is difficult to fully analyze the level of impacts from them. The amount of traditional seismic surveys (i.e. use of airgun arrays) that can be replaced or augmented by these technologies is unknown, the level of impact reduction cannot be determined. This EIS examines a projected amount of use of these technologies but the actual amount that might be used over the next several years is not fully known at this time. Therefore, NMFS has determined that additional NEPA analyses would likely be required if applications are received requesting use of these technologies.

[2] The term negligible in this EIS does not have the same meaning as in the MMPA. The term has different meanings under the two statutes and is being used in two different contexts.

Table ES-2 Comparison of Impacts

Impact Topic	Alternative 1- No Action Alternative	Alternative 2- Authorization for Level 1 Exploration Activity	Alternative 3- Authorization for Level 2 Exploration Activity	Alternative 4- Authorization for Level 3 Exploration Activity	Alternative 5- Authorization for Level 3 Exploration Activity with Additional Required Time/Area Closures	Alternative 6- Authorization for Level 3 Exploration Activity with Use of Alternative Technologies
PHYSICAL ENVIRONMENT						
Physical Oceanography	No effect	Minor impacts from deposition of materials during exploratory drilling, construction of artificial island, ice-breaking, and on-ice seismic surveys.	Same types of impacts as Alternative 2, intensity and extent of the impact would be doubled, level of impact still minor.	Same types of impacts as Alternative 2, intensity and extent of the impact would be doubled for exploratory drilling activities, level of impact still minor.	Same as Alternative 4	Same as Alternative 4
Climate	No effect	Impacts cannot be measured on a project-level basis.	Impacts cannot be measured on a project-level basis.	Impacts cannot be measured on a project-level basis.	Same as Alternative 4	Same as Alternative 4
Air Quality	No effect	Negligible to minor impacts due to emissions from survey vessels and from emissions of CO_2e from drilling programs.	Minor impacts due to emissions from survey vessels and from emissions of CO_2e from drilling programs.	Moderate impacts due to emissions from survey vessels and from emissions of CO_2e from drilling programs.	Same as Alternative 4	Same as Alternative 4
Acoustics	No effect	Moderate impacts from sound of exploration activities.	Moderate, although the number of exploration programs is increased from Alternative 2, the same types of noise-generating sources are to be used.	Moderate, although the number of exploration programs is increased from Alternative 2, the same types of noise-generating sources are to be used.	Same as Alternative 4	Same as Alternative 4
Water Quality	No effect	Impacts reduced to negligible by mitigation measures.	Impacts reduced to negligible by mitigation measures.	Impacts reduced to negligible by mitigation measures.	Same as Alternative 4	Same as Alternative 4
Environmental Contaminants and Ecosystem Functions	No effect	Negligible impacts, they could be medium intensity but would be local and temporary.	Minor impacts due to the greater level of activity increasing the potential volume of contaminants introduced to the project area.	Minor impacts due to the greater level of activity increasing the potential volume of contaminants introduced to the project area.	Same as Alternative 4	Same as Alternative 4
BIOLOGICAL ENVIRONMENT						
Lower Trophic Levels	No effect	Negligible impacts from disturbance of habitat and displacement of organisms from drilling, sediment sampling, ship anchoring, or platform installation; toxicity due to production discharge; increased productivity due to ice breaking. Introduction of invasive species from ship traffic could cause moderate impacts.	Negligible impacts, the increased levels of activity would not generate different types or level of impacts. Introduction of invasive species from ship traffic could cause moderate impacts.	Negligible impacts, the increased levels of activity would not generate different types or level of impacts. Introduction of invasive species from ship traffic could cause moderate impacts.	Same as Alternative 2, the time/area closures would not affect lower trophic levels.	Same as Alternative 2, the use of alternative technologies would not affect lower trophic levels.
Fish/Essential Fish Habitat	No effect	Minor impacts, small scale and temporary only.	Minor impacts, increased activities would not change the impact level.	Minor impacts, increased activities would not change the impact level.	Minor impacts. The time/area closures would reduce the impacts to lower than Alternative 2.	Negligible impacts. The use of alternative technologies may reduce any impact.
Marine and Coastal Birds	No effect	Negligible to minor impacts, depending on species ESA status, from temporary and localized disturbance, injury/mortality, and changes in habitat.	Negligible to minor impacts, depending on the species ESA status, increased activities would not change the impact level.	Moderate impacts from the increased level of activity.	Same as Alternative 4	Same as Alternative 4

Impact Topic	Alternative 1- No Action Alternative	Alternative 2- Authorization for Level 1 Exploration Activity	Alternative 3- Authorization for Level 2 Exploration Activity	Alternative 4- Authorization for Level 3 Exploration Activity	Alternative 5- Authorization for Level 3 Exploration Activity with Additional Required Time/Area Closures	Alternative 6- Authorization for Level 3 Exploration Activity with Use of Alternative Technologies
Marine Mammals: Bowhead Whales	No effect	Moderate impacts from noise disturbance, possible ship strikes, or habitat degradation.	Moderate impacts from noise disturbance, possible ship strikes, or habitat degradation.	Moderate to major impacts from noise disturbance, possible ship strikes, or habitat degradation.	Moderate impacts, as the Time/Area closures could reduce adverse impacts in particular times and locations.	Moderate to major impacts. Despite possible localized mitigating capabilities of alternative technologies the impact level would not change.
Marine Mammals: Beluga Whales	No effect	Moderate impacts from noise disturbance, possible ship strikes, or habitat degradation.	Moderate impacts from noise disturbance, possible ship strikes, or habitat degradation.	Moderate impacts from noise disturbance, possible ship strikes, or habitat degradation.	Minor to moderate impacts. The effects on beluga whales would be similar to Alternative 4 but may occur in different times and places.	Moderate impacts. Although the gradual introduction of these alternative technologies could eventually reduce the amount of seismic noise introduced into the marine environment, alternative technologies would not completely replace the existing technology, so moderate impacts would remain.
Marine Mammals: Other Cetaceans	No effect	Minor impacts from temporary, local disturbance.	Minor to moderate impacts from temporary, local disturbance. Increased activities would not change the impact level.	Minor to moderate impacts from temporary, local disturbance. Increased activities would not change the impact level.	Minor to moderate impacts. Although the time/area closures could reduce adverse impacts in particular times and locations, the overall exploration effort may not be reduced, but, rather, redistributed and possibly concentrated in other areas, so the impact would not change.	Minor to moderate impacts. Alternative technologies could reduce the extent to localized areas on a small scale; it is not currently possible to assess potential behavioral reactions and determine if intensity level would change as a result.
Marine Mammals: Ice Seals	No effect	Minor impacts from temporary localized disturbance.	Minor to moderate impacts from temporary localized disturbance. Increased activities would not change the impact level.	Minor to moderate impacts from temporary localized disturbance. Increased activities would not change the impact level.	Minor impacts, as the time/area closures could reduce potentially adverse effects on seals in those areas.	Minor to moderate impact. Alternative technologies would presumably reduce the amount of noise introduced but would still use marine vessels which are at least as important for disturbance to seals in the water.
Marine Mammals: Pacific Walrus	No effect	Minor impacts from disturbance, risk of injury or mortality, and changes in habitat in the Chukchi Sea. No impact from activities in the Beaufort Sea as they are uncommon there.	Minor impacts from disturbance, risk of injury or mortality, and changes in habitat in the Chukchi Sea. Despite the increased activity, there would be no increase in the impact level. No impact from activities in the Beaufort Sea as they are uncommon there.	Minor impacts from disturbance, risk of injury or mortality, and changes in habitat in the Chukchi Sea. Despite the increased activity, there would be no increase in the impact level. No impact from activities in the Beaufort Sea as they are uncommon there.	Minor impacts, although time/area closures would reduce potentially adverse effects on walrus in those areas. No impact from activities in the Beaufort Sea as they are uncommon there.	Minor impacts. Alternative seismic technologies for in-ice surveys would likely still require the use of ice and would therefore have similar disturbance effects on walrus as those technologies currently in use. No impact from activities in the Beaufort Sea as they are uncommon there.
Marine Mammals: Polar Bears	No effect	Minor impacts from temporary localized disturbance.	Minor impacts from temporary localized disturbance. Despite the increased activity, there would be no increase in the impact level.	Minor impacts from temporary localized disturbance. Despite the increased activity, there would be no increase in the impact level.	Minor impacts. The time/area closures may protect ice seals, a primary food source for polar bears.	Minor impacts. Alternative technologies would presumably reduce the amount of noise introduced but would still use marine vessels which are at least as important for disturbance to polar bears in the water.
Terrestrial Mammals	No effect	Minor impacts from temporary localized disturbance, risk of vehicle strikes, and habitat alternations.	Minor impacts. Despite the increased activity, there would be no increase in the impact level.	Minor impacts. Despite the increased activity, there would be no increase in the impact level.	Minor impacts. The time/area closures would not affect terrestrial mammals.	Minor impacts. The use of alternative technologies would not affect terrestrial mammals.
SOCIAL ENVIRONMENT						
Socioeconomics	Minor adverse impact from unrealized local employment and tax revenue.	Minor beneficial impact from temporary rise in regional personal income and employment rates.	Minor beneficial impact. Despite the increased activity, there would be no increase in the impact level because the increases in income and employment rates are not more than 5 percent.	Minor beneficial impact. Despite the increased activity, there would be no increase in the impact level because the increases in income and employment rates are not more than 5 percent.	Minor beneficial impact. The time/area closures could reduce total local employment rates and personal income so the positive impact would be less than Alternative 2.	Minor beneficial impact. The alternative technologies could result in additional costs from lost productivity so the positive impact would be less than Alternative 2.
Subsistence	No effect	Negligible to minor impacts from disturbance, depending on the species.	Negligible to moderate impacts from disturbance, depending on the species. Even with the increased activities, the impacts to subsistence resources and harvest would be similar in type, intensity, and duration, but would occur in more locations.	Negligible to moderate impacts from disturbance, depending on the species. Even with the increased activities, the impacts to subsistence resources and harvest would be similar in type, intensity, and duration, but would occur in more locations.	Negligible to minor impacts from disturbance, depending on the species. Impacts would be slightly reduced because of the required time/area closures that would be applied in all circumstances instead of being considered as additional mitigation measures.	Negligible to moderate impacts from disturbance, depending on the species. The effectiveness of these alternative technologies to reduce adverse impacts to subsistence uses is unknown. If alternative technologies reduce disturbance to marine mammals, that would reduce impacts to subsistence users.

Impact Topic	Alternative 1- No Action Alternative	Alternative 2- Authorization for Level 1 Exploration Activity	Alternative 3- Authorization for Level 2 Exploration Activity	Alternative 4- Authorization for Level 3 Exploration Activity	Alternative 5- Authorization for Level 3 Exploration Activity with Additional Required Time/Area Closures	Alternative 6- Authorization for Level 3 Exploration Activity with Use of Alternative Technologies
Public Health	No effect	Negligible impacts, both beneficial and adverse, from changes to: • Diet and nutrition • Contamination • Safety • Acculturative stress • Economic impacts • Health care services	Negligible impacts, both beneficial and adverse, from changes to: • Diet and nutrition • Contamination • Safety • Acculturative stress • Economic impacts • Health care services Despite the increased activity, there would be no increase in the impact level.	Negligible impacts, both beneficial and adverse, from changes to: • Diet and nutrition • Contamination • Safety • Acculturative stress • Economic impacts • Health care services Despite the increased activity, there would be no increase in the impact level.	Negligible impacts, both beneficial and adverse. If the time/area closures improve the likelihood of maintaining a strong subsistence harvest, there will also be resulting benefits to public health. If the closures allow hunters to complete their hunts with less travel time, it will benefit safety. However, these benefits do not affect the overall impact criteria rating, as it is are already negligible.	Negligible impacts, both beneficial and adverse. The alternative technologies may reduce disturbance to marine mammals, which could reduce adverse impacts to subsistence users. However, the effectiveness of the alternative technologies in reducing adverse impacts to subsistence uses is unknown, and thus the benefits are theoretical. Therefore, the impact rating remains the same. If the alternative technologies are demonstrated to be effective, they would benefit public health.
Cultural Resources	No effect	Negligible impact.	Negligible impact.	Negligible impact.	Minor impact. The time/area closures would not affect cultural resources.	Minor impact. The alternative technologies would not affect cultural resources.
Land and Water Ownership, Use, and Management	Major adverse impacts from loss of opportunity to explore for oil and gas.	Moderate impacts to land and water use from activity in new areas and potential long-term development. Negligible impacts to land and water ownership and management as no changes in management or ownership would occur.	Moderate impacts to land and water use from possible conflict between subsistence use and seismic surveys, changes in industrial, transportation, and commercial land use and management. Slightly higher possibility of new facilities and infrastructure, higher levels of air and vessel traffic, and commercial activity associated with survey support. Minor impacts to land and water management - as activities increase, the possibility for conflicts with borough offshore development policies goes up as well. Negligible impacts to land and water ownership as no changes in ownership would occur.	Moderate impacts to land and water use from possible conflict between subsistence use and seismic surveys, changes in industrial, transportation, and commercial land use and management. Slightly higher possibility of new facilities and infrastructure, higher levels of air and vessel traffic, and commercial activity associated with survey support. Minor impacts to land and water management - as activities increase, the possibility for conflicts with borough offshore development policies goes up as well. Negligible impacts to land and water ownership as no changes in ownership would occur.	Moderate impacts to land and water use. As time/area closures are implemented, the likelihood of conflicts decreases because the closures would lessen the exposure of subsistence species to seismic activities and exploratory drilling at critical locations and during critical seasons of the year. Time/area closures would shorten the timeframe available for oil and gas exploration activities and potentially impede exploration activity. As a result, there may be a reduction in transportation and commercial uses during certain times of the year. Minor impacts to land and water management. Constraining exploration to certain times and locations may result in more moderate state and federal resource development goals, while promoting management practices to protect the human, marine and coastal environments, and improve consistency with North Slope Borough and Northwest Arctic Borough comprehensive plans and Land Management Regulations. Therefore, because these techniques reflect balanced management and do not prohibit resource development, no inconsistencies or changes in federal or state land or water management are anticipated. Negligible impacts to land and water ownership as no changes in ownership would occur.	Moderate impacts to land and water use from activity in new areas and potential long-term development. Minor impacts to land and water management. Negligible impacts to land and water ownership as no changes in ownership would occur.
Transportation	No effect	Negligible (aircraft and vehicle) to minor (vessel) impacts from increased traffic.	Minor to moderate impacts from increased traffic.	Minor to moderate impacts from increased traffic.	Minor to moderate impacts from increased traffic. The time/area closures would limit the amount of aircraft overflights in these areas.	Minor to moderate impacts from increased traffic. It is assumed that these new alternative technologies would require the same levels of aircraft and surface and vessel support as under Alternative 3, and, therefore, the impacts are expected to be similar.
Recreation and Tourism	No effect	Minor impacts from temporary and local effects on recreational setting.	Minor impacts from temporary and local effects on recreational setting. The increased levels of activity would not generate different types or level of impacts.	Minor impacts from temporary and local effects on recreational setting. The increased levels of activity would not generate different types or level of impacts.	Minor impacts from temporary and local effects on recreational setting. If the time/area closures benefit marine mammals, they would also benefit recreation and tourism based on wildlife viewing.	Minor impacts from temporary and local effects on recreational setting. The alternative technologies would not affect recreation or tourism.
Visual Resources	No effect	Moderate impacts from high contrast of drill sites and associated activities.	Moderate impacts from high contrast of drill sites and associated activities.	Moderate impacts from high contrast of drill sites and associated activities.	Same as Alternative 3.	Same as Alternative 3.

Impact Topic	Alternative 1- No Action Alternative	Alternative 2- Authorization for Level 1 Exploration Activity	Alternative 3- Authorization for Level 2 Exploration Activity	Alternative 4- Authorization for Level 3 Exploration Activity	Alternative 5- Authorization for Level 3 Exploration Activity with Additional Required Time/Area Closures	Alternative 6- Authorization for Level 3 Exploration Activity with Use of Alternative Technologies
Environmental Justice	No effect	Minor adverse impacts from disruption of subsistence activities and potential contamination of subsistence food. Minor beneficial impacts from local employment opportunities.	Minor adverse impacts from disruption of subsistence activities and contamination of subsistence food. Minor beneficial impacts from local employment opportunities.	Minor adverse impacts from disruption of subsistence activities and contamination of subsistence food. Minor beneficial impacts from local employment opportunities.	Minor impacts. With the time/area closures, the impacts to subsistence activities could be further minimized but would remain minor.	Minor impacts. With the alternative technologies, the impacts to subsistence foods and human health could be further minimized but would remain minor.

3.5 Physical Environment

3.5.1 Air Quality

The EIS project area is in attainment (or unclassifiable) for all air quality criteria pollutants. The maximum measured concentrations are all well below the National Ambient Air Quality Standards and Alaska State Standards. These values are indicative of the relatively good air quality in the area, and indicate that future development that would not necessarily jeopardize the region's ability to meet the federal and State of Alaska air quality standards.

Impacts

- All action alternatives would cause minor to moderate adverse impacts to air quality from air pollutant emissions. The majority of emissions are from fuel combustion for vessel propulsion and power generation. The expected emission levels would equal but not exceed air quality regulatory limits.
- The increase in emissions from the additional activities under Alternatives 3, 4, and 5 would be minimal so the impact remains moderate.

3.5.2 Acoustics

The existing airborne and underwater noise environment in the EIS project area is influenced by sounds from natural and anthropogenic sources. The primary natural source of airborne noise on the offshore, nearshore, and onshore regions is wind, although wildlife can produce considerable sound during specific seasons in certain nearshore and onshore regions. Anthropogenic noise levels in the Beaufort Sea region are higher than the Chukchi Sea due to the oil and gas developments of the nearshore and onshore regions of the North Slope, particularly in the vicinity of Prudhoe Bay. Noise sources consist of regular air traffic, vehicular traffic on the numerous roads within the development areas (such as around Deadhorse). Noise is also produced by the operations of heavy construction and industrial equipment that service the wells, processing facilities, pipelines, and camps. Industrial activities occur throughout the region on a year-round basis.

Anthropogenic noise levels in the nearshore and onshore region will be higher in populated areas – the coastal communities of Wainwright, Point Lay, Point Hope, Kivalina, and Barrow – with increasing noise levels associated with the larger communities. Community noise consists of aircraft, vehicular traffic (including all-terrain vehicles and snow machines), construction equipment, people talking/yelling, dogs barking, power plants, skiffs used for hunting, generators, etc.

Underwater noise is comprised of natural and anthropogenic sources. It varies temporally (daily, seasonally, annually) depending on weather conditions and the presence of anthropogenic and biological sources. Natural sound sources in the Arctic Ocean include earthquakes, wind, ice, and sounds from several animal species. Anthropogenic noise sources include vessel traffic, oil and gas exploration, and other miscellaneous sources.

Impacts

- While high sound levels do not constitute an effect, the presence of high sound levels from anthropogenic activity and consequent exposures of marine wildlife to these conditions could potentially cause adverse effects. The impact criteria for acoustics are based on the existence of sound levels that could cause effects.
- All action alternatives would cause moderate adverse impacts to acoustics because they produce underwater sound levels that could exceed ambient noise levels or exceed disturbance and injury thresholds.

- The increased activity under Alternatives 3, 4 5, and 6 would not raise the sound level above the moderate impact level.
- The time/area closures under Alternative 5 do not reduce sound levels but they do reduce the likelihood that exploration activities would occur when marine mammals would be present and consequently reduce the chances of injurious exposures. Moderate adverse impacts remain, as the exploration activities in non-closure areas/periods will introduce sources that produce underwater sound levels that exceed disturbance and injury thresholds.
- Under Alternative 6, the use of alternative technologies that reduce sound levels from seismic survey sources would not reduce the impact level which would be moderate. This is because it is unlikely the technologies will entirely preclude the generation of sound levels exceeding the injury and disturbance criteria.

3.6 Biological Environment

3.6.1 Marine Mammals

Bowhead and belugas whales are discussed below. The alternatives would be expected to have mostly minor adverse impacts to other marine mammals (other cetaceans, ice seals, Pacific walrus, and polar bear) which are not discussed here. Mechanisms for disturbance would be similar amongst all marine mammal species. Please see Chapter 4 of the EIS for a complete discussion of impacts to these species.

Both bowhead and beluga whales could be present in the EIS project area throughout the spring, summer, and fall. Both species use the area during migration and for feeding. Bowhead whales are known to concentrate in the Barrow area for feeding during the spring and fall, and conduct migrations through the Beaufort and Chukchi seas in both the spring and fall. Beluga whales are known to feed in Barrow Canyon, the Shelf Break of the Beaufort Sea, and in Kasegaluk Lagoon.

The primary adverse impact on bowhead and beluga whales resulting from the action alternatives would be from noise exposure. Noise can cause behavioral disturbance and auditory impairment. Disturbance to feeding, resting, or migrating bowhead or beluga whales could cause whales to leave areas of exploration activity and avoid them in the future, effectively reducing their available habitat. Ship strikes and habitat degradation is also possible. Oil and gas exploration activities that may alter whale habitat include: disturbance of sea ice from icebreaking, disturbance of benthic sediments during drilling, contamination of the marine environment from discharge of drilling muds and other waste streams from ships and support facilities.

Impacts

- All action alternatives would cause moderate adverse impacts to bowhead and beluga whales from noise disturbance, risk of ship strikes, and habitat degradation.
- The increased activity under Alternative 4 could increase the impact level to major adverse for bowhead whales.
- The time/area closures under Alternative 5 would reduce the potential disturbance to bowhead and beluga whales in the closure areas during time periods specified. Exploration activities could, however, occur during different time periods within these areas, leading to a short-term reduction of effects. In addition, industry may relocate exploration activities to other, possibly adjacent, areas until the closure areas are available. Exploration effort may not be reduced, but, rather, redistributed and possibly concentrated in other areas. The time/area closures that mitigate adverse impacts on concentrations of bowhead whales, mothers and calves, and important life history functions, such as feeding, could reduce impacts to a lower intensity, shorter duration and more localized areas than would result in the absence of closures. However, bowhead whale

habitat use in the EIS project area is dynamic and, when migration corridors are considered includes large portions of the Beaufort and Chukchi seas that are not included in the time/area closures. Although the time/area closures could mitigate adverse impacts in particular times and locations, the impact on bowhead whales and beluga whales of oil and gas exploration activities allowed under Alternative 5 would be similar to Alternative 3 and would be considered moderate.

- The use of alternative technologies under Alternative 6 may reduce adverse impacts associated with the use of airgun arrays, but the results are difficult to determine and the overall reduction would likely be minimal. Airgun noise would not be eliminated, however, since these alternative technologies would not completely replace the existing technology, and what may be replaced is limited. In addition, surveys conducted with alternative technologies would still use marine vessels to tow or deploy equipment which could disturb bowhead whales, beluga whales, and other cetaceans. While alternative technologies could reduce the extent to localized areas on a small scale; it is not currently possible to assess potential behavioral reactions and determine if intensity level would change.

3.7 Social Environment

3.7.1 Socioeconomics

Exploration, development, production, and transportation of oil and gas are the major contributors to the economy of Alaska and the NSB. Other sectors include government, transportation, and mining.

Impacts

- Alternative 1 (No Action) would cause minor adverse impacts from unrealized local employment and tax revenue. The potential unrealized revenue for state and federal governments is unknown since the likelihood of exploration resulting in production cannot be predicted.
- All five action alternatives would cause minor beneficial impacts from a temporary rise in regional personal income and employment rates.
- Alternatives 3, 4, 5, and 6 would not cause an increase in the level of beneficial impact because income and employment rates are not expected to rise more than five percent.
- The time/area closures under Alternative 5 could reduce total income and employment rates and therefore the beneficial impact would be less than Alternative 4, but would still be minor.
- The alternative technologies requirement under Alternative 6 could cause additional costs from lost productivity so the beneficial impact would be less than Alternative 4, but would still be minor.

3.7.2 Subsistence

Subsistence resources in the EIS project area are harvested by the communities of Kaktovik, Nuiqsut, Barrow, Wainwright, Point Lay, Point Hope, Kivalina, and Kotzebue. Resources harvested include the bowhead whale, beluga whale, seals (bearded, ribbon, ringed, and spotted), walrus, polar bear, fish, migratory waterfowl (including their eggs), and caribou.

Oil and gas exploration activities could disturb and displace subsistence resources, causing them to move away from coastal waters and become less readily available to subsistence hunters. Contamination of subsistence resources through discharge of drilling muds and other waste streams from ships and support facilities industrial pollution would be possible.

Impacts

- All action alternatives except Alternatives 2 and 5 would have impacts to subsistence ranging from negligible to moderate adverse depending on the species to be harvested.
- Alternative 5 could reduce adverse impacts in areas where the required time/area closures would occur if they overlapped with subsistence hunting seasons.
- The adverse impact level under Alternative 6 would be reduced if the alternative technologies are successful in reducing disturbance to marine mammals.

3.7.3 Land and Water Ownership, Use, and Management

The lands and waters within the EIS project area is owned and managed by many different entities including: the federal government, state government, borough government, Alaska Native corporations, and Alaska Native allottees. Land and water uses in the area include; recreation, subsistence, industrial, residential, mining, protected natural areas, transportation, and commercial activities.

Oil and gas exploration activities could affect land and water ownership, use, or management by causing a change in the ownership, use, or management of land or water in the EIS project area. These changes could include; rezoning, increases in transportation activity, construction of infrastructure, and seismic surveys in subsistence hunting areas.

Impacts

- The No Action alternative would have a major adverse impact on land and water use and management because it would be a significant change from existing conditions. This alternative would be contrary to current federal and state management of offshore waters. This alternative would reduce activity levels and affect management plans and would fundamentally change federal, state, and private development rights by preventing exploration for oil and gas resources.
- Impacts to land and water use would be moderate adverse for all four action alternatives due to changes in use patterns.
- Impacts to land and water management would be as follows for the four action alternatives: negligible for Alternative 2 as no changes are expected; minor adverse for Alternatives 3 and 4 as the increased activity level may cause conflicts with management plans; minor adverse for Alternative 5 because the time/area restrictions are a change in management; and minor adverse for Alternative 6.
- Impacts to land and water ownership would be negligible for Alternatives 2, 3, 4, 5, and 6 as no changes in ownership would occur.

3.7.4 Visual Resources

Visual resources within the EIS project area are dominated by characteristics of the Beaufort and Chukchi seas. The visual characters of these water bodies undergo dramatic changes across seasons, due in large part to the dynamic seasonal cycle of sea ice. During the fall, winter, and spring seasons, both the Beaufort and Chukchi seas are covered by sea ice. The scenic quality of the EIS project area (separated into the east/west portions of the Beaufort and Chukchi seas) was ranked using the following seven key factors: landform, vegetation, water, color, adjacent scenery, scarcity, and cultural modification. All four sections were ranked as having Class A scenery during summer months and Class B scenery during the winter months.

Oil and gas exploration activities would impact visual resources by creating visual contrast that may diminish the scenic quality of the area.

Impacts

- All five action alternatives would have short-term, moderate adverse impacts on scenic quality and visual resources.
- Alternatives 3 through 6 could have higher intensity impacts because of the greater number of support vessels used in the two exploratory drilling programs if both programs are implemented close to each other. However, impacts would not increase above the moderate level.
- Neither the implementation of time/area closures nor the use of alternative technologies would affect visual resources.

3.8 Cumulative Impacts

Cumulative effects of development are a major concern of many stakeholders in the Chukchi and Beaufort seas. The nature and level of activities in the Arctic have been increasing over time, particularly in offshore areas. Changes in climate characteristics are also factors in potential cumulative effects. Past, present, and reasonably foreseeable future actions and activities considered for the cumulative effects analysis include: oil and gas exploration, development, and production activities; scientific research; mining exploration, development, and production; military facilities and training exercises; increased air and marine transportation; major community development projects; subsistence activities; recreation and tourism; and climate change. Commercial whaling in the late 19th century is also a past adverse effect specific to bowhead whales that still influences population levels because the population is still recovering from depletion caused by commercial whaling.

Alternative 1 would have minor cumulative adverse impacts to socioeconomics, and major cumulative adverse impacts to land and water ownership, use and management.

Any of the five action alternatives would have major adverse cumulative impacts on visual resources, moderate to major adverse impacts on bowhead whales, and moderate adverse impacts on climate, air quality, lower trophic levels, beluga whales, subsistence, and visual resources.

4.0 OIL SPILL ANALYSIS

While not considered part of any of the proposed alternatives, NMFS analyzed the potential environmental effects of a low-probability, high impact event, a hypothetical very large oil spill (VLOS) in the Chukchi and Beaufort seas. For the Chukchi Sea, the discussion relies heavily on the recent BOEM Lease Sale 193 Revised Draft Supplemental EIS (BOEM 2011b) and other publicly available information. For the Beaufort Sea, the discussion and analysis is incorporated from the recent BOEM 2012-2017 OCS Oil and Gas Leasing Program Draft Programmatic EIS (BOEM 2011d).

In summary, a VLOS in either the Chukchi or Beaufort seas would have:

- Major adverse impacts to water quality; environmental contaminants and ecosystem functions; marine and coastal birds; bowhead whales; beluga whales; other cetaceans; socioeconomics; subsistence; land and water ownership, use, and management; recreation and tourism; and visual resources.
- Moderate to major adverse impacts to acoustics, lower trophic levels, polar bears, public health, transportation, and environmental justice.
- Moderate adverse impacts to physical oceanography and fish/essential fish habitat.
- Minor to moderate adverse impacts to climate, seals, walrus, terrestrial mammals, and cultural resources.
- Minor adverse impacts to air quality.

5.0 IMPLEMENTATION, MONITORING AND REPORTING, AND ADAPTIVE MANAGEMENT

5.1 EIS Implementation and NEPA Compliance

The Final EIS will identify the Preferred Alternative. The Record of Decision (ROD) will provide a listing of activities addressed by the Preferred Alternative and will identify any conditions of approval that are relevant to industry authorization requests. The EIS and ROD together constitute a decision document to be used for ongoing and future permitting activities addressed by this EIS. NMFS and BOEM will use the EIS when issuing ITAs and G&G permits and ancillary activity notices for oil and gas exploration activities. Because the EIS addresses general effects and is not specific to the request for an ITA for a particular activity, additional NEPA review may be required for each application for authorization. The form of the additional review will depend on the nature and scope of the proposed activity. The review may take the form of:

- Categorical Exclusion and/or a Memorandum to the File;
- An Environmental Assessment (EA);
- A Supplemental EIS; or
- A new EIS.

BOEM intends to conduct site-specific NEPA analyses that either tier from the EIS or incorporate it by reference. BOEM would also use the EIS to assist in carrying out other statutory responsibilities such as working with NMFS and the U.S. Fish and Wildlife Service to ensure compliance with the Endangered Species Act and Magnuson-Stevens Fishery Conservation and Management Act, and where needed could modify permit conditions or lease operation to meet the requirements of any Endangered Species Act or MMPA authorization.

5.2 Monitoring and Reporting

The MMPA mandates that an authorization issued for the incidental take of marine mammals include a requirement that the taking be monitored and reported. The purposes, goals, and objectives of monitoring and reporting under the MMPA are summarized below.

Monitoring measures should be designed to accomplish or contribute to one or more of the following goals:

To increase the understanding of –

- The likely occurrence of marine mammal species in the vicinity of the action, i.e., presence, abundance, distribution, and/or density of species.
- The nature, scope, or context of the likely exposure of marine mammal species to any of the potential stressor(s) associated with the action (e.g. sound or visual stimuli), through a better understanding of one or more of the following:
  - the action itself and its environment (e.g. sound source characterization, propagation, and ambient noise levels);
  - the affected species (e.g. life history or dive patterns);
  - the likely co-occurrence of marine mammal species with the action (in whole or part) associated with specific adverse effects, and/or;
  - the likely biological or behavioral context of exposure to the stressor for the marine mammal (e.g. age class of exposed animals or known pupping, calving or feeding areas).

- How individual marine mammals respond (behaviorally or physiologically) to the specific stressors associated with the action (in specific contexts, where possible, e.g., at what distance or received level).
- How anticipated individual responses, to individual stressors or anticipated combinations of stressors, may impact either: 1) the long-term fitness and survival of an individual; or 2) the population, species, or stock (e.g. through effects on annual rates of recruitment or survival).
- How the activity affects marine mammal habitat, such as through effects on prey sources or acoustic habitat (e.g., through characterization of longer-term contributions of multiple sound sources to rising ambient noise levels and assessment of the potential chronic effects on marine mammals).
- The impacts of the activity on marine mammals in combination with the impacts of other anthropogenic activities or natural factors occurring in the region.
- The effectiveness of mitigation and monitoring measures.
- The manner in which the authorized entity complies with the incidental take authorization and incidental take statement.
- An increase in the probability of detecting marine mammals (through improved technology or methodology), both specifically within the safety zone (thus allowing for more effective implementation of the mitigation) and in general, to better achieve the above goals.

Applicants should target questions that have been identified as priorities (i.e. to fill data gaps). Proposed monitoring plans are evaluated using the above guidance, considering the likelihood of effectively answering the questions. Regulations prescribe that monitoring plans undergo an independent peer review where the proposed activity may affect the availability of marine mammals for taking for subsistence uses.

5.2.1 Monitoring Plan Peer Review

The MMPA requires that monitoring plans be independently peer reviewed "where the proposed activity may affect the availability of a species or stock for taking for subsistence uses." NMFS's regulations written to implement this requirement state, "Upon receipt of a complete monitoring plan, and at its discretion, [NMFS] will either submit the plan to members of a peer review panel for review or within 60 days of receipt of the proposed monitoring plan, schedule a workshop to review the plan." Although the MMPA only includes this requirement for IHAs, in its implementing regulations, NMFS extended this requirement to include LOAs as well.

In the 1980s and 1990s, NMFS convened a meeting each year between the applicable Federal agencies, ITA applicants for the upcoming open-water season, industry and agency scientists, and Native Alaskan subsistence hunters to discuss best ways to monitor the effects of the upcoming programs on marine mammals. These meetings would typically last a few days where there would be a robust discussion between all parties involved. ITA applicants would then adjust their monitoring programs based on the discussions. At that time, these meetings served to meet the requirement for an independent peer review via the workshop option described in the regulations.

In the late 1990s and early 2000s, these meetings were not held because there was very little activity during the open-water season in the U.S. Arctic Ocean. NMFS began to reconvene the meetings in 2006 when the level of activities for the open-water season began to increase. These annual meetings came to be known as the Arctic Open-Water Meeting. However, while these meetings were initially small gatherings of 15 to 30 people in the 1980s and early 1990s, from 2006 through 2013 the meetings drew approximately 150 to 250 participants each day, thus making it difficult to include the focused and detailed reviews of the applicants' monitoring plans.

In order to ensure the focused independent peer review of the monitoring plans prescribed by the regulations, in 2010, NMFS divided the annual meeting into two separate parts, one larger and more open to stakeholder input, and one smaller meeting where a group of scientists specifically gathers to review the monitoring reports. In 2010, 2011, 2012, and 2013, after soliciting nominations from the industry ITA applicants, the Marine Mammal Commission, and the affected subsistence communities and representative organizations, NMFS convened panels of approximately five to seven scientists to provide an independent scientific review of the plans. During these reviews, NMFS charged the panel members with determining whether or not the monitoring plans, as put forth by the applicants, would accomplish the goals described earlier in this Executive Summary. After the meetings, the panel members provided a final report to NMFS with their recommendations. NMFS reviewed the peer review panel report in the context of the applicants' activities and the requirements of the MMPA and selects those that were appropriate for potential inclusion in the applicant's final monitoring plans. NMFS then works with the applicants regarding the practicability of including these measures and protocols, and then includes the selected measures as requirements in the issued authorizations.

This process is still developing, and some strengths and weaknesses have been identified. Utilizing a smaller group chosen from nominated scientists, with affected subsistence hunters available to share information and respond to questions, allows for a true scientific and independent review of the monitoring plans. The peer review panel report (which was not provided prior to 2010) provides NMFS with concrete recommendations that can be shared with the applicants and allows NMFS and the applicants to identify ways to improve the plans for current and future actions. However, panel members have suggested that the time allotted for interaction with the applicants in 2010 and 2011 was too short, so NMFS added additional time for interaction at the 2012 peer review panel meeting. Therefore, NMFS will strive to provide additional time for interaction where feasible. Also, at the request of the applicants, beginning in 2012, questions were provided to them in advance so that they could be prepared to discuss specific issues identified by the panel members. Generally, both scientist reviewers and applicants have indicated that this more focused method for peer review of the monitoring plans is more effective than the larger meeting format used in 2006 through 2009. However, it is an iterative process, and NMFS intends to continue modifying the methods as necessary to most effectively solicit input.

5.2.2 Potential Improvements for Monitoring and Reporting Plans

Recommendations from improvements to monitoring plans have been made to NMFS at the Arctic Open-Water Meetings, through public comments on NEPA and MMPA documents, and at Plan of Cooperation (POC) meetings. The new peer review format that has been developed includes:

- focused prioritization of needs, and
- guidance to applicants before they develop their initial applications.

In 2010 and 2011, the independent peer reviewers included recommendations in their reports (related to both the goals of monitoring, in addition to methodology) that could be more broadly applied to multiple applicants. This type of comprehensive consideration of multiple monitoring activities across multiple years is what was identified as a mechanism to accomplish combined monitoring in the U.S. Arctic.

NMFS is considering several methods to more comprehensively prioritize and plan ITA monitoring:

- Developing and maintaining (on the NMFS website) a list of monitoring priorities and data gaps for Arctic oil and gas development projects;
- Soliciting input for this list from Open-Water Meetings, peer review panels, public comment periods, or, potentially, a longer term panel convened specifically to develop these priorities;

- Including specific recommendations for discrete monitoring projects (with suggested methodologies) that could be adopted by new applicants; and
- Considering and describing how to best build on existing monitoring results and best integrate data collection, analysis, and reporting with simultaneous monitoring efforts.

NMFS intends to explore the possibility of using the existing public input tools to develop an iterative and systematic annual means of identifying and prioritizing the monitoring goals for Arctic oil and gas exploration activities. These priorities could be available to potential applicants on the NMFS website along with specific methodology recommendations summarized from previous peer review recommendations to provide direction and guidance to applicants and allow for the most effective use of resources to answer the most pressing questions related to the effects of oil and gas exploration on marine mammals.

5.2.3 BOEM's Environmental Studies Program

The OCS Lands Act authorizes an Environmental Studies Program (ESP) to establish the information needed for assessment and management of environmental impacts on the human, marine, and coastal environments of the OCS. The Alaska Studies Plan complements and reinforces the goals of the ESP. The ESP is guided by several broad themes:

- Monitoring Marine Environments;
- Conducting Oil-Spill Fate and Effects Research;
- Minimizing Seismic and Acoustic Impacts;
- Understanding Social and Economic Impacts; and
- Maintaining Efficient and Effective Information Management;

The Alaska OCS Region continually proposes new studies and pursues information needs in conjunction with ESP goals in order to answer the following fundamental questions:

- What is the expected change in the human, marine, and coastal environment due to offshore activity?
- Can undesirable change be minimized by mitigation measures?

Currently, the Alaska ESP is primarily focused on upcoming developments, exploration activities, and existing and potential future lease sales in the Beaufort Sea and Chukchi Sea Planning Areas. The Alaska ESP maintains a long list of ongoing and proposed studies in both seas.

5.3 Tools for Mitigating Impacts on Subsistence

Several processes and programs have evolved to facilitate interaction between the industry and the affected local communities to ensure that the Arctic subsistence culture can continue to thrive in conjunction with oil and gas exploration. Some of these processes are Federally-mandated while others have been voluntary between the industry and local communities. This section discusses three of these tools:

(1) Plans of Cooperation (POC), which are required by NMFS' implementing regulations;

(2) Open Water Season Conflict Avoidance Agreements (CAA), which are voluntary and not required by any statute or regulation; and

(3) The annual Arctic Open-Water Meeting.

For the purposes of protecting the subsistence uses of marine mammals, the MMPA implementing regulations require that for an activity that will take place near a traditional Arctic hunting ground, or may affect the availability of marine mammals for subsistence uses – an applicant for MMPA authorization must either submit a POC or information that identifies the measures that have been taken to minimize adverse impacts on subsistence uses. The regulations provide further guidance by describing that a POC must include the following:

- a statement that the applicant has notified the affected subsistence community and provided them a draft POC;
- a schedule for meeting with the communities to discuss proposed activities and resolve potential conflicts regarding any aspects of the operation or POC;
- a description of measures the applicant has taken or would take to ensure that proposed activities would not interfere with subsistence hunting; and
- what plans the applicant has to continue to meet with the communities, prior to and during the activity, to resolve conflicts and notify the community of any changes in the activity.

5.3.1 Conflict Avoidance Agreement and Plan of Cooperation

Subsistence communities and the oil and gas industry have worked together to develop documents called Conflict Avoidance Agreements (CAA), which were intended to ensure that there would be "no unmitigable impacts to subsistence uses of marine mammals" resulting from industry activities and generally included (among many other measures) the components identified in the requirements for the POC. The CAA was a binding legal agreement signed by individual companies and the Alaska Eskimo Whaling Commission (AEWC) that put agreed-upon measures in place that would purportedly allow the industry to conduct the indicated activity while ensuring there were no conflicts with the subsistence hunt that would result in unmitigable adverse impacts.

For many years, NMFS generally found, after conducting an independent analysis, that if a company and the AEWC signed a CAA, then it was possible for a company to conduct their activity without having an unmitigable adverse impact on the subsistence hunt. However, in more recent years, some companies have become reluctant to sign a CAA with the AEWC. Additionally, stakeholders have raised the issue that a CAA developed by the AEWC does not represent the interests of subsistence hunts of species other than bowhead whales. As companies and the public began to voice these concerns, it became apparent that companies may not agree upon terms or sign CAAs, and NMFS would need to conduct a more rigorous and comprehensive independent analysis of the likely subsistence impacts and to specifically review the contents of each company's POC (since there might no longer be a CAA).

POCs are required by NMFS' implementing regulations, and CAAs are not. However, input from the impacted subsistence communities indicates that they have found that the CAA process, through its highly interactive and legally binding aspects, has effectively resulted in the development and implementation of measures that will ensure no unmitigable adverse impact. Alternatively, subsistence communities have found that the POC process has not been effective because it has been implemented in a one-way fashion (i.e. the company develops a POC without meaningful input from the subsistence communities) that has not included measures adequate to ensure no unmitigable adverse impact on subsistence uses.

Because the current process requires both negotiating CAAs (regardless of whether they are ultimately signed by either party) and developing POCs, NMFS plans to explore methods of clarifying the POC requirements of the MMPA. With input from both subsistence communities and the applicants for MMPA authorizations, NMFS plans to incorporate the effective pieces of the CAA negotiations into the POC while ensuring compliance with the MMPA.

NMFS foresees developing this more effective process to ensure no unmitigable adverse impact as an iterative process that would be addressed specifically at future annual Arctic Open-Water Meetings, as well as independently with NMFS, the industry, and the affected subsistence communities. NMFS further foresees more direct involvement in this process than has occurred in the past, and more transparency regarding what measures are necessary to protect the subsistence hunts of all species under NMFS' jurisdiction.

5.3.2 Arctic Open-Water Meeting

The Arctic Open-Water Meeting is the stakeholder meeting that is conducted to ensure NMFS' understanding of the effects of industry activity on the subsistence uses of marine mammals, with input from the subsistence users. The Arctic Open-Water Meeting has typically attracted members of industry, Federal, state, and local government officials and scientists, Native Alaskan marine mammal commissions, affected Native Alaskan hunters and community members, environmental non-governmental organizations, and other interested members of the public. Typically, the industry presents the results of their marine mammal monitoring programs from the previous year and activities proposed for the upcoming season along with the associated monitoring plans. Alaska Native subsistence group representatives (e.g. whaling captains and AEWC members.) present information related to impacts that industry activities may have had (either in the past year or historically) on their ability to effectively hunt a given species. There have also been presentations regarding ongoing western and traditional science programs conducted in the region.

The Artic Open-Water Meeting is not specifically required by statute or regulation. However, NMFS has continued to organize this annual meeting because of the importance of stakeholder input and interaction in NMFS' determination of whether a specific activity will likely have an unmitigable adverse impact on subsistence uses. The meeting allows the public to provide input on industry proposals while the federal agencies that are responsible for authorizing the activity itself and the incidental take of marine mammals can listen to those comments and participate in the interaction. There is a separate monitoring plan peer review session that is required to be held.

5.4 Adaptive Management

NMFS and BOEM historically used, and will likely use in the future, adaptive management principles in the issuance of permits and authorizations and any adaptive adjustments of mitigation and monitoring. The intent of adaptive management here is to ensure:

(1) The minimization of adverse impacts to marine mammals, subsistence uses of marine mammals, endangered species, and other protected resources, within the context of the associated regulations and statutes;

(2) The maximization of value of the information gathered via required monitoring, and;

(3) Industry compliance with environmental protection statutes and regulations.

Following are some of the specific sources of information upon which adaptive management decisions could be based:

(1) Results of monitoring required pursuant to MMPA ITAs or other Federal statutes for Arctic oil and gas development activities;

(2) Stakeholder input during the annual Arctic Open-Water Meetings;

(3) Scientific input from the independent peer review;

(4) Public input during comment periods on MMPA authorizations;

(5) Results from BOEM's Environmental Studies Program;

(6) Results from general marine mammal and sound research;

(7) Results from the efforts of the NOAA Working Groups working on Underwater Soundmapping and Cetacean Mapping in the Arctic and elsewhere;

(8) Results of the BP Cumulative Impact modeling of multiple sound sources in the Beaufort Sea; and

(9) Any information that reveals that marine mammals may have been taken in a manner, extent, or number not authorized.

VOC	volatile organic compounds
WAH	Western Arctic Caribou Herd
WCD	Worst Case Discharge

1.0 PURPOSE AND NEED

This chapter establishes the purpose and need for the Effects of Oil and Gas Activities in the Arctic Ocean Environmental Impact Statement (EIS). It also contains background information on previous planning processes related to this EIS. The information contained in the following sections is intended to provide an analysis of management alternatives and help set the stage for informed decision-making for future management actions. The overall organization of the document is outlined in Section 1.9.

1.1 Background

Pursuant to the National Environmental Policy Act (NEPA), the U.S. Department of Commerce (DOC), National Oceanic and Atmospheric Administration (NOAA), National Marine Fisheries Service (NMFS) and the U.S. Department of the Interior (USDOI), Bureau of Ocean Energy Management (BOEM) have prepared an EIS to describe and analyze the potential impacts to the human environment related to oil and gas industry offshore exploration activities (e.g. seismic surveys and exploratory drilling activities) in the U.S. Beaufort and Chukchi seas, Alaska.

Department of the Interior – Agency Reorganization

Pursuant to DOI Secretarial Order No. 3299 (May 19, 2010), the Minerals Management Service (MMS) began a reorganization process toward establishing three separate and independent management structures to carry out the functions once performed by MMS. To facilitate this reorganization, on June 18, 2010, MMS was given the interim name, Bureau of Ocean Energy Management, Regulation and Enforcement (BOEMRE). On October 1, 2010, the revenue collection arm of BOEMRE became the Office of Natural Resources Revenue (ONRR), and one year later, on October 1, 2011, BOEMRE completed the final step in its reorganization by establishing the Bureau of Ocean Energy Management (BOEM) and the Bureau of Safety and Environmental Enforcement (BSEE).BOEM is now the cooperating agency for this EIS, and designations for MMS, BOEMRE, and BOEM are used interchangeably below, but in accordance with the historical context

On April 6, 2007, NMFS and MMS published a Notice of Availability (NOA) for a Draft Programmatic Environmental Impact Statement (DPEIS) (72 *Federal Register* [FR] 17117). The DPEIS assessed the impacts of MMS' issuance of permits and authorizations under the Outer Continental Shelf Lands Act (OCS Lands Act) for seismic surveys in the U.S. Beaufort and Chukchi seas off the coast of Alaska, and NMFS' issuance of incidental take authorizations (ITAs) under Section 101(a)(5) of the Marine Mammal Protection Act (MMPA) to take marine mammals incidental to conducting those permitted activities.

The scope and effects of the seismic survey activities analyzed in the DPEIS were based on the best available information at the time. However, since 2007, new information that alters the scope, set of alternatives, and analyses in the DPEIS has become available (e.g. scientific study results, changes in projections of level and types of offshore exploration activities). In addition, NMFS determined that an EIS should also address the potential effects of exploratory drilling, which was not addressed in the 2007 DPEIS. Therefore, NMFS and MMS filed a Notice of Withdrawal of the DPEIS on October 28, 2009, (74 FR 55539) and announced their decision to prepare a new EIS, the *Effects of Oil and Gas Activities in the Arctic Ocean*. A Notice of Intent (NOI) to prepare the new EIS was announced in the *Federal Register* on February 8, 2010 (75 FR 6175). The purpose of the NOI was to announce the preparation of a new EIS that would analyze the potential effects of both geophysical surveys and exploratory drilling, address cumulative effects over a longer time frame, consider a range of reasonable alternatives consistent with the agencies' statutory mandates, and analyze the range of practicable mitigation and monitoring measures for protecting marine mammals and their availability for subsistence uses. The NOI asked for public comments and stated that MMS (now BOEM) would be a cooperating agency on this EIS. The North Slope Borough (a local governmental entity of the State of Alaska) is also a cooperating agency on the EIS. NMFS invited the U.S. Environmental Protection Agency (EPA) to be a cooperating agency, but the EPA chose to participate as a "consulting" agency on this EIS and has provided input into sections where the EPA has subject matter expertise. NMFS also coordinated with the Alaska Eskimo Whaling Commission (AEWC) pursuant to our co-management agreement under the MMPA on the preparation of this EIS. NMFS invited the U.S. Fish and Wildlife Service (USFWS) to join the effort as a cooperating agency, but they declined the request.

On December 30, 2011, NMFS published an NOA for the *Effects of Oil and Gas Activities in the Arctic Ocean Draft Environmental Impact Statement* in the *Federal Register* (76 FR 82275). The public was afforded 60 days to comment on that document. Consistent with comments on the Draft EIS, NMFS and BOEM determined that the Final EIS would benefit from the inclusion of additional alternatives for analysis that cover a broader range of potential levels of exploratory drilling, including scenarios in the Beaufort and Chukchi seas that are more reflective of the levels of activity that oil and gas companies have indicated may be pursued in the region within the coming years. The alternatives are based upon the agencies' analysis of additional information, including the comments and information submitted by stakeholders during the Draft EIS public comment period. For this reason, the agencies determined it appropriate to prepare this Supplemental Draft EIS and allow for an additional public comment period before releasing the Final EIS and Record of Decision (ROD). Table 1.1 identifies the differences in the alternatives between the December 2011 Draft EIS and this document. In addition to the range of alternatives, public comments and information have informed changes and additions to other components of the document, including descriptions of the affected environment, analysis of direct, indirect, and cumulative impacts, and analysis of potential mitigation measures. While NMFS has made several changes to the document based on public comments received on the 2011 Draft EIS, an appendix addressing responses to all public comments on both the 2011 Draft EIS and this Supplemental Draft EIS will appear in the Final EIS. On January 30, 2013, NMFS published an NOI informing the public of its determination to prepare a Supplemental Draft EIS in the *Federal Register* (78 FR 6303).

Table 1.1 Differences in the Alternatives between the December 2011 Draft EIS and this Supplemental Draft EIS

Alternative	2011 Draft EIS	2013 Supplemental Draft EIS
Alternative 1 (No Action)	NMFS would not issue ITAs under the MMPA, and BOEM would not issue permits and notices under the OCS Lands Act.	Same as in 2011 Draft EIS
Alternative 2	Considered up to: • Four 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to three 2D/3D seismic or CSEM surveys in the Chukchi Sea, with up to one of that total number in each done in-ice if necessary. • Three site clearance and high resolution shallow hazards survey programs in each sea per year • One on-ice seismic survey in the Beaufort Sea per year • One exploratory drilling program in each sea per year Considered inclusion of required standard mitigation measures and additional mitigation measures.	Same as in 2011 Draft EIS
Alternative 3	Considered up to: • Six 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to five 2D/3D seismic or CSEM surveys in the Chukchi Sea, with up to one of that total number in each done in-ice if necessary. • Five site clearance and high resolution shallow hazards survey programs in each sea per year • One on-ice seismic survey in the Beaufort Sea per year • Two exploratory drilling programs in each sea per year Considered inclusion of required standard mitigation measures and additional mitigation measures.	Same as in 2011 Draft EIS

Alternative 4	Considered up to: • Six 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to five 2D/3D seismic or CSEM surveys in the Chukchi Sea, with up to one of that total number in each done in-ice if necessary. • Five site clearance and high resolution shallow hazards survey programs in each sea per year • One on-ice seismic survey in the Beaufort Sea per year • Two exploratory drilling programs in each sea per year Considered inclusion of required standard mitigation measures and additional mitigation measures. Considered inclusion of required time/area closures for specific areas important to biological productivity, life history functions for specific species of concern, and subsistence activities. Areas considered were: • Camden Bay; • Barrow Canyon and the Western Beaufort Sea; • Shelf Break of the Beaufort Sea; • Hanna Shoal; and • Kasegaluk Lagoon/Ledyard Bay Critical Habitat Unit.	This alternative differs from Alternative 4 from the 2011 Draft EIS in the following ways: • Considers up to four exploratory drilling programs in each sea per year • It does not consider inclusion of any required time/area closures. Everything else about the alternative remains the same.
Alternative 5	Considered up to: • Six 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to five 2D/3D seismic or CSEM surveys in the Chukchi Sea, with up to one of that total number in each done in-ice if necessary. • Five site clearance and high resolution shallow hazards survey programs in each sea per year • One on-ice seismic survey in the Beaufort Sea per year	Alternative 5 in this EIS is similar to Alternative 4 from the 2011 Draft EIS with some slight changes: • Increase in the maximum level of exploratory drilling programs from up to two per sea per year to up to four per sea per year • Inclusion of required time/area closures. However, there are changes. The following are the required time/area closures considered in this EIS:

	• Two exploratory drilling programs in each sea per year Considered inclusion of required standard mitigation measures and additional mitigation measures. Considered including specific additional measures that focus on the use of alternative technologies that have the potential to augment or replace traditional airgun-based seismic exploration activities.	o Kaktovik and Cross Island o Barrow Canyon and the Western Beaufort Sea o Shelf Break of the Beaufort Sea o Hanna Shoal o Kasegaluk Lagoon o Ledyard Bay
Alternative 6	There was no Alternative 6 in this version of the EIS.	Alternative 6 in this EIS is similar to Alternative 5 from the 2011 Draft EIS. The only change is the maximum amount of exploratory drilling activities that could potentially occur under this alternative increases from up to two per sea per year to up to four per sea per year.

This EIS will evaluate the potential effects to the environment from geological and geophysical exploration activities in the U.S. Beaufort and Chukchi seas, Alaska, including: 1) deep penetration and high-resolution seismic surveys as permitted under 30 Code of Federal Regulations (CFR) Part 551 regulations; and 2) exploratory drilling, deep penetration surveys, and high-resolution site clearance/shallow hazards surveys as authorized under 30 CFR Part 550 regulations. Geological and Geophysical (G&G) permitted operations are conducted primarily off lease or on another lease holder's area, by the lessee or a third party under 30 CFR Part 551. Ancillary activities are conducted on-lease under 30 CFR Part 550. BSEE also permits and regulates the exploratory drilling activities under 30 CFR Part 250 regulations. Deep penetration and high resolution seismic surveys can be performed as either G&G permitted or ancillary activities. This EIS will also evaluate the potential effects to the environment of authorizing takes of marine mammals incidental to such activities occurring in either federal or State of Alaska waters. Activities that could occur in state waters include on-ice and open water seismic surveys, high-resolution site clearance/shallow hazards surveys, geotechnical studies, ice gouge surveys, strudel scour surveys, environmental studies, and exploratory drilling.

For clarity, the oil and gas exploration activities that will be assessed and evaluated throughout the EIS for potential environmental impacts are categorized as:

- **Deep penetration geophysical surveys** (e.g. seismic surveys, including open-water, towed streamer 2-dimensional [2D] or 3-dimensional [3D] surveys, in-ice towed streamer 2D or 3D surveys, on-ice 2D or 3D surveys or Ocean-Bottom-Receiver [cable or node; OBC] surveys; gravity and gradiometry surveys; and controlled source electromagnetic surveys [CSEM]). These surveys are conducted to identify prospective blocks for bidding in lease sales and to optimize drilling sites on leases acquired in sales. On average, data from deep penetration geophysical surveys provide imagery to a depth of approximately 10,000 meters (m) (6.2 miles [mi]) below the seafloor. However, penetration may be deeper or shallower depending on the equipment used and the depth to the geologic formations to be imaged. Companies can submit requests to conduct these types of deep penetration surveys to BOEM for approval under the regulations found at 30 CFR Parts 550 and 551.

- **Shallow hazards surveys** (also called high-resolution or site clearance surveys) and geological studies are considered ancillary activities when conducted on-lease under the 30 CFR Part 550 regulations. These surveys are used to examine the area of potential drill sites for geologic hazards, man-made hazards, prehistoric and historic archaeological resources, and biological populations. These types of activities either use acoustic sources to provide imagery of the sub-seafloor to a depth of less than 1,500 m (0.9 mi) or sediment sampling devices. A suite of instruments could be used depending upon the information needed. Standard equipment for shallow hazards surveys includes: single beam and multibeam echosounders; side scan sonar; magnetometer; subbottom profiler; and other seismic sources. Sediment sampling devices include grab samplers and coring equipment, and may result in bottom disturbance from associated activities, such as anchoring. Shallow hazards activities can also be authorized under BOEM regulations found at 30 CFR Part 551.
- **Exploratory drilling**. Any drilling conducted by a lessee for the purpose of searching for commercial quantities of oil, gas, and sulfur is authorized under 30 CFR Parts 250 and 550, regulated by BSEE and BOEM, respectively.

The specific equipment used will determine the sound levels and frequencies associated with each activity. Information on various sound sources and characteristics of sounds related to the activities listed above are governed by the specific equipment being used. This information is provided in Chapter 2, Sections 2.3.2 and 2.3.3, and Appendix B.

The environmental effects associated with deep penetration geophysical surveys, shallow hazards surveys, and exploratory drilling activities, as well as current and proposed mitigation measures, are evaluated in this EIS. This will allow NMFS to comprehensively assess activities that may occur in a given season in advance of receiving applications to authorize incidental takes of marine mammals associated with deep penetration geophysical surveys, shallow hazards surveys, and exploratory drilling activities. The analyses aid BOEM and BSEE in the environmental review required before issuing permits or authorizations. This analysis evaluates the direct, indirect and cumulative impacts that could occur under each of the proposed alternatives, and decisions will be based on the best available science regarding all of the resources potentially impacted. Moreover, the EIS will include an analysis of potential mitigation and monitoring measures that could be included in future authorizations to allow the issuance of multiple MMPA ITAs during a given season.

The EIS will assist NMFS and BOEM in carrying out other statutory responsibilities and serve to support future decisions relating to the agencies' roles in authorizing or permitting deep penetration geophysical surveys, shallow hazards surveys, and exploratory drilling activities or incidental take of marine mammals. Other statutory responsibilities include assessing environmental impacts on listed species under the Endangered Species Act [Section 7 consultation] and effects of the proposed action on essential fish habitat [EFH] under the Magnuson-Stevens Fishery Conservation and Management Act. BOEM will coordinate closely with NMFS and the USFWS to ensure compliance with these statutes and, where needed, will modify permit conditions or OCS operations to meet the requirements of Endangered Species Act (ESA) or MMPA authorizations. BOEM will also coordinate with BSEE to ensure compliance with OCS authorizations.

NMFS' issuance of ITAs for the take of marine mammals is a federal action for which environmental review is required under the Council on Environmental Quality (CEQ) regulations. While NEPA does not dictate a substantive outcome for an MMPA ITA, it requires consideration of environmental issues in federal agency planning and decision making and requires an analysis of alternatives and direct, indirect, and cumulative environmental effects of the NMFS action to authorize take under the MMPA. It also calls for the identification and consideration of reasonable mitigation measures to avoid, minimize, off-set or compensate for potential adverse effects. The EIS will assist NMFS in performing NEPA evaluations for MMPA ITAs for G&G, ancillary, and exploratory drilling activities and will assist BOEM in performing NEPA evaluations for G&G permit applications and ancillary activity notices. NMFS intends to use this EIS as the required NEPA documentation for the issuance of ITAs for Arctic oil and gas exploration activities. NMFS may tier from this EIS to support future Arctic MMPA authorization decisions if proposed oil and gas activities fall outside the scope of this EIS. NMFS also intends to utilize information and analysis from this EIS to inform agency analyses and decisions pursuant to its ESA and EFH consultation responsibilities. BOEM intends to conduct site-specific NEPA analyses that either tier from this EIS or incorporate this EIS by reference. Sections 5.1.2 and 5.1.3 of this document provide additional detail regarding NMFS and BOEM NEPA compliance for these proposed actions.

1.1.1 NMFS Statutory and Regulatory Mandates Relevant to EIS Scope of Analysis

The MMPA prohibits the unauthorized "take" of marine mammals by any person or vessel within the waters of the U.S., to include the U.S. Beaufort and Chukchi seas (16 United States Code [U.S.C.] § 1372 (102)(a)). Sections 101(a)(5)(A) and (D) of the MMPA (16 United States Code [U.S.C.] § 1361 *et seq.*) direct the Secretary of Commerce to allow, upon request, the incidental, but not intentional taking of small numbers of marine mammals by U.S. citizens who engage in a specified activity (other than commercial fishing) within a specified geographical region, if certain findings are made and either regulations are issued or, if the taking is limited to harassment, a notice of proposed authorization is provided to the public for review. For example, a disruption of marine mammal migratory behavior, feeding, or nursing activities, perhaps resulting in cessation of the activity or separation of cow/calf pairs, would constitute an incidental taking. Authorization for incidental takings shall be granted if:

- NMFS finds that the taking will have a negligible impact on the species or stock(s);
- NMFS finds that the taking will not have an unmitigable adverse impact on the availability of the species or stock(s) for subsistence uses (where relevant); and
- the permissible methods of taking and requirements pertaining to the mitigation, monitoring, and reporting of such takings are set forth.

NMFS has defined "negligible impact" in 50 CFR § 216.103 as "... an impact resulting from the specified activity that cannot be reasonably expected to, and is not reasonably likely to, adversely affect the species or stock through effects on annual rates of recruitment or survival." Additionally, NMFS has defined "unmitigable adverse impact" in 50 CFR § 216.103 as:

> *…an impact resulting from the specified activity: (1) That is likely to reduce the availability of the species to a level insufficient for a harvest to meet subsistence needs by: (i) Causing the marine mammals to abandon or avoid hunting areas; (ii) Directly displacing subsistence users; or (iii) Placing physical barriers between the marine mammals and the subsistence hunters; and (2) That cannot be sufficiently mitigated by other measures to increase the availability of marine mammals to allow subsistence needs to be met.*

The geographic scope of exploration activities requiring compliance with the MMPA includes both federal and state marine waters.

1.1.2 BOEM and BSEE Statutory and Regulatory Mandates Relevant to EIS Scope of Analysis

The OCS Lands Act, 43 U.S.C. § 1331 *et seq.* prescribes a four stage process for development of offshore federal oil and gas resources: (1) a five-year oil and gas leasing program; (2) lease sales; (3) exploration pursuant to exploration plans; and (4) development and production plans. Environmental reviews are conducted for each of these stages. Government-to-Government consultation occurs in stages two through four, and there is opportunity for public comment in all four stages.

The OCS Lands Act directs BOEM and BSEE to oversee the "expeditious and orderly development [of OCS resources] subject to environmental safeguards" (43 U.S.C. §§ 1332(3), (6), 1334(a)(7)). Critical to the potential development of OCS resources is the ability to gather geological and geophysical data needed to assess the resource potential of the OCS. BOEM, which has rights to all data collected under the OCS Lands Act and implementing regulations, needs the best available data to ensure that the Federal Government (i.e. the American people) receives fair market value for leased resources. The OCS Lands Act establishes U.S. Department of Interior authority, delegated to BOEM by regulation, to issue G&G permits or notice approvals for G&G, ancillary, and exploration activities, and approve exploratory drilling plans for these and related purposes. BOEM's regulations for G&G permits are at 30 CFR Part 551 and for ancillary activities and Exploration Plans are at 30 CFR Part 550.

The OCS Lands Act (43 U.S.C. §§ 1340(a)(1) (g)), and BOEM's and BSEE's implementing regulations, require that OCS data and information collected be obtained in a technically safe and environmentally sound manner. BOEM conducts NEPA analyses for proposed OCS activities and includes measures, if necessary, in permits, plan approvals, and other authorizations to minimize potential adverse effects to the human, marine, and coastal environment (30 CFR Parts 550 and 551). BSEE is responsible for technical review and approval of Applications for Permits to Drill (APDs), for ensuring safe OCS operations, and for monitoring OCS activities to ensure compliance with Federal laws, regulations, lease stipulations, permit or plan conditions, and required mitigation. BSEE is also responsible for oversight of pollution prevention and oil spill contingency and response planning for OCS operations. BSEE's regulations are at 30 CFR Parts 250 and 254.

BOEM regulations for G&G permit activities (30 CFR Part 551) specifically state that such activities cannot:

- interfere with or endanger operations under any lease or right-of-way, easement, right-of-use, notice, or permit issued or maintained under the OCS Lands Act;
- cause harm or damage to life (including fish and other aquatic life), property, or to the marine, coastal, or human environment;
- cause harm or damage to any mineral resource (in areas leased or not leased);
- cause pollution;
- create hazardous or unsafe conditions;
- disturb archaeological resources; or
- unreasonably interfere with or cause harm to other uses of the area.

Pursuant to 30 CFR Part 551.4, a G&G permit must be obtained from BOEM to conduct G&G exploration for oil, gas, and sulphur resources when operations occur on unleased lands or on lands leased to a third party. Ancillary activities are regulated under 30 CFR Part 550.207 through 550.210, which also states that a notice must be submitted before conducting such activities pursuant to a lease issued or maintained under the OCS Lands Act.

1.1.3 New Requirements for OCS Offshore Oil and Gas Exploration and Development Drilling Operations

Following the Deepwater Horizon Event and resulting oil spill in the Gulf of Mexico, comprehensive reforms to offshore oil and gas regulation and oversight were developed and implemented by BOEM and BSEE. The reforms strengthen requirements for everything from well design and workplace safety to corporate accountability.

The Secretary's Safety Measures Report, dated May 27, 2010, presents recommendations for immediate and long-term requirements to improve the safety of oil and gas operations in shallow and deep waters. In light of the Safety Measures Report, the MMS issued Notice to Lessees and Operators (NTL) 2010-N05, Increased Safety Measures for Energy Development on the OCS.

Pursuant to 30 CFR Part 550.213(g) and 30 CFR Part 550.219, an Exploration Plan must be accompanied by a blowout scenario description and information regarding liquid hydrocarbons, including calculations of a worst case discharge scenario. Under the new requirements for enhanced drilling safety (NTL 2010-N06, Information Requirements for Exploration Plans, Development and Production Plans, and Development Operations Coordination Documents on the OCS), operators must demonstrate that they are prepared to deal with the potential for a blowout and worst-case discharge.

NTL 2010-N10, Statement of Compliance with Applicable Regulations and Evaluation of Information Demonstrating Adequate Spill Response and Well Containment Resources, requires to be included with every APD a statement signed by an authorized company official stating that the operator will conduct all authorized activities in compliance with all applicable regulations, including the Increased Safety Measures for Energy Development on the Outer Continental Shelf rulemaking (75 FR 62246, October 7, 2010). In compliance with the NTL and pursuant to 30 CFR Part 254, each operator using subsea blowout preventers (BOPs) or BOPs on floating facilities must submit information demonstrating that it has access to and can deploy surface and subsea containment resources that would be adequate to promptly respond to a blowout or other loss of well control.

BOEM and BSEE overhauled and continue to proactively reform the offshore regulatory process. Similarly, the oil and gas industry has voluntarily responded with rigorous reform measures, including new and revised industry standards, recommended practices, specifications, and guidelines. For example, the new Drilling Safety Rule imposes requirements that will enhance the safety of OCS oil and gas drilling operations. It addresses both well bore integrity and well control equipment and procedures. Well bore integrity provides the first line of defense against a blowout by preventing a loss of well control through the appropriate use of drilling fluids and the well bore casing and cementing program. Applications for Permits to drill must meet new standards for well-design, casing, and cementing, and be independently certified by a professional engineer.

The new Workplace Safety Rule covers all offshore oil and gas operations in federal waters, including equipment, safety practices, environmental safeguards, and management oversight of operations and contractors. The Workplace Safety Rule makes mandatory the previously voluntary practices in the American Petroleum Institute's Recommended Practice 75 (RP 75). Companies are required to develop and maintain a Safety and Environmental Management System (SEMS). A SEMS program is a comprehensive management program for identifying, addressing, and managing operational safety hazards and impacts, with the goal of promoting both human safety and environmental protection. BOEM's latest 2012-2017 OCS Oil and Gas Leasing Program Final Programmatic EIS, Section 4.3.3.3.4 Reforms and Research to Reduce Risk, robustly describes all recent reforms. This document is available at: http://www.boem.gov/Oil-and-Gas-Energy-Program/Leasing/Five-Year-Program/2012-2017/Five-Year-Program.aspx.

1.2 Proposed Action

The proposed actions of two federal agencies considered in this EIS are:

- The issuance of ITAs under Sections 101(a)(5)(A) and (D) of the MMPA, by NMFS, for the incidental taking of marine mammals during G&G permitted activities, ancillary activities, and exploratory drilling activities in the U.S. Beaufort and Chukchi seas, Alaska, and
- The authorization of G&G permits and ancillary activities in the U.S. Beaufort and Chukchi seas, Alaska, by BOEM under the OCS Lands Act.

As described below in Section 1.3, these federal actions are related, but distinct, actions.

1.3 Purpose and Need for Action

1.3.1 Purpose

Energy use in the U.S. is expected to continue to increase from present levels through 2040 and beyond (EIA 2012). For example, the U.S. consumption of crude oil and petroleum products has been projected to increase from about 19.1 million barrels (Mbbl) per day in 2010 to about 21.9 Mbbl per day in 2035 (EIA 2011). Oil and gas reserves in the OCS represent significant sources that currently help meet U.S. energy demands and are expected to continue to do so in the future. The benefits of producing oil and natural gas from the OCS include not only helping to meet this national energy need but also generating money for public use. In this context, the purpose for issuing permits for seismic surveying activities under the OCS Lands Act and issuing authorizations to "take" marine mammals under the MMPA are discussed below.

Authorizing Take under the MMPA: Under the MMPA, the 'taking' of marine mammals, incidental or otherwise, without a permit or exemption is prohibited. Among the activities exempt from the MMPA's moratorium on the take of marine mammals is subsistence hunting of marine mammals by Alaska Natives (Section 101(b)). Among the exceptions allowed to the moratorium on marine mammal takes (as stated in Sections 101(a)(5)(A) and (D)) is for the incidental, but not intentional, "taking," by U.S. citizens, while engaging in an activity (other than commercial fishing) of small numbers of marine mammals. The MMPA directs the Secretary of Commerce to authorize the take of small numbers of marine mammals provided that the taking will have a negligible impact on such species or stock, will not have an unmitigable adverse impact on the availability of such species or stock for taking for subsistence uses, and the permissible methods of taking and requirements pertaining to mitigation, monitoring, and reporting are set forth. Additionally, pursuant to Section 101(a)(5)(D) of the MMPA monitoring plans are required to be independently peer reviewed where the proposed activity may affect the availability of a species or stock for taking for subsistence uses.

The term "take" under the MMPA means "to harass, hunt, capture, or kill, or attempt to harass, hunt, capture, or kill any marine mammal." The MMPA further defines "harassment" as "any act of pursuit, torment, or annoyance which (i) has the potential to injure a marine mammal or marine mammal stock in the wild [Level A harassment]; or (ii) has the potential to disturb a marine mammal or marine mammal stock in the wild by causing disruption of behavioral patterns, including, but not limited to, migration, breathing, nursing, breeding, feeding, or sheltering [Level B harassment]."

ITAs issued by the Secretary of Commerce, pursuant to Section 101(a)(5) of the MMPA, as indicated above, provide a limited exception to the take prohibition in the MMPA. Therefore, NMFS and BOEM have, through this EIS, analyzed the environmental impacts associated with authorizing the take of marine mammals incidental to oil and gas exploration activities in the U.S. Beaufort and Chukchi seas, Alaska, using the best available science and including impacts to marine mammals and the subsistence uses of these species. The analysis considers the effects associated with issuing ITAs for oil and gas activities such as seismic surveys, exploratory drilling activities, and aircraft and support vessel activity (including, for example, icebreaking and resupply). This EIS also includes an analysis of the environmental impacts associated with authorizing seismic surveys under the OCS Lands Act.

ITAs may be issued as either (1) regulations and associated Letters of Authorization (LOAs) or (2) Incidental Harassment Authorizations (IHAs). An IHA can only be issued if the proposed action will not result in a potential for serious injury and/or mortality or where any such potential can be negated through required mitigation measures. Where the proposed activity has the potential to result in serious injury and/or mortality (that cannot be negated through mitigation measures), only regulations and associated LOAs may be used to authorize take. However, regulations and LOAs may also be issued when there is no potential for serious injury and/or mortality if the applicant requests it, which applicants sometimes do for multi-year activities because it offers some administrative streamlining benefits. NMFS could issue ITAs for oil and gas exploration activities in either federal or State of Alaska waters. Given the widespread presence of several species of marine mammals in the Beaufort and Chukchi seas and the nature of oil and gas exploration activities, there is the potential that some seismic and exploratory drilling activities may result in the take of marine mammals through sound, permitted discharge of pollutants, and/or the physical presence of vessels. Because of the potential for these activities to "take" marine mammals, oil and gas operators may choose to apply for an ITA.

Authorizing Offshore Oil & Gas Activities: Regulation of these activities is in part determined by their location. Activities in the Beaufort Sea and Chukchi Sea Planning Areas of the Arctic OCS include exploration seismic surveys conducted under BOEM-issued geophysical permits, BOEM-authorized ancillary survey activities on federal leases, and BOEM/BSEE-approved exploratory drilling activities on federal leases. Proposed activities in state waters would be authorized and regulated by the State of Alaska. NMFS has jurisdiction to authorize incidental take under the MMPA resulting from certain activities whether they occur in Federal or state waters.

Regarding mineral resources in federal waters, the OCS Lands Act directs the Secretary of the Interior to oversee the "expeditious and orderly development" of OCS resources subject to environmental safeguards (43 U.S.C. §§ 1332(3), (6), 1334(a)(7)). Critical to the potential development of OCS resources is the ability to gather G&G data on the resource potential of the OCS. Pursuant to 30 CFR Part 551.4, a G&G permit must be obtained from BOEM to conduct G&G exploration for oil, gas, and sulphur resources when operations occur on unleased lands or on lands leased to a third party. Ancillary activities are regulated under 30 CFR Part 250, which states that a notice must be submitted before conducting G&G data collection pursuant to a lease issued or maintained under the OCS Lands Act (30 CFR Part 550.208).

1.3.2 Need

Authorizing "Take" under the MMPA: NMFS expects to receive applications to take marine mammals incidental to oil and gas industry exploration activities (i.e. G&G and ancillary surveys and exploratory drilling) pursuant to Sections 101(a)(5)(A) and (D) of the MMPA. This EIS is intended to assist NMFS in its MMPA decision-making process related to projected requests for ITAs by providing a comprehensive understanding of deep penetration geophysical surveys and exploratory drilling in the U.S Beaufort and Chukchi seas for future years and may be revised as necessary. NMFS intends to use this EIS as the required NEPA analysis to support the issuance of ITAs for Arctic oil and gas exploration activities. It is the intent of NMFS that the scope of this EIS covers as many actions as possible. However, if necessary, NMFS may need to conduct additional NEPA analysis to support future Arctic MMPA oil and gas permit decisions if such activities fall outside the scope of this EIS. This applies to actions taken under Sections 101(a)(5)(A) and (D) (i.e. issuance of LOAs and IHAs) Please see Chapter 5 (Sections 5.1.2 and 5.1.3) for additional discussions on NEPA compliance related to this EIS.

Authorizing Offshore Oil & Gas Activities: BOEM expects to receive applications to conduct exploration surveys, ancillary activities, and exploration drilling pursuant to the OCS Lands Act. To fulfill statutory mandates for proposed exploratory drilling projects, BOEM requires lessees to submit industry-obtained seismic survey data, high-resolution shallow hazards data, and well information with an Exploration Plan. BOEM and BSEE use the information to: (a) ensure safe operations, which refers to detection of shallow gas pockets, faults, channel boundaries or other geological or man-made features that could be hazards to drilling; (b) support environmental impact analyses; (c) protect resources through avoidance measures, such as prohibiting anchor locations within a boulder patch area or a potential archeological site; and (d) perform other statutory responsibilities.

Exploration seismic surveys (both 2D and 3D) provide industry with information on subsurface geology to identify prospective blocks and to make decisions on competitive bids in Federal OCS lease sales.

Under the OCS Lands Act, the government must receive "fair market value" for the lands that it leases. BOEM uses a two-phased system of bid evaluation to assess the adequacy of bids. Each high bid is first examined for technical and legal adequacy (i.e., conformity with antitrust laws). Each valid high bid is then analyzed from a fair market value perspective, which assesses the value of the right to explore for, develop, and produce the hydrocarbon potential of the block. The value is based on BOEM's analysis and interpretation of geologic and geophysical information obtained through industry's exploration seismic surveys, and previous exploration drilling. BOEM estimates the likelihood of oil and/or gas being discovered on the area of the lease and completes an economic analysis of the possible oil/gas development options. Bids that do not meet BOEM's fair market value criteria may be rejected.

BOEM regulations implementing the OCS Lands Act set the initial lease term for oil and gas leases (30 CFR 556). In the Arctic OCS, the initial lease term is set at ten years. The lease will expire at the end of its primary term if the leaseholder (or lessee or operator) is not conducting operations on the lease (30 CFR 550.180 and 30 CFR 556.70). The leaseholder may retain the lease as long as oil or gas is produced from the lease in paying quantities, or while drilling or well reworking activities are conducted, or a suspension has been granted by BOEM.

1.4 Scope and Objectives

The scope of the proposed action involves two parts: (1) to continue permitting or authorizing exploration activities that will provide the oil and gas industry and BOEM with the best available data on the location, extent, and properties of hydrocarbon resources, as well as information on shallow geological hazards and seafloor geotechnical properties; and (2) to support MMPA authorizations for the take of marine mammals incidental to conducting deep penetration seismic surveys, shallow hazards surveys, and exploratory drilling activities under the Proposed Action. Therefore, the objectives of the EIS are to:

1. Evaluate a broad range of reasonably foreseeable levels of exploration activities (e.g. deep penetration seismic surveys, shallow hazards surveys, and exploratory drilling activities), including the use of alternative technologies and methodologies intended to reduce the amount and/or intensity of sound output, in state and federal waters in the U.S. Beaufort and Chukchi seas. The EIS may be used, based on a case-by-case evaluation, as the sole NEPA compliance document for future agency actions covered by this EIS, or it may serve as a tiering document (as contemplated by the CEQ regulations) where it is determined that further NEPA analysis may be required.
2. Provide environmental information that can be used to help NMFS evaluate whether to issue ITAs under the MMPA for activities in state and federal waters in the U.S. Beaufort and Chukchi seas and to help BOEM evaluate whether to grant G&G permits or other authorizations under the OCS Lands Act for proposed activities.
3. Project the amount and extent of OCS and state water G&G, ancillary, and exploratory drilling activities that are likely to occur in the U.S. Beaufort and Chukchi seas based on the best available information.
4. Identify and analyze any direct, indirect, and cumulative impacts that may result from the proposed action, including the benefits of one or more measures to mitigate adverse environmental effects.
5. Evaluate a range of monitoring and mitigation measures that might be implemented relative to the level of deep penetration geophysical surveys, shallow hazards surveys, and exploratory drilling to minimize impacts to marine resources and to ensure no unmitigable adverse impact to subsistence users.

The analyses contained in this EIS provide decision-makers and the public with an evaluation of the potential environmental, social, and economic effects of a range of reasonable alternatives, including the proposed action. The EIS also includes an analysis of the potential cumulative impacts of the proposed action, particularly as they relate to marine resources (e.g. marine mammals, fish, etc.) and subsistence harvest activities.

Specifically, NMFS and BOEM have, through this EIS:

- Described the Proposed Action and a range of reasonable alternatives, including a suite of proposed mitigation measures, as well as consideration of other mitigation measures;
- Assessed the direct and indirect effects of the Proposed Action and alternative approaches to authorize oil and gas deep penetration geophysical surveys and shallow hazards surveys under the OCS Lands Act and the taking of marine mammals incidental to seismic and shallow hazards surveys and exploratory drilling activities under the MMPA;
- Assessed the effects on the marine mammal species and the availability of those species for subsistence uses, as well as other components of the marine ecosystem and human environment;
- Assessed the cumulative impacts associated with the Proposed Action; and
- Analyzed the effects of obtaining geotechnical data for pre-feasibility analyses of shallow sub-sea sediments associated with identifying potential shallow geophysical hazards, as part of proposed exploratory drilling.

NMFS will use the EIS to support the consideration of future MMPA authorizations for deep penetration geophysical surveys, shallow hazards surveys, and exploratory drilling activities in state and federal waters in the U.S. Beaufort and Chukchi seas. There are multiple scenarios under which NMFS can obtain input from the public regarding the agency's issuance of MMPA authorizations (e.g. through the structure of the Open Water Meeting or Monitoring peer review, public comment periods on the proposed authorizations). The history and known strengths and challenges of various scenarios NMFS has used to gain stakeholder and public input will be discussed in Chapter 5. The EIS will assist BOEM in identifying and evaluating potential adverse effects to the environment and in developing appropriate mitigation measures. The EIS will assist BOEM and BSEE in the analysis needed to ensure safe operations, meet regulatory requirements, and protect benthic habitat in federal waters.

It should be noted that BOEM will perform separate NEPA analyses on any exploration drilling proposals it may receive for leased tracts in the Beaufort Sea OCS or the Chukchi Sea OCS. While information and analysis from this EIS may inform those separate analyses, it is not intended to wholly satisfy BOEM's NEPA obligation with respect to proposed exploration plans.

1.5 Issues and Concerns to be Addressed in the EIS

The NOI to prepare the EIS (75 FR 6175, February 8, 2010) provided a list of issues on which NMFS was seeking public input. These issues included:

- Protection of subsistence resources and Iñupiat culture and way of life;
- Disturbance to bowhead whale migration patterns;
- Impacts of seismic operations on marine fish reproduction, growth, and development;
- Harassment and potential harm of wildlife, including marine mammals and marine birds, by vessel operations, movements, and noise;
- Impacts on water quality;
- Changes in the socioeconomic environment;
- Impacts to threatened and endangered species;
- Impacts to marine mammals, including disturbance and changes in behavior;

- Incorporation of traditional knowledge in the decision-making process; and
- Effectiveness and feasibility of marine mammal monitoring and other mitigation and monitoring measures.

The scoping period for the *Effects of Oil and Gas Activities in the Arctic Ocean EIS* began on February 8, 2010 and ended April 9, 2010. Public scoping meetings were held during February and March 2010 in the communities of Kotzebue, Point Hope, Point Lay, Wainwright, Barrow, Nuiqsut, Kaktovik, and Anchorage. Scoping comments were received verbally and in writing through discussion, testimony, fax, regular mail, and electronic mail.

Of the issues identified during scoping, those that were most commonly raised included:

- Concerns regarding the NEPA process;
- Impacts to marine mammals and habitats;
- Risks of oil spills;
- Climate change;
- Protection of subsistence resources and the Iñupiat culture and way of life;
- Availability of research and monitoring data for decision-making;
- Monitoring requirements; and
- Suggestions for, or implementation of, mitigation measures.

Concerns related to the need for a stable domestic energy supply and benefits to the state and nation from oil and gas development were also raised during scoping. These issues were determined to be beyond the scope of the environmental analysis within this EIS and are therefore not discussed further. For more detail on the issues raised during the scoping process, please refer to Appendix C of the 2011 Draft EIS.

Issues and concerns associated with oil and gas related activities in the marine environment have also been documented for decades by the scientific community, in government publications, at scientific symposia, and through scoping and public meetings/comments, and other NMFS and BOEM NEPA analyses. In addition, public testimony and Traditional Knowledge from Alaska Natives have provided valuable information about seismic survey operations and exploratory drilling activities. NMFS and BOEM address this information in the relevant sections of the EIS.

1.6 Description of the Project Area

The project area for this EIS, illustrated in Figure 1.1, covers a total area of approximately 200,331 square miles within the U.S. portion of the Beaufort and Chukchi seas. It includes State of Alaska and OCS waters adjacent to the North Slope of Alaska and transit areas of the Chukchi Sea north of the Bering Straits. The oceanographic area extends from Kotzebue on the west to the U.S.-Canada border on the east. The offshore boundary is the OCS Beaufort Sea and Chukchi Sea Planning Areas, approximately 322 km (200 mi) offshore. Onshore locations included within the EIS project area include Arctic communities of the Northwest Arctic and North Slope Boroughs: Kotzebue; Kivalina; Point Hope; Point Lay; Wainwright; Barrow; Nuiqsut; Kaktovik; and the Prudhoe Bay area. Areas of special importance for this EIS are identified in Figures 3.2-25 and 3.2-26, and are typically associated with important biological or subsistence use areas.

1.7 Recent Chronology of NEPA Activities and Documents that Influence the Scope of the EIS

The effects of oil and gas related deep penetration geophysical surveys, shallow hazard surveys, and exploratory drilling activities in the U.S. Beaufort and Chukchi seas have been evaluated to some degree in previous NEPA documents produced by both the NMFS and MMS. Summaries of these documents are contained herein. Portions of these NEPA documents are appropriately incorporated by reference in other chapters of this EIS, as directed by 40 CFR 1502.21 of the CEQ's regulations.

- In 2003, MMS prepared the ***Beaufort Sea Planning Area Oil and Gas Lease Sales 186, 195, 202 Final Environmental Impact Statement (OCS EIS/EA MMS 2003-001)***. The Final EIS analyzed the environmental effects of these three sales – Sale 186 in 2003, Sale 195 in 2005 and Sale 202 in 2007 – all of which consider leasing the same geographical area in the Beaufort Sea.
- In 2006, MMS prepared Draft and Final Programmatic Environmental Assessments (PEAs) on the *Arctic Ocean Outer Continental Shelf Seismic Surveys - 2006* (MMS 2006, or PEA) for permitting up to four seismic surveys to be conducted in the open water season in both the Beaufort and Chukchi seas, for a total of up to eight annual surveys. NMFS was a cooperating agency in the preparation of the MMS PEA. A Final PEA was released by MMS on June 22, 2006 and adopted by NMFS.
- On November 17, 2006, NMFS and MMS issued a NOI to jointly prepare a **Programmatic EIS (PEIS) for *Seismic Surveys in the Chukchi and Beaufort seas, Alaska***. The PEIS assessed the impacts of MMS' six annual authorizations under the OCS Lands Act to the U.S. oil and gas industry, to conduct a higher level of offshore geophysical seismic surveys in the Beaufort and Chukchi seas off Alaska over a longer time frame than evaluated in the PEA, and to assess the impacts of NMFS' authorizations under the MMPA to incidentally harass marine mammals while conducting those surveys. The Draft PEIS assumed that up to six offshore geophysical seismic surveys would be conducted annually in both the Beaufort and Chukchi seas off Alaska (for a total of up to 12 annual surveys) and evaluated the environmental effects of the increased level of seismic effort (which represents a 50 percent increase in activity compared to the level of seismic effort analyzed in the MMS 2006 PEA). On March 30, 2007, the EPA announced the availability for comment of the MMS/NMFS Draft PEIS (MMS 2007a). However, on October 28, 2009, NMFS published a notice of withdrawal of the 2007 PEIS (74 FR 55539).
- In May 2007, MMS issued the **Final EIS for the *Chukchi Sea Planning Area Oil and Gas Lease Sale 193 and Seismic Surveying Activity in the Chukchi Sea*** and also examined a proposal for exploration seismic survey permitting in 2007 in the proposed sale area and two alternatives for the 2007 seismic surveys (OCS EIS/EA MMS 2007-026).
- In August 2007, NMFS prepared a **Supplemental EA** (SEA; NMFS 2007a) and issued a new Finding of No Significant Impact (FONSI) to update the 2006 Final PEA for analysis of an **Arctic seismic survey ITA**, including NMFS' issuance of an IHA to Shell Offshore Inc. (Shell) for the 2007 season. The 2007 SEA analyzed the effects on the human environment of issuing an IHA to Shell for the take of marine mammals incidental to conducting deep penetration 3D seismic surveys in both the Beaufort and Chukchi seas and marine surveys, including site clearance and shallow hazards surveys, in the Beaufort Sea during the 2007 Arctic open-water season. Where appropriate, sections of the 2006 Final PEA and 2007 Draft PEIS were incorporated into the 2007 SEA by reference.
- In October 2007, NMFS prepared an **EA for the issuance of an IHA to Shell** to take marine mammals incidental to conducting an offshore drilling project in the U.S. Beaufort Sea (NMFS 2007b) and issued a FONSI on October 24, 2007. This EA analyzed the effects on the human

environment of issuing an IHA to Shell for the take of marine mammals incidental to conducting open-water offshore exploratory drilling in OCS blocks of the U.S. Beaufort Sea.

- For the 2008 Arctic open-water season, NMFS received applications from five oil and gas companies requesting IHAs to conduct various types of seismic and site clearance and shallow hazards surveys in the Arctic Ocean. In July 2008, NMFS prepared a new **seismic/site clearance survey SEA** (2008 SEA; NMFS 2008) to update analyses contained in the 2006 Final PEA since it was determined that the 2008 surveys would have environmental impacts similar to the activities analyzed in the 2006 Final PEA. Where appropriate, sections of the 2006 Final PEA and 2007 Draft PEIS, as well as NMFS' 2007 SEA, Arctic Regional Biological Opinion, MMS' 2007 *Chukchi Sea Planning Area Oil and Gas Lease Sale 193 and Seismic Surveying Activities in the Chukchi Sea - Final Environmental Impact Statement* (MMS 2007b), and MMS' *Beaufort Sea Planning Area Oil and Gas Lease Sales 186, 195, 202 Final Environmental Impact Statement* (MMS 2003), were incorporated into the 2008 SEA by reference. After completion of the 2008 SEA, NMFS issued five FONSIs in July and August 2008 for each of the five IHAs issued by NMFS.

- In August 2009, NMFS published an **EA for the issuance of an IHA to Shell**, which analyzed the impacts to the human environment that may result from the take of marine mammals incidental to conducting an open water marine survey program in the Chukchi Sea, Alaska, during 2009. Portions of several of the NEPA documents mentioned above were incorporated by reference into the 2009 EA. Among other things, the 2009 EA updated information on the potential impacts to marine mammals based on previous years of monitoring. NMFS issued a FONSI on August 14, 2009.

- In October 2009, MMS published an **EA for the Shell *2010 Exploration Drilling Program-Camden Bay, Beaufort Sea, Alaska* (OCS EIS/EA MMS 2009-052)**, which analyzed the environmental impacts of exploration drilling. Shell proposed to drill two exploration wells during the July to October 2010 open-water-drilling season. The EA tiered from existing environmental documents and incorporated by reference other environmental documents (see EA pages 2 and 3 for the list of environmental documents).

- In December 2009, MMS published an **EA for the Shell *2010 Exploration Drilling Program—Burger, Crackerjack, and Southwest Shoebill Prospects in the Chukchi Sea Outer Continental Shelf, Alaska* (OCS EIS/EA MMS 2009-061)**. Shell proposed to drill exploration wells at up to three of five possible drill sites during the July to October 2010 open-water-drilling season. The EA tiered from existing environmental documents and incorporated by reference other environmental documents (see EA pages 6 and 7 for the list of environmental documents).

- In June 2010, BOEMRE published an **EA for Statoil's *Proposed Seismic Survey Activity in the Chukchi Sea Planning Area* (OCS EIS/EA BOEMRE 2010-020)**. The EA tiered from two previous environmental documents: (1) Final PEA, Arctic Ocean Outer Continental Shelf, Seismic Surveys—2006 (OCS EIS/EA MMS 2006-038) June 2006; and (2) Final EIS, Chukchi Sea Planning Area, Oil and Gas Lease Sale 193 EIS and Seismic Surveying Activities in the Chukchi Sea (OCS EIS/EA MMS 2007-026) May 2007.

- In July 2010, BOEMRE published an **EA for Shell *Exploration & Production Proposed Ancillary Activities—Marine Surveys in the Beaufort Sea, Alaska* (OCS EIS/EA MMS 2010-022)**. Ancillary activities are activities conducted by a leaseholder on BOEMRE-issued leases for the purposes of obtaining data and information to develop an Exploration Plan or Development and Production Plan. Shell proposed shallow hazard and site clearance surveys, ice gouge surveys, strudel scour surveys, marine baseline studies, and seafloor soil sampling. The EA tiered from existing environmental documents and incorporated by reference other environmental documents (see EA pages 2 and 3 for the list of environmental documents).

- In July 2010, NMFS prepared an EA for the issuance of IHAs to take marine mammals incidental to conducting open-water seismic and marine survey programs in the U.S. Beaufort and Chukchi seas (NMFS 2010). This EA analyzed the impacts to the human environment from the issuance of an IHA to Shell for the take of marine mammals incidental to conducting an open-water marine survey program in the U.S. Beaufort and Chukchi seas and the issuance of an IHA to Statoil for the take of marine mammals incidental to conducting 3D and 2D open-water seismic surveys in the Chukchi sea. Several of the earlier NEPA documents mentioned in this list were incorporated into NMFS's 2010 EA by reference. After completion of the EA, NMFS issued two FONSIs for each of the IHAs issued by NMFS.
- In July 2011, NMFS prepared an SEA and issued a FONSI for the issuance of an IHA to Statoil for the take of marine mammals incidental to open-water shallow hazards surveys in the U.S. Chukchi Sea (NMFS 2011). This 2011 SEA was a supplement to the July 2010 EA prepared by NMFS regarding oil and gas exploration activities conducted by Shell and Statoil in the U.S. Chukchi Sea. This SEA analyzed the impacts to the human environment from the issuance of an IHA to Statoil for the take of marine mammals incidental to conducting an open-water marine survey program in the Chukchi Sea.
- In July 2011, BOEMRE issued an EA and issued a FONSI on the **Statoil USA E&P Inc. *2011 Ancillary Activities, Chukchi Sea, Alaska* (OCS EIS/EA BOEMRE 2011-020)**. The EA analyzed potential environmental impacts resulting from an open-water shallow hazards seismic survey program. The proposed activity area encompasses the 16 leases owned by Statoil and three leases jointly owned by Statoil and CPAI in the Chukchi Sea. All leases were obtained in Lease Sale 193 held in February 2008.
- In August 2011, BOEMRE issued an EA and a FONSI on the **Shell Offshore Inc. *Revised Outer Continental Shelf Lease Exploration Plan Camden Bay, Alaska* (OCS EIS/EA BOEMRE 2011-039)**. The purpose of the project analyzed in the EA was for Shell to evaluate the mineral resource potential of three lease tracts within two distinct oil and gas prospects: "Sivulliq" (NR 06-04 Flaxman Island, block 6658, OCS-Y-1805) and "Torpedo" (NR 06-04 Flaxman Island, block 6659, OCS-Y-1936 and NR 06-04 Flaxman Island, block 6610, OCS-Y-1941). The proposed action calls for two wells each to be drilled into the two prospects (Sivulliq and Torpedo) during the open-water season beginning in 2012.
- In August 2011, BOEMRE issued the ***Final Supplemental EIS for the Chukchi Sea Planning Area Oil and Gas Lease Sale 193*** (BOEMRE 2011b). The 2008 FEIS for Lease Sale 193 was challenged in the U.S. District Court for the District of Alaska. On July 21, 2010, the District Court issued an Order remanding Sale 193 to BOEMRE to satisfy its obligations under NEPA in accordance with the Court's opinion. The District Court's Order was amended on August 5, 2010, and guidelines for compliance with the Order were established by the Court on September 2, 2010. The Draft Supplemental EIS augments the analysis in the Final EIS for Lease Sale 193 by analyzing the environmental impact of natural gas development and evaluating incomplete, missing, or unavailable information pursuant to 40 CFR 1502.22 to respond to the Court's remand. A Draft Supplemental EIS was made available to the public on October 15, 2010. In March 2011, BOEMRE announced that a Very Large Oil Spill analysis would also be included in the Supplemental EIS. The analysis was completed and integrated within the Revised Draft Supplemental EIS, which was released for public comment on May 27, 2011.
- In December 2011, BOEM issued an EA and a FONSI for the ***Shell Revised Chukchi Sea Exploration Plan.*** The EA evaluates the potential impacts from proposed exploratory drilling to evaluate oil and gas resources on six of Shell's OCS leases in the Chukchi Sea.

- On December 30, 2011, NMFS published an NOA in the *Federal Register* announcing the availability of the ***Effects of Oil and Gas Activities in the Arctic Ocean Draft EIS*** (76 FR 82275). The public was afforded 60 days to comment on that document. Many of the comments received on the 2011 Draft EIS have been incorporated into this Supplemental Draft EIS.
- In May 2012, NMFS prepared an EA for the issuance of IHAs to Shell for the take of marine mammals incidental to conducting offshore exploratory drilling programs in the U.S. Beaufort and Chukchi seas. The EA analyzed impacts to marine mammals and their habitats and to the subsistence uses of marine mammals, as well as to other resources in the affected environment. After completion of the EA, NMFS issued two FONSIs for each of the IHAs issued by NMFS.
- In July 2012, BOEM issued the ***Outer Continental Shelf Oil and Gas Leasing Program 2012-2017 Final Programmatic EIS*** (BOEM 2012). The Final PEIS evaluates the potential impacts from oil and gas exploration and development on six planning areas of the OCS, including Western Gulf of Mexico, Central Gulf of Mexico, Eastern Gulf of Mexico, Cook Inlet, Beaufort Sea, and Chukchi Sea. The analysis adopts a broad regional perspective; BOEM intends for more detailed and geographically-focused analyses to be done as the five-year program progresses from the planning stage through the leasing, exploration, and development stages.
- In October 2012, BOEM issued an **EA for ION's *Geological and Geophysical Surveys* (OCS EIS/EA BOEMRE 2012-081)**. The EA analyzed the environmental impacts associated with an airgun array and echosounders operated during 2D seismic survey, as well as potential impacts from icebreaking during the survey. The survey in the U.S. Beaufort and Chukchi seas would extend from the U.S.-Canada border in the east to Point Barrow in the west. The EA incorporated by reference past NEPA documents that provided a comprehensive characterization of the Arctic Ocean's physical, biological, and socioeconomic resources and Alaska Native subsistence activities, and evaluated a broad spectrum of potential seismic survey-related impacts (see EA page 2 for the list of these documents).

1.8 Federal Laws and Other Requirements Applicable to Oil and Gas Activities in the Arctic Ocean

The federal issuance of permits and authorizations under the OCS Lands Act in the U.S. Beaufort and Chukchi seas off the coast of Alaska and NMFS' authorizations under the MMPA are subject to a number of federal laws and regulations and Executive Orders. There are also relevant State laws and regulations for oil and gas exploration activities in State of Alaska waters. These are briefly summarized below.

1.8.1 National Environmental Policy Act of 1969

NEPA establishes a nationwide policy and goal of environmental protection, and provides legal authority for federal agencies to carry out that policy (40 CFR 1500.1(a)). It requires federal agencies to study and consider the environmental consequences of their actions and to use an interdisciplinary framework for environmental decision-making, which includes the consideration of environmental amenities and values (42 U.S.C. § 4332(B)).

NEPA also requires federal agencies to make environmental information available to the public and to public officials and to consider their comments before making decisions that could affect the environment. Documents prepared by federal agencies in compliance with NEPA must be streamlined to focus on the issues that are truly significant to the action in question and present alternatives in a way that allows potential environmental consequences to be clearly distinguished, along with "advice and information useful in restoring, maintaining, and enhancing the quality of the environment" (43 FR 55990, November 28, 1978, and 40 CFR 1502.1, 1502.2, and 1502.14).

The provisions of NEPA require that an EIS contain the following elements:

1. Statement of Purpose and Need for the Proposed Action;
2. Description of Alternatives Evaluated in the EIS, including the Proposed Action, the No Action Alternative, and Alternatives Evaluated but Eliminated from Further Consideration;
3. Description of the Affected Environment;
4. Analysis of Environmental Consequences of Alternatives Carried Forward in the EIS;
5. The Relationship Between Local Short-Term Uses of Man's Environment and the Maintenance and Enhancement of Long-Term Productivity; and
6. Any Irreversible and Irretrievable Commitments of Resources Which Would be Involved in the Proposed Action Should it be Implemented.

The preparation of an EIS must include the following five basic steps:

1. **Scoping**. As the first step in the EIS process, scoping provides an opportunity for the public, government agencies, and other interested groups to provide information and advice on issues that might be associated with the proposed project, so that the lead federal agency can decide whether and how to address them in the EIS. Scoping can also identify new alternatives to be considered in the EIS.
2. **Draft Environmental Impact Statement (DEIS)**. After scoping is completed, a DEIS is prepared. The DEIS describes and evaluates a range of reasonable alternative actions, including no action. If the lead agency has decided upon a preferred alternative by the time a DEIS is prepared, it is identified. The DEIS evaluates physical, biological, socioeconomic, and environmental impacts that might result from the alternatives carried forward for analysis, and it describes the significance of environmental effects surrounding the various alternatives, including the proposed action. Finally, it identifies ways to mitigate the potential impacts – to avoid, minimize, rectify, reduce, or eliminate those impacts over time or to compensate for any potential harm to the environment that might be caused by any of the alternatives.
3. **Public Comment on the DEIS**. Following publication of a DEIS, a public NOA for review is published in the FR, which begins a public comment period of no less than 45 days. A public hearing may be conducted to provide an opportunity for interested parties to provide oral comments on the DEIS. Following the public comment period, the lead agency considers all of the comments received and prepares a final EIS (FEIS) and includes responses to the comments on the DEIS.
4. **Final Environmental Impact Statement (FEIS)**. The FEIS must identify the lead agency's preferred alternative (unless another law prohibits the expression of such a preference) and may identify the environmentally preferable alternative, which may be different. Once the FEIS is completed and published, there is a 30-day "wait" period before an agency may issue its Record of Decision (ROD) (see below).
5. **Record of Decision**. Following completion of the FEIS process as described above, the lead agency prepares a ROD. The ROD must: (1) state what the decision was; (2) identify all alternatives considered in reaching the decision and which were considered to be environmentally preferable; and (3) state whether all practicable means to avoid or minimize environmental harm have been adopted, and if not, why not (40 CFR 1505.2). If a monitoring and enforcement program is applicable for any mitigation, it must be adopted and summarized in the ROD (40 CFR 1505.2).

As noted earlier in this Chapter, NMFS determined to prepare a Supplemental Draft EIS prior to issuing the FEIS. While not one of the five required steps in the EIS process, NMFS and BOEM determined that the Final EIS would benefit from the inclusion of additional alternatives for analysis that cover a broader range of potential levels of exploratory drilling scenarios in the Beaufort and Chukchi Seas. Additional revisions were made to the document, including the analysis of potential mitigation measures. Based on the nature of the changes to the document from the 2011 Draft EIS, the agencies determined a Supplemental Draft EIS should be released for public comment. Following the public comment period, the lead agency will consider all comments received and prepare an FEIS, which will include responses to comments on the 2011 Draft EIS and this Supplemental Draft EIS.

1.8.2 National Oceanic and Atmospheric Administration Administrative Order (NAO) 216-6

NAO 216-6 describes NOAA's policies, requirements, and procedures for complying with NEPA and the implementing regulations issued by CEQ as codified in Parts 1500-1508 of Title 40 of the CFR (40 CFR Parts 1500-1508) and those issued by the DOC in Department Administrative Order (DAO) 216-6, *Implementing the NEPA*. NAO 216-6 incorporates the requirements of Executive Order (EO) 12898, *Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations*. Also, the Order reiterates provisions of EO 12114, *Environmental Effects Abroad of Major Federal Actions*, as implemented by DOC in DAO 216-12, *Environmental Effects Abroad of Major Federal Actions* (NAO 216-6).

1.8.3 DOI Implementation of the National Environmental Policy Act of 1969

DOI has established procedures (43 CFR Part 46) for the Department and for its constituent bureaus (including BOEM) to use for compliance with NEPA and with CEQ regulations (40 CFR 1500-1508) for implementing the procedural provisions of NEPA. This regulation is intended to supplement and to be used in conjunction with the CEQ regulations, except where it is inconsistent with other statutory requirements.

1.8.4 Endangered Species Act

NMFS and BOEM have shared mandates under the Endangered Species Act (ESA). Section 7 (16 U.S.C. § 1536) of the ESA states that all federal agencies shall, in consultation with, and with the assistance of the Secretary of the Interior or Commerce (Secretary), ensure that any action authorized, funded, or carried out by such agency is not likely to jeopardize the continued existence of any endangered species or threatened species or result in the destruction or adverse modification of habitat of such species, which is determined by the Secretary to be critical. Section 9 (16 U.S.C. § 1538) of the ESA identifies prohibited acts related to endangered species and prohibits all persons, including all federal, state and local governments, from taking listed species of fish and wildlife, except as specified under provisions for exemption (16 U.S.C. §§1535(g)(2) and 1539). Generally, the USFWS manages land and freshwater species while NMFS manages marine species, including anadromous salmon. However, the USFWS has responsibility for some marine animals such as nesting sea turtles, walrus, polar bears, sea otters, and manatees.

For actions that may result in prohibited "take" of a listed species, federal agencies must obtain authorization for incidental take through Section 7 of the ESA's formal consultation process. Under the ESA, "take" means to "harass, harm, pursue, hunt, shoot, wound, kill, trap, capture, or collect, or attempt to engage in any such conduct" to species listed as threatened or endangered in 16 U.S.C. § 1532(19). NMFS has further defined harm as follows: "harm" is "…an act which actually kills or injures fish or wildlife. Such an act may include significant habitat modification or degradation which actually kills or injures fish or wildlife by significantly impairing essential behavioral patterns, including, breeding, spawning, rearing, migrating, feeding or sheltering" (50 CFR 222.102). NMFS has not defined the term "harass" under the ESA.

Under Section 7 of the ESA, federal agencies consult with the USFWS and/or NMFS and submit a consultation package for proposed actions that may affect listed species or critical habitat. If a listed species or critical habitat is likely to be affected by a proposed federal action, the federal agency must provide the USFWS and NMFS with an evaluation whether or not the effect on the listed species or critical habitat is likely to be adverse. The USFWS and/or NMFS uses this documentation along with any other available information to determine if a formal consultation or a conference is necessary for actions likely to result in adverse effects to a listed species or its designated critical habitat. If a federal action is likely to adversely affect endangered or threatened species or designated critical habitat, then USFWS and/or NMFS prepares a Biological Opinion, which makes a determination as to whether the action is likely to jeopardize an endangered or threatened species. If take is anticipated, the USFWS and/or NMFS must also issue an Incidental Take Statement, which includes terms and conditions and reasonable and prudent measures which must be followed.

1.8.5 Marine Mammal Protection Act

Under the MMPA (16 U.S.C. § 1361 *et seq.*), the taking of marine mammals without a permit or exception is prohibited. The term, "take" under the MMPA, means "to harass, hunt, capture, or kill, or attempt to harass, hunt, capture, or kill any marine mammal." The MMPA defines "harassment" as "any act of pursuit, torment, or annoyance which (i) has the potential to injure a marine mammal or marine mammal stock in the wild [Level A harassment]; or (ii) has the potential to disturb a marine mammal or marine mammal stock in the wild by causing disruption of behavioral patterns, including, but not limited to, migration, breathing, nursing, breeding, feeding, or sheltering [Level B harassment]".

In order to obtain an exemption from the MMPA's prohibition on taking marine mammals, a citizen of the U.S. who engages in a specified activity (other than commercial fishing) within a specified geographic region must obtain an ITA under Section 101(a)(5)(A) or (D) of the MMPA. An ITA shall be granted if NMFS finds that the taking of small numbers of marine mammals of a species or stock by such citizen will have a negligible impact on the affected species or stock(s) and will not have an unmitigable adverse impact on the availability of the species or stock(s) for taking for subsistence uses. NMFS must base its findings on the best scientific information available (50 CFR Part 216.102(a)). NMFS shall also prescribe, where applicable, the permissible methods of taking and other means of affecting the least practicable impact on the species or stock and its habitat (i.e. mitigation, monitoring and reporting of such takings). ITAs may be issued as either (1) regulations and associated LOAs or (2) IHAs. IHAs can be issued only when there is no potential for serious injury and/or mortality or where any such potential can be negated through required mitigation measures.

As part of the MMPA authorization process, applicants are required to provide detailed mitigation plans that outline what efforts will be taken to reduce negative impacts to marine mammals, and their availability for subsistence use, to the lowest level practicable. In addition, MMPA authorizations require that operators conduct monitoring, which must be designed to result in an increased knowledge of the species and an understanding of the level and type of takings that result from the authorized activities. Where the proposed activity may affect the availability of a species or stock of marine mammal for taking for subsistence uses, the proposed monitoring plan must be independently peer reviewed pursuant to 16 U.S.C. § 1371(a)(5)(D), prior to issuance of the ITA.

1.8.6 Outer Continental Shelf Lands Act

The OCS Lands Act of 1953 (67 Stat. 462), as amended (43 U.S.C. § 1331 *et seq.* [2006]), established federal jurisdiction over submerged lands on the OCS, seaward of State boundaries. Under the OCS Lands Act, the USDOI is required to manage the leasing, exploration, development, and production of mineral resources on the federal OCS. The OCS Lands Act established that OCS development proceed in a safe and efficient manner that provides for environmental protection, fair and equitable returns to the public, state and local participation in policy and planning decisions, and resolution of conflicts related to other ocean and coastal resources and uses. In 1978, Congress amended the OCS Lands Act, 43 U.S.C. §§ 1331-1356a, 1801-1802, to provide for the "expedited exploration and development of the [OCS]," in a manner that balances the need "to make such resources available to meet the Nation's energy needs as rapidly as possible… with protection of the human, marine, and coastal environments." BOEM and BSEE regulations implementing the OCS Lands Act are at 30 CFR Chapters II and V.

1.8.7 Magnuson-Stevens Fishery Conservation and Management Act

Federal agencies are required to consult with the Secretary of Commerce with respect to any action authorized, funded, or undertaken, or proposed to be authorized, funded, or undertaken, by such agency that may adversely affect essential fish habitat (EFH) identified under the Magnuson Stevens Fishery Conservation and Management Act (MSFCMA).

1.8.8 Coastal Zone Management Act

The Coastal Zone Management Act (CZMA) encourages coastal states to develop comprehensive programs to manage and balance competing uses of and impacts to coastal resources. The CZMA emphasizes the primacy of state decision-making regarding the coastal zone. Section 307 of the CZMA (16 U.S.C. § 1456), called the federal consistency provision, is a major incentive for states to join the national coastal management program and is a powerful tool that states use to manage coastal uses and resources and to facilitate cooperation and coordination with Federal agencies.

Federal consistency is the CZMA requirement where federal agency activities that have reasonably foreseeable effects on any land or water use or natural resource of the coastal zone (also referred to as coastal uses or resources and coastal effects) must be consistent to the maximum extent practicable with the enforceable policies of a coastal state's federally-approved coastal management program.

As of 12:01 AM, Alaska Standard Time, on July 1, 2011, the Alaska Coastal Management Program (ACMP) authorities in AS 46.39, AS 46.40, and other uncodified laws relating to the ACMP were automatically repealed. At that point, the regulations at 11 Alaska Administrative Code (AAC) 110, 11 AAC 112, and 11 AAC 114 and the local coastal management plans lost their statutory authority and became unenforceable. As such, coastal zone management will not be carried forward for analysis in Chapter 4.

1.8.9 Clean Air Act

The Clean Air Act (43 U.S.C. § 7401, et seq.) governs the control of air pollutant emissions from both stationary and mobile sources. Under the Clean Air Act, EPA is authorized to establish National Ambient Air Quality Standards (NAAQS) to limit the concentration of harmful air emissions that, when occurring in sufficient concentrations, can harm human life and wildlife. The Clean Air Act established two types of standards. Primary standards set limits to protect public health, including the health of "sensitive" populations such as asthmatics, children, and the elderly. Secondary standards set limits to protect public welfare, including protection against visibility impairment, damage to animals, crops, vegetation, and buildings.

The Clean Air Act has been amended several times since the first version in 1963. The 1990 Amendments transferred the authority to control emissions caused by oil and gas activities on the Alaska OCS, the Atlantic OCS, and the Pacific OCS from the Department of the Interior to the EPA. The Interior maintained jurisdiction only in areas of the Central and Western Gulf of Mexico OCS Region. However, on December 23, 2011, an amendment to the Clean Air Act Section 328 transferred authority for the control of oil and gas-related emissions on the Arctic OCS back to the Department of the Interior through the Consolidated Appropriations Act, 2012 (Public Law 112-74). The other Alaska OCS Planning Areas remain under EPA jurisdiction.

EPA's requirements for air pollution on the OCS differ depending on location. For sources located within 25 miles of a state's seaward boundary, requirements are based on state rules. For sources located beyond 25 miles, federal requirements apply. The state or local air pollution control agency may request delegation from EPA to implement the air pollution control program within 25 miles of a state's seaward boundary on the OCS, including air permitting. The State of Alaska has delegated authority from EPA for onshore sources and sources within three miles, but has not requested delegation for OCS sources. BOEM regulates the air quality impacts of any newly-proposed OCS sources associated with proposed exploration plans (or development and production plans). BOEM regulations regarding the control of air emissions are found at 30 CFR Part 550.

1.8.10 Clean Water Act

The Clean Water Act (CWA) has several sections or programs applicable to activities in offshore waters. Section 402 of the CWA authorized EPA to administer the National Pollutant Discharge Elimination System (NPDES) permit program to regulate point source discharges into waters of the United States.

Section 403 of the CWA requires that EPA conduct an ocean discharge criteria evaluation for discharges to the territorial seas, contiguous zones, and the oceans. The Ocean Discharge Criteria (40 CFR Part 125, Subpart M) set forth specific determinations of unreasonable degradation that must be made before permit issuance. On October 29, 2012, EPA issued two general permits for exploration discharges to the Beaufort and Chukchi Seas, permit numbers AKG-28-2100 and AKG-28-8100, respectively. The general permits authorize discharges from thirteen categories of waste streams, subject to effluent limitations, restrictions, and requirements. The general permits became effective on November 28, 2012, and are effective for five years. The permits require operators to submit Notices of Intent to EPA requesting authorization to discharge at least 120 days prior to commencing discharges.

The U.S. Coast Guard (USCG) has also promulgated regulations implementing the CWA (33 CFR Part 151).

1.8.11 National Historic Preservation Act of 1966

The National Historic Preservation Act of 1966 (NHPA), specifically Section 106, requires federal agencies to take into account the potential effects of their actions on properties that are listed or are eligible for listing on the National Register of Historic Places (historic properties), and to consult with State Historic Preservation Officers and local governments regarding the effects of federal actions on historic properties. Known historic properties (i.e. archaeological resources) on the Beaufort Sea OCS and Chukchi Sea OCS include historic shipwrecks, sunken aircraft, lighthouses, and prehistoric archaeological sites that have become inundated due to the rise in global sea level since the peak of the last ice age, around 19,000 years ago.

1.8.12 Executive Order 12898: Environmental Justice

EO 12898, signed by the President on February 11, 1994, and published February 16, 1994 (59 FR 7629), requires that federal agencies make achieving "environmental justice" part of their mission by identifying and addressing disproportionately high and adverse human health or environmental effects of their programs, policies, and activities on minority populations and low income populations in the U.S. Many Alaska Natives harvest marine mammals for subsistence purposes and benefit from their continued existence. The effects of the federal action on minority populations are described in Chapter 4.

1.8.13 Executive Order 13175: Consultation and Coordination with Indian Tribal Governments

This EO, signed by the President on November 6, 2000, and published on November 9, 2000 (65 FR 67249), is intended to establish regular and meaningful consultation and collaboration between federal agencies and federally recognized tribal governments in the development of federal regulatory practices that significantly or uniquely affect their communities. In preparing this EIS, NMFS has initiated a government-to-government consultation process with affected federally recognized tribal governments. On January 29, 2010, letters were sent from NMFS to federally recognized Alaska Native tribes within the EIS project area, including the Native Village of Kotzebue, the Native Village of Point Hope, the Native Village of Point Lay, the Inupiat Community of the Arctic Slope, the Native Village of Barrow, the Native Village of Kaktovik, the Native Village of Nuiqsut, and the Wainwright Traditional Council, initiating government-to-government consultations and inviting those governments to participate in the EIS process. The letters provided some background information on the history of the project and the proposed action. The stated goal is to work collaboratively with tribal governments in the area of the U.S. Beaufort and Chukchi seas in order to explore ways that the energy development in the Arctic can best co-exist with the subsistence culture and way of life. NMFS has worked with several ANOs during the development of this EIS. Both BOEM and NMFS value the contribution that Alaska Native traditional ecological knowledge and experience can provide with regard to understanding marine mammals and the environment in general. On August 10, 2012, DOI established a policy on Consultation with Alaska Native Claims Settlement Act Corporations. The DOI policy is read in conjunction with the existing DOI policy on Consultation with Indian Tribes.

1.8.14 State of Alaska Administrative Code (Title 18, Chapter 50 – Air Quality Control)

Certain Alaska Department of Environmental Conservation (ADEC) rules are applicable to offshore areas within 25 kilometers (km) (16 mi) of Alaska’s seaward boundary. The EPA applies the corresponding onshore area rules to these areas. Title 18 of Alaska Administrative Code (AAC) Chapter 50 provides for air quality control including permit requirements, permit review criteria, and regulation compliance criteria. These regulations also may apply to possible onshore facilities as well.

1.8.15 Co-management Agreements

Through Section 119 of the MMPA, NMFS and the USFWS were granted authority to enter into cooperative agreements with ANOs, including, but not limited to, Alaska Native Tribes and tribally authorized co-management bodies. Individual co-management agreements shall incorporate the spirit and intent of co-management through close cooperation and communication between federal agencies and the ANOs, hunters, and subsistence users. Agreements encourage the exchange of information regarding the conservation, management, and utilization of marine mammals in U.S. waters in and around Alaska.

Under Section 119 agreements, marine mammal stocks should not be permitted to diminish beyond the point at which they cease to fulfill their role in their ecosystem or to levels that will not allow for sustainable subsistence harvest. Agreements may involve: (1) developing marine mammal co-management structures and processes with federal and state agencies; (2) monitoring the harvest of marine mammals for subsistence use; (3) participating in marine mammal research; and (4) collecting and analyzing data on marine mammal populations.

NMFS currently has three co-management agreements with Alaska Native groups specific to species found in the U.S. Beaufort and Chukchi seas and which are relevant to the scope of this EIS. Those agreements are with the Alaska Beluga Whale Committee for Western Alaska beluga whales, with the AEWC for the Western Arctic stock of bowhead whales (also known as the Bering-Chukchi-Beaufort stock), and with the Ice Seal Committee for the Alaska stocks of ringed, bearded, spotted, and ribbon seals. The NOAA-AEWC cooperative agreement is entered into under Section 112(c) of the MMPA and the Whaling Convention Act.

1.9 Organization of the Document

The format and content of this document was guided by the CEQ regulations at 1502.10 and NOAA NEPA guidance. The EIS includes the following sections:

Cover Page

Dear Reviewer Letter

Executive Summary

Table of Contents

Acronym List

1.0 Purpose and Need

- Summarizes the purpose and need for the Proposed Action, the major issues, background actions, pertinent laws and regulations, and the decisions to be made.

2.0 Proposed Action and Alternatives

- Describes and compares the Proposed Action and a range of reasonable alternatives.
- Lists alternatives considered but rejected from detailed analysis.
- Describes project activities that will be considered, as well as potential mitigation measures to be applied.

3.0 Affected Environment

- Describes the current condition of relevant resources in the EIS project area and establishes the baseline for comparing the predicted effects of the alternatives.

4.0 Environmental Consequences

- Analytically predicts and compares the consequences to relevant resources from implementing each alternative.
- The predictions include the direct, indirect, and cumulative effects of each alternative.

5.0 NEPA Compliance Implementation and Recommendations

- Outlines how NMFS will implement the EIS procedurally, including descriptions of adaptive management components and additional mitigation measures that could be utilized.

6.0 Consultation and Coordination

- Documents scoping, meetings, compliance with consultation requirements, and preparers of the EIS.

7.0 References

- Lists the documents and other sources used to prepare the EIS.

8.0 Glossary

- Contains useful definitions of terms found in the EIS.

Figures

- Contains all project figures and maps.

Appendices

- Includes important documents concerning the Proposed Action, public involvement, and consultation and coordination activities.

2.0 PROPOSED ACTION AND ALTERNATIVES

2.1 Introduction

This chapter describes the range of potential alternatives evaluated and those determined reasonable to meet the purpose and need of the proposed action as described in Chapter 1. These alternatives include the No Action alternative (no issuance of geological and geophysical (G&G) permits or authorizations of ancillary activity notices by the Bureau of Ocean Energy Management (BOEM) under the Outer Continental Shelf (OCS) Lands Act and no marine mammal take authorizations incidental to oil and gas exploration activities issued by the National Marine Fisheries Service (NMFS)) and five action alternatives that would allow for the issuance of G&G permits and authorization of ancillary activity notices under the OCS Lands Act and marine mammal incidental take authorizations (ITAs) under the Marine Mammal Protection Act (MMPA) associated with a range of oil and gas exploration activities. NMFS' consideration of issuance of MMPA ITAs is for activities in both the OCS and in State of Alaska waters.

2.2 Issues Considered in Developing the Alternatives

The first step in preparing an environmental impact statement (EIS) is publishing a Notice of Intent (NOI) in the Federal Register (FR). On February 8, 2010, the NOI announcing the preparation of this EIS was published (75 FR 6175), requesting public participation in the scoping process for 60 days. The public comment period ended on April 9, 2010. In addition to providing background information on the purpose of issuing MMPA authorizations for the incidental take of marine mammals, the NOI provided a list of issues on which NMFS was seeking public input. These issues included:

- Protection of subsistence resources and Iñupiat culture and way of life;
- Disturbance to bowhead whale migration patterns;
- Impacts of seismic operations on marine fish reproduction, growth, and development;
- Harassment and potential harm of wildlife, including marine mammals and marine birds, by vessel operations, movements, and noise;
- Impacts on water quality;
- Changes in the socioeconomic environment;
- Impacts to threatened and endangered species;
- Impacts to marine mammals, including disturbance and changes in behavior;
- Incorporation of traditional knowledge in the decision-making process; and
- Efficacy and feasibility of marine mammal monitoring and other mitigation and monitoring measures.

Public scoping meetings were held in all of the coastal Alaskan communities affected by the proposed action, as well as Anchorage, on the following dates:

- Kotzebue – February 18, 2010
- Point Hope – February 19, 2010
- Point Lay – February 22, 2010
- Wainwright – March 9, 2010
- Barrow – March 10, 2010
- Nuiqsut – March 11, 2010
- Kaktovik – March 12, 2010
- Anchorage – March 23, 2010

In a separate but parallel process for government-to-government consultation, federally-recognized Tribal governments in each North Slope community were notified of the EIS process and invited to participate.

The first contact was via letter, dated January 29, 2010; follow-up calls were made with the potentially affected Tribal governments, and each entity was visited during the scoping process. The Scoping Comment Analysis Report (CAR) (see Appendix C in the 2011 Draft EIS) includes comments received during the scoping period as a result of government-to-government consultation between NMFS, BOEM, and the Tribal governments.

Table 2.1 presents a summary of the substantive comments about alternatives and mitigation measures NMFS may require in their ITAs that were raised during public scoping meetings and submitted to NMFS during the public comment period. A more complete presentation of formal comments received during the scoping process is included in Appendix C of the 2011 Draft EIS.

Many of the comments received during the public comment period for the 2011 Draft EIS were similar to issues raised during the public scoping period in early 2010. Issues raised by the public during the 60-day comment period (from December 30, 2011, through February 28, 2012) include:

- Concerns related to public participation and review process;
- Compliance with NEPA, the MMPA, and other applicable statutes;
- Inadequacy with the range of alternatives;
- Improper dismissal of alternatives;
- Inadequacy of description and analysis of certain physical, biological, and social resources and failure to include newer data; and
- Insufficient analysis and information related to the effectiveness and implementation of mitigation measures.

As noted in Chapter 1, NMFS has revised the range of alternatives, provided additional analysis regarding effectiveness and practicability for implementation of mitigation measures considered in this EIS, and updated baseline descriptions of affected resources and analyses of potential impacts to affected resources with newer literature and data based on comments received from the public. The Final EIS will include an appendix that contains a summary of comments and responses received on the 2011 Draft EIS and this Supplemental Draft EIS.

Table 2.1 Summary of the Substantive Comments on the Alternative Development Process Received During Scoping

Category	Comment
No Action Alternative	NMFS should explain why it is including a No Action Alternative because that option is not within the authority of the agency to enforce.
	There are significant economic consequences to the No Action Alternative that need to be analyzed, including importing oil from foreign nations.
Flexibility in Managing and Authorizing Seismic and Exploratory Activities	NMFS should consider a sufficient range of alternatives to provide for maximum flexibility in determining the final course of action pursuant to the purpose and need statement.
	The alternatives should treat the Beaufort and Chukchi seas separately and adopt a flexible program with realistic operating scenarios.
	The alternatives should adopt a flexible approach to the various seismic and drilling activities taking place within a defined area and evaluate the impacts of proposed operations on an annual basis.
	NMFS should consider a broader range of exploration scenarios, given that industry estimates are not always reflective of actual activity into the future.
	Alternatives that consider five-year permits should provide for notice and public comment on an annual basis, particularly with concern to subsistence users.
	Establish a cap to limit the total number of oil and gas activities that may occur in a planning area on a per season basis.
	Arbitrary restrictions on concurrent operations could undermine a lessee's ability to explore its leases.
	Because BOEM regulations (30 CFR Part 551) state that G&G activities cannot create or cause hazardous or unsafe conditions, any mitigation and monitoring measures imposed on seismic surveys by NMFS and BOEM must not result in hazardous or unsafe conditions.
Protection of Sensitive Areas	Areas of high ecological or biological significance should be protected with seasonal restrictions on the types of activities that can occur there. Specific areas suggested include: ◊ Critical feeding and resting grounds near Camden Bay in the mid-Beaufort Sea; ◊ Critical feeding grounds in the eastern Alaskan Beaufort Sea and near Barrow Canyon in the western Beaufort Sea; ◊ Nearshore areas (within 50 miles of the coast); ◊ Areas that are important for denning, feeding, and/or migration for Arctic marine mammal species such as Pacific walrus, bowhead whales, beluga whales, or polar bears; and ◊ Ledyard Bay critical habitat area for spectacled eiders.
	Subsistence use areas should also be protected with seasonal restrictions on the types of activities that can occur there, such as: ◊ Areas used by the Village of Kaktovik in the eastern Beaufort Sea; ◊ Areas around Cross Island used by the Village of Nuiqsut; ◊ Areas used by the Village of Barrow in the western Beaufort Sea; ◊ Areas used by Wainwright and Point Lay along the Chukchi Sea coast; and Kotzebue Sound (through July 10); and ◊ Proposed access routes should be surveyed for ice seal lairs, breathing holes, and resting locales to avoid disturbance of these animals.

Category	Comment
Monitoring and Mitigation Measures	NMFS should not issue ITAs unless they can ensure that mitigation measures will remove the potential for serious injuries or mortality to marine mammals from activities associated with oil and gas operations.
	The proposed EIS should consider alternatives that address shortcomings in monitoring and mitigation measures.
	The EIS should include a list of Conflict Avoidance Agreements for all Native groups in Alaska and adopt similar requirements to minimize impacts on subsistence hunting activities.
	Required mitigation measures, specifically safety and exclusion zones, should be adaptive and based on sound research and must be reasonable and feasible. Specific suggestions include: ◊ Exclusion zones and other regulatory threshold criteria for the implementation of mitigation measures (e.g. 180/190 dB safety and exclusion zones) should be adjusted upwards to 230 dB re:1 uPa (peak, flat) for cetaceans and 218 dB re:1 uPa (peak, flat) for pinnipeds. ◊ NMFS should use the noise exposure criteria proposed in Southall et al. (2007) to determine the thresholds for sound exposure and exclusion zones for marine mammals during seismic surveys.
	Marine mammal monitoring should be required for oil and gas activities. Technologies and methods suggested include: ◊ Acoustic recorders; ◊ Aerial monitoring; ◊ Satellite tagging; and ◊ On-board marine mammal observers.
	A sound cap or budget that limits the total amount of noise allowed per season should be considered as a mitigation measure.
	Safety and exclusion zone distances should be calculated based on peak levels of sound generated by the oil and gas equipment.
	Mitigation measures are needed to minimize or avoid ship strikes of marine mammals. Suggested measures include: ◊ Designating specific shipping lanes; ◊ Implementing seasonal restrictions to protect marine mammals during their migration; and ◊ Establishing speed restrictions.
	Require the use of fish finding equipment and procedures to shut down seismic activity when large schools of fish are encountered.
Best Available Technology for Exploratory Activities	The best available technology should be used to minimize impacts. Specific suggestions include: ◊ Vibroseis; ◊ Extended reach drilling; ◊ Zero discharge technology (as implemented in Norway); ◊ Gravity, magnetic, and gravity gradiometry data collection; and ◊ Low-sulfur fuel.

2.3 Oil and Gas Exploration Activities Evaluated in the EIS

2.3.1 BOEM Process for Permitting

In addition to applying for an ITA from NMFS, industry applicants will work closely with other federal and state agencies to obtain additional permits and authorizations. The permits and authorizations required by BOEM guide the progression of exploration activities. It is important to understand this progression of activities as they are approved and permitted, as it can help explain the timing, stages, and sequence of exploration for offshore oil and gas resources. The following summarizes these processes, as it pertains to a description of these types of exploratory activities:

- **Geological & Geophysical (G&G) Exploration Permits** – In accordance with 30 CFR Part 551, a permit must be obtained from BOEM prior to conducting geological or geophysical exploration on unleased lands or on lands under lease by a third party (someone other than the applicant). On-lease G&G exploration can be conducted under a G&G permit or an Ancillary Activity Notice in accordance with 30 CFR Part 550 Subpart B.
- **Ancillary Activities** – These on-lease geological and geophysical activities include shallow hazards and site clearance surveys and two-dimensional (2D) and/or three-dimensional (3D) deep penetration seismic. Ancillary activities also include on-lease geotechnical sampling; however, these activities are not addressed in this EIS. A notice of proposed ancillary activities must be submitted to BOEM, which conducts technical and environmental review to ensure that the ancillary activities comply with the performance standards listed in 30 CFR Part 550.202(a), (b), (d), and (e). The data and information acquired through the ancillary activities are required in support of an Exploration Plan (EP). Ancillary activities are conducted in accordance with 30 CFR Part 550.
- **Exploration Plans** – Before exploration drilling can be conducted on a lease(s), an EP must be submitted to BOEM (30 CFR Part 550 Subpart B). The EP must include information on the timing and location(s) of the proposed activity, a plan of operations, the affected environment, and the potential effects on the environment. BOEM conducts a technical and environmental review of the proposed EP and may approve a proposed EP only if the exploration activities described therein comply with the performance standards in 30 CFR Part 550.202.
- **Application for Permit to Drill (APD)** – No drilling may commence without an approved APD. An approved EP, along with all other necessary federal permits, is a prerequisite for APD approval. Authority to review and approve APDs belongs to BSEE.

The permitting process listed above shows a general progression or sequence of events that occurs during OCS oil and gas leasing and exploration as companies seek to locate hydrocarbon deposits that could be developed in the future after further evaluation by the agencies. If development and production are proposed at some later point, Federal agency decisions regarding those activities will be informed by additional NEPA documents that take into account current conditions and specific project plans. The data and information gathered during OCS activities determine the activities likely to occur in subsequent years.

The following bulleted narrative summarizes how oil and gas prospects on the Beaufort Sea OCS and Chukchi Sea OCS are typically identified, leased, and explored:

- The first step is to search for prospective areas that could contain hydrocarbon accumulations. This is primarily accomplished using deep penetration seismic surveying techniques. Companies conduct 2D or 3D geophysical seismic surveys to identify areas of interest. Deep penetration seismic surveying techniques are used to provide broad-scale information over a relatively large area. The results of these surveys may indicate areas of potential hydrocarbon accumulations.

Companies can invest in these surveys either in advance of a lease sale (to help advise their bidding or other decisions) or on speculation to sell to other companies later. Lessees may also conduct these surveys to further evaluate leases acquired in a lease sale and the surrounding area prior to drilling. Gravity, magnetic, and electromagnetic surveys may also be conducted. Under the OCS Lands Act, BOEM has the right to copies of any data and information resulting from exploration activities conducted under a G&G permit. BOEM in turn uses these data to determine the fair market value of a potential lease block bid for the lease sale.

- Once companies have identified hydrocarbon prospects, they submit bids for leases in a lease sale, where exploration and development rights are conveyed. The competitive lease sale awards leases on individual blocks to the highest bidders. Some companies bid on and acquire leases on contiguous blocks that cover what they consider a large prospect. Other companies may win leases in or near these prospective areas as well. Past lease sales in the Beaufort and Chukchi seas have resulted in a mosaic of lease ownership clustered over prospects. After obtaining a lease, companies may conduct 3D deep penetration seismic surveys and may also add controlled source electromagnetic (CSEM) studies to further define prospects and select proposed drilling locations.

- Prior to submitting an EP and drilling a well, companies are required to conduct shallow hazards surveys (also called "site clearance" or "high-resolution geophysical surveys") to provide information on water depth, seafloor morphology, near-surface morphology, potential shallow faults or gas zones, depth and distribution of ice gouges in the seabed, and other natural or manmade hazards. These shallow hazards surveys are used to evaluate the near-surface geology, locate shallow hazards, obtain engineering data for drilling or placement of structures (platforms and pipelines), and detect archaeological resources and certain types of benthic communities. These surveys may be conducted over portions of individual lease blocks (about 3 mi x 3 mi) or several contiguous lease blocks, depending on the exploration targets of the company. These surveys would typically need to be completed at least one season in advance of submittal of an EP and a drilling operation. Companies may also use high resolution geophysical equipment to survey off-lease areas for possible subsea pipeline routes.

- Based on the evaluation of 2D/3D seismic data and shallow hazard surveys, companies may propose in the EP to drill one or more exploration (test) wells in the area of interest. The type of drilling rig used depends on water depth, sea ice conditions, ice-resistance of the rigs, and unit availability. Data obtained from drill cuttings, well cores, and various measurements in the borehole are used by industry to evaluate the properties of the geologic formations (porosity, permeability, fluid content, potential flow rates, etc.) to inform decisions on whether to pursue additional drilling and eventually possible economic development. Vertical seismic profiling (VSP) of the well could be conducted to verify the acoustic properties of the various geologic formations to facilitate correlations with the seismic survey data.

All of these operations require some form of additional support, such as crew change and supply vessels, ice-management vessels, oil spill response equipment, fuel barges, aircraft, and staging areas. Therefore, the description of each activity in the following sections will identify the associated typical support operations. Table 2.2 summarizes the support vessels and operations associated with each activity.

Table 2.2 Summary of Typical Support Operations for Exploration Activities

Activity	Typical Support Operations
Marine streamer 2D and 3D surveys	• 1 source/receiver vessel • 1 support vessel • Likely 1 vessel for monitoring

Activity	Typical Support Operations
Multi-azimuth seismic survey (multiple passes in different directions with one source/receiver vessel)	• 1 source /receiver vessel • 1 support vessel • Likely 1 vessel for monitoring
Wide-azimuth seismic survey (multiple passes with multiple source vessels and at least one receiver vessel	• 2 to 4 source vessels • 1 to 2 receiver vessels • 1 support vessel • 1 vessel for monitoring
Rich-azimuth seismic survey (multiple passes with multiple source vessels and at least 1 receiver vessel)	• 2 to 4 source vessels • 1 to 2 receiver vessels • 1 support vessel • 1 vessel for monitoring
Full-azimuth coil-pattern seismic survey (single source/receiver vessel)	• 1 source/receiver vessel • 1 support vessel • Likely 1 vessel for monitoring
In-ice seismic survey	• 1 source/receiver vessel • 1 icebreaker • Possible 1 support vessel
Ocean-bottom cable surveys	• 2 vessels for cable layout/pickup • 1 recording vessel • 1 to 2 source vessels • 1 to 2 small support vessels
Ocean-bottom node survey	• 2 source vessels • 1-3 node deployment vessels • 1 vessel for support monitoring
High-resolution airgun surveys	• 1 source/receiver vessel • Possible 1 vessel for monitoring
High-resolution sonar surveys	• 1 source vessel
On ice vibroseis	• Truck-mounted vibrators over ice • No vessels
Electromagnetic surveys	• 1 receiver/layout/pickup source vessel
Artificial island drilling	• Sea lift or ice road operations to transport drilling rig and support modules • Drilling on island • Small support vessels • Aircraft for crew changes
Steel-drilling caisson drilling	• Modified very large crude carrier vessel • 2-3 tugs and supply to and from drill site • Aircraft for crew changes

Activity	Typical Support Operations
Exploratory Drilling Program from a Drillship or Floating Drilling Unit	• Drillship • 1 or 2 icebreakers • 1 anchor handler • 1 or 2 oil spill response barge and tug • Tank vessel for spill storage • 2-3 support vessels • Aircraft for crew changes
Exploratory Drilling Program from a Jackup rig	• Jackup rig • 1 or 2 icebreakers • 1 or 2 oil spill response barge and tug • Tank vessel for spill storage • 2-3 support vessels • Aircraft for crew changes

2.3.2 Overview of Commercially-Available Geophysical Survey Methods

2.3.2.1 Background

Seismic exploration is used in the search for commercially and economically valuable subsurface deposits of crude oil, natural gas, and minerals. Recording, processing, and interpreting reflected seismic waves, created by introducing controlled source energy (such as seismic airgun impulses, and vibratory waves) into the earth, provides a means to develop geological models to aid in resource evaluation.

Seismic surveys can be characterized by the type of data being collected (e.g. 2D, 3D, high-resolution, etc.) or by the type of survey being conducted (e.g. open-water towed marine streamer, ocean-bottom cable, in-ice towed streamer, over ice, etc.). Survey data may be described by the acoustic sound source (e.g. airgun, water gun, sparker, pinger) or by the purpose for which the data are being collected (e.g. speculative shoot, exclusive shoot, site clearance, ancillary activity for exploration).

Seismic surveys may also be described by the configuration of the survey and/or the location of the receivers. Vertical seismic profiling, in which the hydrophone is located in a borehole, and vertical cable surveys are conducted only as part of a drilling program. Both use standard seismic sources and do not need to be discussed in detail separately from standard seismic surveys. The analysis in Chapter 4 of potential impacts of airgun use on the human environment is applicable for all types of surveys.

Multi-azimuth and full-azimuth coil pattern surveys also use a standard source and single source/receiver vessel. During multi-azimuth surveys, the survey is designed so the vessel acquires data in several directions over the same survey location. The lines are not necessarily perpendicular. Full-azimuth coil patterns are run in circles like a spirograph around a center point. These two survey patterns do not need to be discussed separately from the standard seismic surveys.

A wide-azimuth survey consists of multiple source vessels and at least one receiver vessel run in a typical parallel survey configuration. A rich-azimuth survey incorporates both the multiple source vessel wide-azimuth type survey with a multi-azimuth survey configuration. None of the azimuth style surveys have been performed in the Arctic OCS to date primarily because of the cost of these types of surveys and no significant information gain for the extra cost. However, they are common in the rest of the world. No wide- or rich-azimuth surveys are expected to be conducted in the Arctic in the foreseeable future; therefore, they will not be discussed further in this document.

The most commonly used marine energy sources are airguns, which emit highly compressed air bubbles that transmit acoustic energy though the water column into the subsurface. Seismic waves reflect and refract off subsurface rock formations and travel back to acoustic receivers called hydrophones. Streamers are passive listening equipment, consisting of multiple hydrophone elements, which are towed behind the vessel. The characteristics of the reflected seismic waves (such as travel time and intensity) are used to evaluate geologic structures, subsurface deposits, and natural resources to help facilitate the location of prospective drilling targets and provide the information for a company to determine their bidding strategy for an OCS lease sale. The seismic information would also be used to optimize the location of drilling operations on leases to reduce safety and environmental risks.

An individual airgun size can range from five to 1,500 cubic inches (in^3) (0.081 to 24.58 liters). A combination of airguns is called an array; operators vary the source-array size to optimize the resolution of the geophysical data collected. Airgun array sizes for 2D/3D deep penetration seismic surveys in the Arctic Seas are expected to range from 1,800 to 5,000 in^3 (29.50 to 81.94 liters) but may range up to 6,000 in^3 (98.32 liters). Appendix B provides details on the acoustic characteristics of each of these exploration methods, including source levels, frequency, propagation, and the effect of environmental factors on these characteristics. However, in general, broadband peak source levels of a typical full-scale array range from 248 to 255 dB re 1 µPa at 1 m with most of the energy emitted between 10 and 120 Hz, although pulses may contain energy up to 1,000 Hz (Richardson et al. 1995).

2.3.2.2 Marine Deep Penetration Towed-Streamer 3D and 2D Surveys

Marine deep penetration towed-streamer 3D seismic surveys vary markedly depending on client specifications, subsurface geology, water depth, and target reservoir(s). Individual survey parameters may vary from the descriptions presented here. The vessels conducting these surveys generally are 70 to 120 meters (m) (230 to 394 feet [ft]) long. Vessels typically tow one to three source arrays, of six to nine airguns each, depending on the survey design specifications required for the geologic target. Most operations use a single source vessel. However, more than one source vessel will be used in wide or rich azimuth surveys or when using smaller vessels, which cannot provide a large enough platform for the total seismic gun array necessary to obtain target depth. The overall energy output for the permitted activity will be the same, but the firing of the source arrays on the individual vessels will be alternated.

Vessel transit speeds are highly variable, ranging from 8 to 20 knots (kn) (14.8 to 37.0 kilometers [km]/hour) depending on a number of factors including, but not limited to, the vessel itself, sea state, urgency (the need to run at top speed versus normal cruising speed), and ice conditions. Marine 3D and 2D surveys are acquired at typical vessel speeds of approximately 4.5 kn (8.3 km/hour).

The source array is triggered approximately every 10 to 15 seconds (s), depending on vessel speed. The timing between shots varies and is determined by the spacing required to meet the geological objectives of the survey; typical spacing is either 25 or 37.5 m (82 or 123 ft) but may vary depending on the design and objectives of the survey. Airguns can be fired between 20 and 70 times per km. Modern marine-seismic vessels tow up to 20 streamers with an equipment-tow width of up to approximately 1,500 m (4,921 ft) between outermost streamers. Biodegradable liquid paraffin, kerosene, and solid/gel are materials used to fill the streamer and provide buoyancy.

The 3D survey data are acquired along a survey grid of pre-plotted tracklines (i.e. a pre-determined line along which the source vessel travels at a constant speed to effectively transmit sound to the bottom in a manner that allows for predictable receipt of acoustic reflections at the receiver cable) within a specific, permitted, survey area. Adjacent tracklines for a 3D survey are generally spaced parallel to each other several hundred meters apart. The areal extent of the equipment limits both the turning speed and the area a vessel covers in one pass. It is, therefore, common practice to acquire data using an offset racetrack pattern, whereby the next acquisition line is several km away from, and traversed in the opposite direction of, the track line just completed. Seismic vessels operate day and night, and a survey may continue for days, weeks, or months, depending on the size of the survey, data-acquisition capabilities of the vessel, and weather or ice conditions. Vessel operation time includes not only data collection but also deployment and retrieval of gear, line turns between survey lines, equipment repair, and other planned or unplanned operations.

The 2D and 3D surveys use similar survey methods but different operational configurations. Three dimensional survey lines are spaced closer together and are concentrated in a specific area of interest. These surveys provide the resolution needed for detailed geological evaluation. A 2D survey provides less detailed geological information because the survey lines are spaced farther apart. These surveys are used to cover wider areas to map geologic structures on a regional scale.

The 2D seismic survey vessels generally are smaller than 3D survey vessels; however, the larger 3D survey vessels are also able to conduct 2D surveys. The source array typically consists of three or more sub-arrays of six to eight airgun sources each, but may vary as newer technology is developed. Only one streamer is towed during 2D operations. Figure 2.1 illustrates a typical 2D marine towed-streamer seismic survey.

Seismic vessels acquiring 2D data are able to acquire data at four to five kn (7.4 to 9.3 km/hour), 24 hours a day, and collect between 85 to 110 line-miles (mi) (137 to 177 line-km) per day, depending on the distance between line changes, weather conditions, and downtime for equipment problems. Typically, a survey vessel can collect 5,000 to 8,000 line-mi (8,047 to 12,875 line-km) during an open water seismic operational season in Arctic waters.

At least one support vessel would be used for safety considerations, general support, maintenance, and resupply of the main vessel, but it would not be directly involved with the collection of seismic data. Crew changes, refueling, and resupply for the seismic vessels are generally on a four to six week schedule. Helicopters, when available, also may be used for vessel support and crew changes, if there are no safety concerns. An additional support vessel may be used to monitor for marine mammals ahead of the survey vessel. For operational purposes, BOEM requires that all deep penetration seismic surveys maintain a minimum spacing of 24.1 km (15 mi) between source vessels when actively shooting. This is an operational constraint to prevent acoustic interference during data acquisition and has no special biological significance.

2.3.2.3 In-Ice Towed-Streamer 2D/3D Surveys

A change in technology has allowed geophysical (seismic reflection and refraction) surveys to be conducted in greater sea ice concentrations. Sea ice concentration is defined in terms of percent coverage in tenths. An area with 1/10 coverage of ice means the area contains sporadic ice floes that provides for easy vessel navigation; whereas, 10/10 coverage of ice means there is no open water in the area. This new technology currently uses a 2D seismic source vessel and an icebreaker. The icebreaker generally operates ~0.5 to 1 km (~0.3 to 0.62 mi) ahead of the seismic acquisition vessel, which follows at speeds ranging from 4 to 5 kn (7.4 to 9.3 km/hour). Like open-water 2D surveys, in-ice surveys operate 24 hours a day or as conditions permit. A third vessel may be used for one or more support trips as conditions allow during the length of the survey. The possibility exists that within the life of this EIS, equipment could be developed to allow towing of multiple streamers in ice covered waters, thus facilitating the ability to conduct 3D surveys in ice. This EIS analyzes effects from both 2D and 3D in-ice towed streamer surveys.

The in-ice seismic airgun arrays are similar to those used in open water marine surveys, as is the streamer. A single hydrophone streamer, which uses a solid fill material to produce constant and consistent streamer buoyancy, is towed behind the vessel. The streamer receives the reflected signals from the subsurface and transfers the data to an on-board processing system. The survey vessel has limited maneuverability while towing the streamer and thus requires a 10 km (6.2 mi) run-in for the start of a seismic line, and a 4 to 5 km (2.5 to 3.1 mi) run-out at the end of the line.

2.3.2.4 Ocean-Bottom Receiver Seismic Surveys

Ocean-bottom Cable Seismic Surveys

Ocean-bottom cable (OBC) seismic surveys are used in Alaska primarily to acquire seismic data in transition zones where water is too shallow for a towed marine streamer seismic survey vessel and too deep to have grounded ice in the winter. The OBC seismic survey requires the use of multiple vessels. A typical survey includes: (a) two vessels for cable layout/pickup; (b) one vessel for recording; (c) one or two source vessels; and (d) possibly one or two smaller utility boats.

Most operations use a single source vessel, but multiple source vessels may be used if size prohibits loading the full airgun array required for the survey on one vessel. The overall energy output for the permitted activity would be the same for a two vessel shoot, as the source arrays alternate vessels when firing. These vessels are generally, but not necessarily, smaller than those used in towed-streamer operations. OBC seismic arrays are frequently smaller in size than the towed marine streamer arrays due to the shallower water depths in which OBC surveys are usually conducted. The utility boats can be small, in the range of 10 to 15 m (33 to 49 ft).

An OBC operation begins by laying cables off the back of the layout boat. Cable length typically is 4 to 6 km (2.5 to 3.7 mi) but can be up to 12 km (7.5 mi). Groups of dual component (2C) or multiple component (4C) seismic-survey receivers (a combination of both hydrophones and vertical-motion geophones) are attached to the cable in intervals of 12 to 50 m (39 to 164 ft). Multiple cables are laid on the seafloor parallel to each other using this layout method, with a cable spacing of between hundreds of meters to several kilometers, depending on the geophysical objective of the seismic survey. When the cable is in place, a vessel towing the source array passes over the cables with the source being activated every 25 m (82 ft). The source array may be a single or dual array of multiple airguns, which is similar to the 3D marine seismic survey. Figure 2.2 illustrates an OBC operation.

After a survey line is completed, the source ship takes about 10 to 15 minutes to turn around and pass over the next cable. When a cable is no longer needed to record seismic survey data, it is recovered by the cable-pickup ship and moved to the next recording position. A particular cable can lay on the seafloor anywhere from two hours to several days, depending on operation conditions. Normally, a cable is left in place for about 24 hours.

An OBC seismic survey typically covers a smaller area (approximately 16 by 32 km [10 by 20 mi]) and may spend days in an area. In contrast, 3D towed-streamer seismic surveys cover a much larger area (thousands of square miles) and stay in a particular area for hours. While OBC seismic surveys could occur in the nearshore shallow waters of the Beaufort Sea, they are not anticipated to occur in the Chukchi Sea OCS because of its greater water depths and the exclusion of the near shore OCS area from leasing. Recent technological developments have been introduced that provide improved operational flexibility for equipment deployment, recovery, and data collection in the field, but the costs are high compared to streamer-collected data.

Ocean-bottom Node Seismic Surveys

Ocean-bottom Node (OBN) surveys, like the OBC surveys presented above, place receivers on the seafloor instead of towing them behind a survey vessel. Seafloor seismometers, precursors to modern day nodes, have been used in the academic community for crustal exploration for more than 70 years (Fisher 2004). However, the seismographs typically used to conduct these studies are not the best choice for exploration/production seismic operations as they do not have the required precision (Ronen et al. 2007). In the late 1990s, SeaBird Geophysical developed the first commercially available OBN system, specifically tailored to the oil and gas industry (Durham 2010).

The OBNs used in oil and gas operations are four component (4C) receivers that include three orthogonal geophones and one hydrophone, capable of measuring both shear (S) and compressional (P) waves, which cannot be done using 2C cables or towed streamers. The nodes are typically deployed in groupings called patches, using Remotely Operated Vehicles in deep water and ropes/cables in shallower water. The geologic target depth determines the node spacing and size of the patch. Generally, node spacing ranges between 50 m and 500 m (164 ft and 1,640 ft). If enough nodes are available, large patches (160 to 250 km^2) are collected as a single survey. However, a larger area can also be surveyed using smaller patches (10 to 30 km^2) with fewer nodes, which are combined to complete the entire survey (Ray et al. 2004, Beaudoin and Ross 2007, Chopra 2007, Duey 2007). An Ultra Short Baseline system (which measures the distance and bearing from a transceiver mounted on a survey vessel to an acoustic transponder at the node and combines these data with GPS, vessel heading and attitude) is commonly used to calculate the node position.

To utilize the 4C nodes to their fullest capabilities, survey lines are not only run directly above the nodes in the patch. Additional lines can be run at distances offset from the patch (at least 3 km to 20 km [1.9 mi to 12.4 mi]) to provide wide-azimuth data. If lines are run in several different directions, multi-azimuth data can also be collected. The distance between airgun shots is typically 50 m (164 ft) (Beaudoin and Ross 2007, Smit et al. 2008, Smit 2010, Vázquez Garcia 2005).

Node technology has been used in the deepwater Gulf of Mexico in areas with abundant infrastructure to image below salt (Smit et al. 2008, Baudoin 2010) and to perform 4D surveys (Reasnor 2010, Smit 2010). Nodes have also been used to image offshore fields internationally in: Mexico (Vázquez Garcia 2005); Angola (Lecerf 2010); Nigeria (Subsea World 2009); and West of the Shetland Islands (Oil Voice 2010).

In Alaska, OBNs in conjunction with land based nodes have been successfully tested in Cook Inlet to evaluate the technology's capability to image the transition zone, between shallow water and land, for oil and gas exploration (Fairfieldnodal 2011). These nearshore/transition zone surveys typically require two source vessels, up to three node deployment vessels, and a separate mitigation vessel. While this technology has only been used in Cook Inlet so far, it is easily transferrable to the Beaufort or Chukchi Sea.

This technology has the potential to: improve imagery associated with complicated oil and gas fields; clarify lithology and predict fluids in reservoir rocks; increase oil recovery; and decrease development risks (Enovation Resources 2011). It is reasonable to project that nodes could be used in the Arctic during the life of this EIS.

2.3.2.5 High-Resolution Shallow Hazards Geophysical Surveys

Prior to submitting an exploration or development plan, oil and gas industry operators are required to evaluate any potential geological hazards and document any potential cultural resources or benthic communities pursuant to 30 CFR Part 550 Subpart B. BOEM provides guidelines in Notices to Lessees (NTLs) that require the collection of high-resolution shallow hazards surveys to ensure safe conduct and operations in the OCS at drill sites and along pipeline corridors, unless the operator can demonstrate there is enough previously collected data to evaluate the site.

The suite of equipment used during a typical shallow hazards survey consists of: single beam and multibeam echosounders which provide water depths and seafloor morphology; a side scan sonar that provides acoustic images of the seafloor; a subbottom profiler which provides 20 to 200 m (66 to 656 ft) sub-seafloor penetration with a 6 to 20 cm (2.4 to 7.9 inches [in]) resolution; a single channel seismic system with 40 to 600 m (131 to 1,969 ft) sub-seafloor penetration; and a multichannel seismic system with 1,000 to 2,000 m (3,280 to 6,562 ft) sub-seafloor penetration. Magnetometers, that detect ferrous items, have not been required in the Alaska OCS to date due to the lack of metallic artifacts in the Arctic OCS of Alaska. Typical acoustic characteristics of these sources are:

- Single beam echosounders: 180 to 205 dB re 1 µPa at 1 m between 3.5 and 1,000 kHz (Koomans 2009);

- Multibeam echosounders: 216 to 242 dB re 1 µPa at 1 m between 180 kHz and 500 kHz (Hammerstad 2005, HydroSurveys 2010);
- Side scan sonar: 194 to 249 dB re 1 µPa at 1 m between 100 and 1,600 kHz (HydroSurveys 2008, Dorst 2010);
- Subbottom profilers and single channel seismic: 200 to 250 dB re 1µPa at 1 m between 0.2 kHz and 200 kHz (Laban et al. 2009, Richardson et al. 1995); and
- Multichannel seismic: 196 to 217 dB re 1 µPa at 1 m between 0 and 200 Hz (NMFS 2008a, 2009, 2010; Richardson et al. 1995).

The echosounders and subbottom profilers are generally hull-mounted. All other equipment is usually towed behind the vessel. The multichannel seismic system consists of an acoustic source which may be a single small airgun 10 to 65 in^3 (0.16 to 1.1 liters) or an array of small airguns usually two or four 10 in^3 (0.16 liter) guns. The source array is towed about 3 m (9.8 ft) behind the vessel with a firing interval of approximately 12.5 m (41 ft) or every 7 to 8 s. A single 300 to 600 m (984 to 1,969 ft), 12 to 48 channel streamer with a 12.5 m (41 ft) hydrophone spacing and tail buoy is the passive receiver for the reflected seismic waves. Biodegradable liquid paraffin, kerosene, and solid/gel are materials used to fill the streamer and provide buoyancy.

The ship travels at 3 to 4.5 kn (5.6 to 8.3 km/hour). These survey ships are designed to reduce vessel noise, as the higher frequencies used in high-resolution work are easily masked by the vessel noise if special attention is not paid to keeping the ships quiet. Surveys are site specific and can cover less than one lease block. The survey extent is determined by the number of potential drill sites in an area. BOEM recommends data be gathered on a 150 by 300 m (492 by 984 ft) grid within 600 m (1,969 ft) of the drill site, a 300 by 600 m (984 to 1,969 ft) grid out to 1,200 m (3,937 ft) from the drill site, and a 1,200 by 100 m (3,937 by 328 ft) grid out to 2,400 m (7,874 ft) from the well site.

A single vertical well site survey will collect about 46 line-miles (74 line-km) of data per site and take approximately 24 hours. If there is a high probability of archeological resources, the 150 m by 300 m (492 ft by 984 ft) grid must extend to 1,200 m (3,937 ft) around the drill site.

2.3.2.6 On-Ice Winter Vibroseis Seismic Surveys (also referred to as over-ice or hard water surveys)

Winter vibroseis seismic operations use truck-mounted vibrators that systematically put variable frequency energy through the ice and into the seafloor. At least 1.2 m (3.9 ft) of sea ice is required to support heavy vehicles used to transport equipment offshore for exploration activities. These ice conditions vary, but generally exist from sometime in January until sometime in May in the Arctic. The exploration techniques are most commonly used on landfast ice (ice attached to the shoreline), but they can be used in areas of stable offshore pack ice near shore. Several vehicles are normally associated with a typical vibroseis operation. One or two vehicles with survey crews move ahead of the operation and mark the source receiver points. Occasionally, bulldozers are needed to build snow ramps to smooth offshore rough ice within the survey area.

With the vibroseis technique, activity on the surveyed seismic line begins with the placement of geophones (receivers). All geophones are connected to the recording vehicle by multi-pair cable sections. The vibrators move to the beginning of the line and recording begins. The vibrators move along a source line, which is at some distance or angle to a receiver line. The vibrators begin vibrating in synchrony via a simultaneous radio signal to all vehicles.

In a typical survey, each vibrator will vibrate four times at each location. The entire formation of vibrators subsequently moves forward to the next energy input point (e.g. approximately 67 m [220 ft] in most applications) and repeats the process. Most energy is beamed downward. In a typical 16- to 18-hour day, a survey will complete three survey tracks of 6 to 16 linear km (3.7 to 9.9 mi) in a 2D seismic survey, and 24 to 64 linear km (15 to 40 mi) in a 3D seismic survey. Vibroseis signals typically sweep from 10 to 70 Hz at an estimated source level of 187 dB re 1 µPa at 1 m (Richardson et al. 1995).

2.3.2.7 Vertical Seismic Profiling

Vertical seismic profiling (VSP) is conducted as part of a drilling program in the wellbore. These programs use hydrophones suspended in the well at intervals which receive signals from external sound sources; usually an airgun(s) is suspended from the drill rig or a nearby supply vessel. Data are used to aid in determining the structure of a particular petroleum-bearing zone. Purely defined, VSP refers to measurements made in a vertical wellbore using geophones inside the wellbore and a source at the surface near the well. In the more general context, VSPs vary in the well configuration, the number and location of sources and geophones, and how they are deployed. Most VSPs use a surface seismic source, which is commonly a vibrator on land and an airgun in offshore or marine environments. VSPs include the zero-offset VSP, offset VSP, walk away VSP, walk-above VSP, salt-proximity VSP, shear-wave VSP, and drill-noise or seismic-while-drilling VSP. A VSP is a much more detailed survey than a check-shot survey because the geophones are more closely spaced, typically on the order of 25 m (82 ft), whereas a check-shot survey might include measurements at intervals hundreds of meters apart. Also, a VSP uses the reflected energy contained in the recorded trace at each receiver position, as well as the first direct path from source to receiver. The check-shot survey uses only the direct path travel time. In addition to tying well data to seismic data, the vertical seismic profile also allows for converting seismic data to zero-phase data and distinguishing primary reflections from multiples. VSP operations are not considered to be a seismic survey for analysis purposes in this EIS but rather as part of an exploratory drilling program, even though airguns are used for a short time.

2.3.2.8 Controlled Source Electromagnetic Survey

Measurements of electrical resistivity beneath the seafloor have been used in oil and gas exploration, but historically have been collected through the wire-logging of wells. Since 2002, several electromagnetic methods have been developed for mapping sub-seafloor resistivity, including marine controlled source electromagnetic (CSEM) sounding (Eidesmo et al. 2002). This method uses a mobile horizontal electric dipole source and an array of seafloor electric receivers. The transmitting dipole emits a low frequency (typically 0.5 to 10 Hertz [Hz]) electromagnetic signal into the water column into the underlying sediments. Electromagnetic energy is attenuated in the conductive sediments, but in higher resistive layers (such as hydrocarbon-filled reservoirs), the energy is less attenuated. This contrast is what is detected to provide data on potential areas of interest.

The length of the dipole varies between 10 to 50 m (33 to 164 ft) and the system is towed at approximately 24 to 40 m (79 to 131 ft) above the seafloor at a speed of 5 km/hr (3.1 mi/hr). Figure 2.3 illustrates a CSEM survey.

2.3.2.9 Gravity and Gradiometry Surveys

Gravity surveys have been used for years in the oil and gas industry. Measurements taken at the Earth's surface express the acceleration of gravity of the total mass of the Earth. State of the art gravity meters can sense differences in the acceleration (pull) of gravity to one part in one billion. Because of their high sensitivity, these instruments can detect mass variations in the crustal geology, possible indicators of fault displacement and geologic structures favorable to hydrocarbon production.

In 1994, the U.S. Defense Department declassified the 3D full tensor gradiometer. This allowed the gravity field gradient to be determined by using accelerometers to measure the spatial multi-components of gravity. The equipment utilized for gradiometry surveys is much more complex than that of traditional gravity surveys. The new gravity data are evaluated in three dimensions instead of the two dimensions in traditional gravity surveys and can better define subsurface bodies of varying densities.

The increase in data resolution provided by the new technology has allowed the geology below salt to successfully be imaged in the Gulf of Mexico. This technology could be used in the Arctic Seas as a method for identifying features such as basins and edges, but would not replace 3D seismic.

2.3.3 Exploratory Drilling

Exploratory drilling activities conducted on the OCS must be conducted in accordance with BOEM and BSEE regulations at 30 CFR Part 550 Subpart B and 30 CFR Part 250 Subpart B, respectively. These regulations establish comprehensive requirements for well design based on site specific shallow hazards site clearance information and deep penetration seismic data, redundant pollution prevention equipment, testing and verification that equipment is working properly, and training and testing of personnel in well control procedures. These regulations also establish requirements on the technical specifications for the specific drilling rig and the drilling unit.

No drilling activity can be conducted until the BOEM has approved an EP and BSEE has approved the well-specific APD. BSEE engineers and geoscientists are required by law to review each APD for proper engineering considerations, site specific engineering and geologic conditions, and compliance with BSEE regulations, which include provisions to ensure safe operations and preservation of the environment. Any changes to an approved APD must be submitted, reviewed, and approved by the BSEE.

There are currently three principal forms of exploratory drilling platforms used in offshore exploration: artificial or natural islands; bottom-founded structures; and floating vessels.

Exploratory wells are generally drilled vertically to simplify well design and maximize benefits from subsurface data collection (i.e. well logs, cores). Directional wells (any well that is not vertical) may be drilled if a suitable surface location cannot be used or if there is a subsurface anomaly that should be avoided. A well is considered to be directional when the inclination of the well bore path is over three degrees from vertical. Directional drilling is different than extended reach drilling (ERD). ERD is a term used for wells drilled with significant horizontal departures from the surface location; on the order of several km (10,000s of feet). ERD is an evolving technology for production wells but currently is not used for exploration.

2.3.3.1 Artificial Islands

Artificial islands are constructed in shallow offshore waters for use as drilling platforms. In the Arctic, artificial islands have been constructed from a combination of gravel, boulders, artificial structures (e.g. caissons which are watertight retaining structures), and/or ice. Artificial islands can be constructed at various times of the year. During summer, gravel is removed from the seafloor or onshore sites and barged to the proposed site and deposited to form the island. In the winter, gravel is transported over ice roads from an onshore site to the island site. After the artificial island is constructed to its full size, slope protection systems are installed, as appropriate for local oceanographic conditions, to reduce ice ride-up and erosion of the island. Once the island is complete, a drilling rig is transported to the island. On average, approximately 100 people operate a typical rig site. Due to economic and engineering considerations, gravel island construction has historically been restricted to waters less than 15 m (49 ft) deep. It is anticipated that artificial islands could be constructed in the Beaufort Sea but not in the Chukchi Sea.

2.3.3.2 Caisson-Retained Island

Caisson-retained islands are similar in construction and design to other artificial islands with one significant exception. Rather than relying entirely on gravel or large boulders for support, the island contains one or more floatable concrete or steel caissons, which rest on an underwater gravel berm or on the ocean floor in water less than 6 m (19.7 ft) deep. The berm is constructed with dredged or deposited material to within 6 m (19.7 ft) of the sea surface. When each caisson is in place, the resulting concrete or steel ring is filled with sand to give the structure stability. This design, like the gravel island, allows drilling to occur all year. When drilling is completed, the center core of sand can be dredged out, the caissons refloated, and the structure moved to a new location. The berm is left to erode by the natural action of the ocean.

2.3.3.3 Steel Drilling Caisson

The Steel Drilling Caisson (SDC), a bottom-founded structure, is a "fit for purpose" drilling unit constructed typically by modifying the forward section of an ocean-going Very Large Crude Carrier (see Figure 2.4). The main body of the structure is approximately 162 m (531 ft) long, 53 m (174 ft) wide, and 25 m (82 ft) high. The SDC is designed to conduct exploratory year-round drilling under arctic environmental conditions.

On its first two deployments in the Canadian Beaufort, the SDC was supported by subsea gravel berms. For its third deployment in Harrison Bay in 1986, a steel component was constructed to support the SDC in lieu of the gravel berms. It was also used in 2002 by EnCana on the McCovey prospect. The steel base configuration adds 13 m (42.7 ft) to the design height of the structure and allows deployment of the SDC in water depths of 8 to 24 m (26 to 79 ft) without bottom preparation. The SDC requires minimal support during the drilling season. It is typically stocked with supplies before being moved to a drill site. Two or three tugs and/or supply vessels tow the SDC to or from the drill site during open water periods. Deployment and recovery of the SDC require less than one week each. Personnel (typically a maximum of 100) and some smaller equipment are transported to and from the SDC by helicopter. Fuel and larger items, if required, are transported by supply vessel.

The SDC is the only existing man-made bottom founded structure that could be used in the U.S. Beaufort Sea. The water depths for existing leases in the U.S. Chukchi Sea are too deep for the SDC. A Concrete Island Drilling Structure was used to drill an exploratory well in Camden Bay; however, it has been converted into a permanent development platform offshore Sakhalin, Russia and would not be available for exploratory drilling in the U.S.

2.3.3.4 Floating Drilling Vessels

Floating drilling vessels that have a reasonable probability to be employed in the Arctic include drillships (e.g. *Northern Explorer II, Noble Discoverer*), semi-submersibles, or other floating vessels (e.g. *Kulluk*) in which the hull does not rest on the seafloor. These types of drilling vessels can typically be used in water depths greater than 18 m (59 ft) in the Beaufort and Chukchi seas. This range makes them more suitable for the deeper water exploratory prospects than the "bottom founded" units such as the islands or the SDC mentioned in previous sections. Floating drilling vessel crews typically range from 100 to 200 people to operate the marine and drilling systems and ensure the safety of the operation (not including support or ice management vessels). These types of floating drilling vessels are held over a well drilling location either by a mooring system (consisting of an anchor, chain, and wire rope) or by the use of dynamic positioning (omni-directional thrusters coupled with a computer control system).

Sounds generated from vessel-based drilling operations occur at low frequencies (below 600 Hz), although tones up to 1,850 Hz were recorded by Greene (1987) during drilling operations in the Beaufort Sea. For the drillship *Explorer I*, sound levels of 122 to 125 dB re 1 Pa between 20 to 1,000 Hz band level were measured at a range of 0.17 km (0.10 mi) (Greene 1987). Sound levels from the drillship *Explorer II* were slightly higher (134 dB) at a range of 0.20 km (0.12 mi) although tones were only recorded below 600 Hz (Greene 1987). Sounds from the *Kulluk* at 0.98 km (0.61 mi) were higher (143 dB) than from the other two vessels (Greene 1987).

Drillship

A drillship is a maritime vessel that has been equipped with a drilling apparatus. Most are built to the design specification of the company, but some are modified tanker hulls that have been equipped with a dynamic positioning system. Drillships are completely independent, and some of their greatest advantages are their ability to drill in water depths of more than 2,500 m (8,202 ft) and their ability to sail between areas worldwide.

Shell Oil has proposed, in prior applications, to use the *M/V Noble Discoverer* for drilling in both the Chukchi and Beaufort seas (Shell Incidental Harassment Authorization [IHA] application 2010a). The *Discoverer* is a drillship, built in 1976, that has been retrofitted for operating in Arctic waters. It is a 156 m (512 ft) conventionally-moored drillship with drilling equipment on a turret. It mobilizes under its own power, so it can be moved off the drill site with help of its anchor handler. Depending on the circumstances of the situation, the procedure and time needed to move off a drill site can change. In extreme emergencies, this process can be completed in less than one hour. In the event that operations must be temporarily curtailed due to the advance detection of a hazard, the process could take from 4 to 12 hours. Typical transit speed of the *M/V Noble Discoverer* is 8 kn (14.8 km/hour). The vessel has full accommodations for a crew of up to 124 persons (quarters, galley and sanitation facilities). Figure 2.5 is a photograph of the *M/V Noble Discoverer*. As provided in Shell's 2012 Exploration Plan, measurements of sounds produced by the Discoverer in the South China Sea were performed in 2009. Broadband source levels of the Discoverer ranged from 177 to 185 dB re 1 μPa rms (Shell 2011a).

Support vessels are used to assist the drillship with ice management, anchor handling, oil spill response, refueling, resupply, and servicing. The total number of support vessels depends on the local conditions and the design of the exploration program (see Table 2.2). The ice management vessels typically consist of an icebreaker and an anchor handler, as well as an auxiliary ice management vessel. The oil spill response vessels (OSRV) include an ice-capable oil spill response barge (OSRB) and associated tug, a tank vessel for storage of liquids, and smaller workboats. A re-supply ship would travel to and from the drilling site as needed. Additional vessels for marine mammal monitoring/scientific research may be used. There is also the potential for re-supply to occur via a support helicopter from the shore to the drill site, and fixed-winged aircraft may be used for marine mammal monitoring. Unmanned aerial drones could also potentially be used for marine mammal observation and monitoring of ice conditions but would require approval from the Federal Aviation Administration (FAA).

Jackup Rig

A jackup rig is an offshore structure composed of a hull, support legs, and a lifting system that allows it to be towed to a site, lower its legs into the seabed and elevate its hull to provide a stable work deck. Because jackup rigs are supported by the seabed, they are preloaded when they first arrive at a site to simulate the maximum expected support leg load to ensure that, after they are jacked to full airgap (the maximum height above the water) and experience operating loads, the supporting soil will provide a reliable foundation. Figure 2.6 is a photograph of a jackup rig.

There are three main components of a jackup rig: the hull; the legs and footings; and the equipment. The hull is a watertight structure that houses the equipment, systems, and personnel. When the jackup is afloat, the hull provides buoyancy and supports the weight of the legs and footings, equipment, and variable load. The legs and footings are steel structures that support the hull when elevated and provide stability to resist lateral loads. Most jackup rigs have no more than four legs. Three legs are the minimum required for stability. Units with three legs are arranged in a triangular form, while units with four legs are typically arranged in a rectangular form. Most jackup rigs in use today are equipped with rack and pinion systems for continuous jacking operations.

The actual dimensions of a jackup rig would depend on the environment in which the unit would be operating and the maximum operating water depth. A typical jack up rig with a maximum operating depth of 50 m (164 ft) is approximately 50 m (164 ft) in length, 44 m (144 ft) beam, and 7 m (23 ft) deep.

The jackup rig could have two OSRV and four workboats; each EP may call for different numbers of vessels within regulation requirements. One OSRV and workboat would remain within 16 km (10 mi) of the jackup rig during drilling and one OSRV would be at a distance of at least 40 km (25 mi) from the jackup rig. Two icebreakers would be in proximity of the rig and offshore supply vessels or ware vessels would be used for resupply. A supply tug would be needed to tow the jackup rig to the site and would remain within 40 km (25 mi) of the rig for when it needs to be moved.

Noise levels from jackup rigs have not been measured in the Arctic (Wyatt 2008). The main contributors to the underwater sound levels from jackup rig drilling activities are the use of generators and drilling machinery. Sound levels transmitted into the water from bottom-founded structures are typically less than sound levels from a drillship because the vibrating machinery is not in direct contact with the water because the platform is above water. Because the jackup rig has fewer structures in direct contact with the water (because they are "jacked" above the water), noise levels are expected to be less than drillships. Although sound level measurements have not been conducted to date for jackup rigs in the Arctic, MAI (2012) describe measurements of the Spartan 151 drilling rig operating in Cook Inlet. Results of those measurements indicated the primary sources of underwater sound were produced by the diesel engines, mud pump, ventilation fans (and associated exhaust), and electrical generators. The loudest source levels (from the diesel engines) were estimated at 137 dB re 1 μPa at 1 m (rms) in the 141-178 Hz one-third octave band (MAI 2012). It is assumed that the first time a jackup rig is in operation in the Arctic detailed measurements will be conducted to determine the acoustic characteristics. Noise from icebreakers would also be the same as described above.

2.3.3.5 Exploratory Drilling Activity Discharges and Emissions

Certain discharges from oil and gas exploration facilities in the Chukchi and Beaufort seas are authorized by the U.S. Environmental Protection Agency (EPA) under the Clean Water Act (CWA) Section 402, National Pollutant Discharge Elimination System (NPDES) permitting authority. Prior to issuance of NPDES discharge permits for these actions, EPA is required to comply with the Ocean Discharge Criteria (40 CFR Part 125 Subpart M) for preventing unreasonable degradation of ocean waters; and to consult with the U.S. Fish and Wildlife Service and NMFS to ensure that any action it authorizes is not likely to jeopardize the continued existence of any species listed under the Endangered Species Act, or result in the destruction or adverse modification of critical habitat required by a listed species.

On October 29, 2012, EPA issued two general permits for exploration discharges to the Beaufort and Chukchi Seas, permit numbers AKG-28-2100 and AKG-28-8100, respectively. The general permits authorize discharges from thirteen categories of waste streams, subject to effluent limitations, restrictions, and requirements. The general permits became effective on November 28, 2012, and are effective for five years. The permits require operators to submit Notices of Intent to EPA requesting authorization to discharge at least 120 days prior to commencing discharges

For their 2012 exploratory drilling program in the Beaufort Sea, Shell made a voluntary commitment to collect and transport drilling muds and drill cuttings, sanitary wastes, domestic wastes, ballast water, and bilge water to a disposal site in the Pacific Northwest. This EIS will analyze the reduction of those discharge streams as a mitigation measure in all of the action alternatives.

Jurisdiction for control of air emissions from stationary sources on the Arctic OCS (stationary rigs, drillships, and platforms) was the responsibility of the EPA until amendments to the Clean Air Act Section 328 were enacted on December 23, 2011 (Pub. L. 112-74) in the Consolidated Appropriations Act, 2012. The Arctic OCS is defined to include the Beaufort Sea and Chukchi Sea OCS Planning Areas that are adjacent to the North Slope Borough of Alaska. The signing of Pub. L. 112-74 transferred authority for the control of air stationary source emissions on the Arctic OCS from the EPA to BOEM but only for the Arctic OCS (Consolidated Appropriations Act, 2012). Companies with current permits received from (or initiated with) EPA prior to the transfer of authority retain those valid permits. The other Alaska OCS Planning Areas remain under EPA jurisdiction by the authority granted in the Clean Air Act Section 328. However, all actions on the Alaska OCS proposed within three miles of shore remain subject to air quality regulations of the ADEC and may require permitting.

Control of stationary source emissions within the Beaufort and Chukchi seas is now regulated by BOEM, EPA, and ADEC, depending on the location of the proposed action. For proposed exploration plans or development or production plans located more than three miles offshore on the Arctic OCS, emissions are regulated by BOEM under 30 CFR Part 550 Subpart C (BOEM Subpart C) and by the authority granted in the OCS Lands Act Sec. 5(a)(8). BOEM Alaska OCS Region would conduct an analytical evaluation of the air quality analysis contained in any exploration plan or development or production plan to ensure compliance with BOEM Subpart C. BSEE would be responsible for enforcing any required controls.

Regardless of whether approved under existing EPA permits or via a new BOEM EP approval, emission of air pollutants, such as nitrogen dioxide, sulfur dioxide, and carbon monoxide would be required to meet the NAAQS issued by the EPA. The NAAQS specify maximum allowable concentrations for six principal criteria pollutants (EPA 2011b). A project proposed within three miles of shore may be required to obtain a Title V operating permit under Alaska rules depending on the specific source/facility.

2.3.3.6 Oil Spill Contingency and Response Planning

Oil spill contingency and response plans in the Alaska Arctic region are regulated by a combination of both state and federal requirements. EPA, the State of Alaska (ADEC), BSEE, and the U.S. Coast Guard (USCG) each have a set of requirements for oil spill contingency and response planning. The requirements of the different agencies overlap with each other to some degree. However, in some cases each agency requires independent documentation in order to ensure that the applicable requirements are met[1].

EPA requires Facility Response Plans (FRPs) and Spill Prevention, Control and Countermeasure (SPCC) plans (40 CFR Part 112) for onshore facilities and facilities in State waters. A FRP demonstrates a facility's preparedness to respond to a worst case oil discharge. Under the Clean Water Act (CWA), as amended by the Oil Pollution Act (OPA), certain facilities that store and use oil are required to prepare and submit these plans. Under 40 CFR Part 112 FRPs must: identify a qualified individual having full authority to implement removal actions and require immediate communication between that person and the appropriate federal authorities and responders; identify and ensure availability of resources to remove, to the maximum extent practicable, a worst-case discharge; and describe training, testing, drills, and response actions of persons at the facility. FRPs must also be updated periodically and be resubmitted for approval of each significant change (40 CFR Part 112). The SPCC rule includes requirements for oil spill prevention, preparedness, and response to prevent oil discharges to navigable waters and adjoining shorelines. The rule requires specific facilities to prepare, amend, and implement SPCC Plans. The SPCC rule is part of the Oil Pollution Prevention regulation, which also includes the FRP rule.

---

[1] The 2011 Draft EIS contained a standard mitigation measure (listed in Appendix A of the 2011 Draft EIS as standard measure C4) that would require operators to have a plan in place to minimize the likelihood of an oil spill and outline response protocols in the event of a spill. Operators are required to develop such plans prior to receiving final approval from the appropriate federal and/or state agencies. Because development and approval of such plans is required before activities can be conducted, it is redundant to include development of such a plan in an MMPA ITA, which includes measures that must be carried out during operations. The oil spill contingency and response plans are a required component of the operations at both the planning and execution phases and would therefore already be developed and in place before the point of implementing measures contained in an MMPA ITA.

In addition to the EPA requirements, ADEC regulations (18 AAC 75.400) require that operators prepare Oil Discharge Prevention and Contingency Plans (ODPCPs, or C-plans) for activities within State waters. ODPCPs must set forth measures designed to prevent spills and must demonstrate that sufficient resources are available to contain or control and clean up any spills that may occur. Key components of the ODPCP required by ADEC include (18 AAC 75.425): an emergency action checklist including the immediate response and notification steps to be taken if an oil discharge occurs, to clearly guide responders in an emergency event; a description of the steps necessary to develop an incident-specific safety plan for conducting a response; a description of field communications procedures; procedures for the transport of equipment, personnel, and other resources; and a detailed written description of a hypothetical spill incident and response that demonstrates the plan holder's ability to respond to a discharge. In addition, the ODPCP is required to include detailed information about blowout prevention, fuel transfer procedures, equipment maintenance programs, and operating requirements for exploration. The ODPCP must also present analysis of potential discharges, potential areas for discharge, spill trajectory analysis, and a description of any priority protection sites. Specific information must be provided about procedures to stop the discharge, fire prevention and control, containment, and disposal strategies. The ODPCP must provide trajectories for the transport and disposition of potential spills, identify strategies for the protection of sensitive areas and wildlife, and detail plans for minimizing the impact of a spill on wildlife resources and subsistence activities.

Overlapping with the ADEC requirements, BSEE requires that every operator operating seaward of the coastline, whether in state or federal waters, must submit an oil-spill-response plan (OSRP) for their facilities to BSEE for approval (30 CFR Part 254). Required components of the OSRP include: an emergency response-action plan; equipment inventory; contractual agreements for spill-response services; worst-case discharge scenario; dispersant-use plan; in situ burning plan, and a training and drills plan. As required by 30 CFR Part 254.30, OSRPs must be reviewed at minimum every two years and resulting changes submitted to BSEE. If no changes are required, the operator must submit written notification that the plan has been reviewed and that no changes are required. The operator is required to submit revisions of the plan to BSEE within 15 days of any changes that negatively impact spill response capabilities or increase the worst case discharge scenario.

Also overlapping with the ADEC and BSEE requirements, operators are required to submit "Response Plans for Oil Facilities Transferring Oil or Hazardous Material in Bulk" (33 CFR Part 154) to the USCG, Department of Homeland Security. The USCG response plans must include detailed descriptions of equipment, facility operations, vapor control systems, methods of ensuring the availability of response resources by contract or other approved means, description of worst case discharge, and information on training, exercises, and inspection and maintenance of response resources. Many of the requirements described in 33 CFR Part 154 are analogous to the ADEC (18 AAC 75.425) and BSEE (30 CFR Part 254) requirements, and operators may opt to fulfill requirements of these agencies with a single response plan document (see Beaufort Sea Regional Exploration ODPCP, Shell Offshore Inc., January 2010 [Shell 2010b]). However, oil spill contingency and response planning documents are reviewed independently by each agency to ensure that spill-response resources are appropriate to respond to any spill that might occur.

Section 311 of the CWA provides the overall regulatory framework for oil spills and designated hazardous substances, including national policy and responsibilities. Policy specific to oil spills is further defined in the Oil Pollution Act of 1990 (OPA), Public Law (P.L.) 101-380. Under the OPA, liability for actual costs of removal rests with the responsible party. The OPA establishes oil-spill response planning and preparedness requirements for offshore facilities. Executive Order 12777 implementing OPA assigned regulatory oversight for offshore oil and gas to the Department of the Interior, with oversight delegated to BSEE.

Environmental protection from oil spills is also regulated under the National Oil and Hazardous Substances Pollution Contingency Plan (NCP) (40 CFR Part 300) as required by Section 311(d) of the CWA, 33 USC 1321(d) as amended by the OPA, P.L. 101-380.

The NCP is the federal government's blueprint for responding to both oil spills and hazardous substance releases. The NCP is the result of efforts to develop a national response capability and promote overall coordination among the hierarchy of responders and contingency plans. The NCP and the Alaska Federal and State Preparedness Plan for Response to Oil and Hazardous Substance Discharges and Releases (Unified Plan) have been developed in compliance with the CWA, Section 311(c)(2), and the OPA, Section 1321(d). In addition to the Unified Plan, Alaska has divided the State into 10 geographic regions and developed subarea contingency-response plans for each area. The North Slope Subarea Contingency Plan addresses specific response issues for the Alaska Arctic OCS regions. These plans identify spill-sensitive biological and cultural resources and geographic response scenarios. The subarea contingency plans also identify shoreline types in the subarea and list spill-response tactics that can be used to protect those areas. The subarea contingency plans provide for coordinated and integrated response by departments and agencies of the federal and state governments to protect human health and the environment and to minimize adverse effects due to oil and hazardous substance discharges (MMS 2008).

Responsibility for developing the regional contingency plan rests with the Regional Response Team (RRT) for that area. The Alaska RRT (ARRT) is composed of representatives from USCG and EPA as co-chairs of the RRT, and the following federal departments: Agriculture, Commerce, Defense, Energy, Health and Human Services, Homeland Security, Interior, Justice, Labor, and State. The State of Alaska also participates on the ARRT. The ARRT provides the appropriate regional mechanism for planning and preparedness activities before a response action is taken and for coordination and advice during an event (MMS 2008).

Under the NCP a federal On-Scene Coordinator (FOSC) is pre-designated by the EPA or the USCG to direct and coordinate the response to incidents under the authority of federal laws and regulations. For spill events occurring on the OCS, the USCG will act as the FOSC. The FOSC maintains a responsibility to ensure that the proper initiation of containment countermeasures, cleanup, and disposal actions take place. The State of Alaska also pre-designates a State On-Scene Coordinator (SOSC) to direct and coordinate the response to incidents under the authority of state laws and regulations. A Local On-Scene Coordinator (LOSC) representing the NSB also ensures that local concerns are addressed during a spill response. The FOSC, SOSC, and LOSC join the Responsible Party On-Scene Coordinator, representing the operator, and form a Unified Command (UC), which will direct the spill response. The LOSC is part of the Unified Command as long as there is an immediate threat to public safety, or as pre-identified in the applicable Subarea Contingency Plan. The UC jointly establishes goals and objectives, ensures that agency priorities are addressed, and produces a single-incident-action plan to respond to the spill. In the event the FOSC determines that spill-response efforts by the responsible party are inadequate to properly respond to the spill, the FOSC has the authority to "federalize" the response and use federal assets to continue cleanup activities. The responsible party is financially liable for the costs incurred from a federal response (MMS 2008).

2.3.4 Local Community Interaction

Over the years, through the federal processes the oil and gas industry has engaged in with BOEM and NMFS to obtain the permits and authorizations needed to conduct their activities, several processes and programs have evolved to facilitate interaction between the industry and the local communities to ensure that the Arctic subsistence culture can continue in conjunction with oil and gas development.

Industry interacts with local communities through a local hire program and through community-wide meetings. Local residents are typically trained and hired through several programs to assist with exploration activities, including the Protected Species Observer (PSO) program (formerly referred to as the Marine Mammal Observer program), Subsistence Advisor (SA) program, Communication and Call Centers (Com Centers) program, and Oil Spill Response. The PSO program would employ, among others, local Iñupiat residents to monitor and document protected species in the EIS project area. The PSOs are trained to identify marine mammals and other protected species, document interactions using computers, and comply with health and safety regulations. The SA program recruits local residents to communicate local concerns and subsistence issues to the oil and gas operators. The SA coordinates with other village members and documents subsistence information, which may then be used to develop appropriate mitigation measures, address concerns related to subsistence activities, and to avoid potential conflicts. The Com Center program involves hiring local residents to monitor and relay radio transmissions between subsistence vessels and industry vessels. This sharing of information is intended to reduce or eliminate the potential for conflict between subsistence users and industry vessels. Providing these employment opportunities to local residents creates the potential for positive economic benefits to local communities and provides a vector for communication between industry and local residents.

The three mechanisms that have been or that are currently used for communication, cooperation, and conflict avoidance between industry and local communities include: the Open Water Season Conflict Avoidance Agreement (CAA); Com Centers; and Plans of Cooperation (POC).

The Open Water Season CAA is a private agreement between members of industry and the Alaska Eskimo Whaling Commission (AEWC). In order to ensure that potential adverse impacts to the bowhead whale subsistence hunt are mitigated, the AEWC requests that any operator intending to conduct activities related to offshore oil and gas exploration, development, or production during the open-water season and prior to or during the fall bowhead whale subsistence hunts in the Beaufort and Chukchi seas enter into the CAA. While the CAA is not required by the MMPA, mitigating potential adverse impacts to the availability of marine mammals for subsistence uses is a requirement of the MMPA. CAAs typically include measures and procedures regarding the timing and areas of the operator's planned activities necessary to mitigate potential adverse impacts of the planned oil and gas operations on fall bowhead whale subsistence hunting (i.e. times and places where effects of seismic and/or drilling operations will be monitored and prospectively mitigated to avoid potential conflicts with active subsistence whaling). In addition to temporal and spatial measures, CAAs typically provide for, among other mitigation measures, a communications system between operators' vessels and whaling and hunting crews (i.e. the communications center will be located in strategic areas); provisions for marine mammal observers/Iñupiat communicators aboard all project vessels (i.e. PSOs); conflict resolution procedures; and provisions for rendering emergency assistance to subsistence hunting crews. The mitigation measures contained within CAAs have been developed by particular offshore operators and bowhead whale subsistence hunters through an annual negotiation process (the CAA process), which dates to 1985. Neither NMFS nor BOEM can require agreements between third parties. Neither NMFS nor BOEM is able to enforce the provisions of such agreements because the federal government is not a party to the agreements. While federal statute or regulations do not require a CAA, NMFS' regulations at 50 CFR 216.104(a)(12) require that operators submit a POC containing mitigation measures to minimize adverse effects on the availability of marine mammals for subsistence uses. NMFS has used measures specific to protecting marine mammals or the availability of marine mammals for subsistence uses developed during the CAA process in previous ITAs.

To minimize potential interference with marine mammal hunts on a real-time basis, to the AEWC has requested companies to participate in the establishment of and interaction with Com Centers in affected subsistence communities. The Com Centers are established prior to exploration activities, including ancillary activities, in the vicinity of a potentially affected community and are operated on a 24-hour basis during the subsistence hunts. Companies may contribute to the establishment of Com Centers whether or not they sign a CAA.

A POC requires consultation and community meetings with potentially affected communities. It must also describe the measures the applicant has taken and/or will take to ensure that the proposed activities will not interfere with subsistence whaling or sealing. These mitigation measures should be agreed to by both the operators and the subsistence users. In the case of the bowhead whale subsistence hunt and the communities represented by the AEWC, a CAA can help support the POC process.

The previous paragraphs describe these programs and processes as they currently exist. Chapter 5 contains an evaluation of these programs and processes, as well as potential modifications to these programs or the addition of new programs to accomplish some of the same goals.

2.3.5 Alternative Technologies for Hydrocarbon Exploration

The impulsive airgun has been under scrutiny as a sound source for seismic exploration due to concerns that the propagated sound waves may harm marine life during operations (Weilgart 2010). Alternative acoustic source technologies generally put the same level of useable energy into the water as airguns, but over a longer period of time with a resulting reduced acoustic footprint. One potential alternative, the low frequency passive seismic method, relies on naturally produced sounds and does not introduce any sound into the environment. Table 2.3 summarizes some of the alternative technologies in consideration by the oil and gas industry. However, these alternative acoustic sources are in various stages of development, and none of the systems with the potential to augment or replace airguns as a seismic source for subsurface data collection are currently commercially available. It is uncertain at this time exactly when these technologies could become available for commercial use; however, it is possible that some of them could be used during the timeframe of this EIS. Therefore, they are analyzed in this EIS based on the limited data currently available. BOEM hosted a workshop in February 2013 titled “Quieting Technologies for Reducing Noise during Seismic Surveying and Pile Driving.” The goal of the workshop was to provide information about emerging technologies with potential utility for seismic exploration.

Technologies supplemental to seismic operations such as gravity/gradiometry and controlled source electromagnetics are commercially available and discussed in Section 2.3.2.

Table 2.3 Alternative Technologies Summary

Technology	Potential Availability Date	Activity the Technology Could Potentially Replace or Mitigate
Marine Vibrators – Hydraulic	System has been built and tested but requires renovation prior to deployment. Estimated time is 3 months to 1 year.	This tool cannot replace all airgun surveys but has the potential to replace airguns for certain geologic prospects in certain environments.
Marine Vibrators – Electric	If funds were available, it would take 2 to 4 years to fully develop and test a system for commercial use.	This tool cannot replace all airgun surveys but has the potential to replace airguns for certain geologic prospects in certain environments.
Low-frequency Acoustic Combustion Source (patented) (LACS)	Two LACS systems are under development. However, the first is not fully proven, and the second has not been built. Additional tests of the LACS 4A system must be performed prior to deployment. The LACS 8A system currently does not exist, and the project is presently on hold. It would take at least 18 months to build and field test one of these systems.	The LACS 4A system has been reported to be currently suitable for shallow penetration towed-streamer seismic surveys or vertical seismic profiling in certain environments. Theoretically, the LACS 8A system has the potential to compete with a conventional deep penetration airgun seismic array. However, it is impossible to compare this system with an airgun array or project its capabilities until such a system has been built and tested.
Deep-Towed Acoustics/Geophysics System (DTAGS)	While there is one DTAGS currently in existence, it is not designed to conduct deep penetration oil and gas exploration. There is no projected timeframe to produce a low-frequency DTAGS.	It is impossible to compare this system with an airgun array or project its capabilities until such a system has been built and tested.
Low Frequency Passive Seismic Methods for Exploration	This is being offered commercially.	This technology is not yet proven in all environments. Passive acoustic data have the potential to enhance oil recovery at a better resolution than magnetic or gravimetric methods especially in areas that are environmentally sensitive (Bussat and Kugler 2009).

2.3.5.1 Marine Vibrators

Hydraulic

In 1983, Industrial Vehicle International, Inc. (IVI) began developing a new marine vibrator seismic source system with the goal of producing a marine source able to emit a broad band, high amplitude, modulating frequency output. In 1985, the first commercial system was offered (IVI 2003). The developed system consists of a marine vibrator, vibrator controller, and a power unit. The source is capable of generating modulated frequencies between 10 and 250 Hz and can be used in water depths as shallow as one meter.

The system has been tested in various environments from transition zones to deepwater. A comparison of marine vibrator, dynamite, and airgun sources in southern Louisiana concluded that the marine vibrator was a viable source for environmentally sensitive areas (Potter et al. 1997, Smith and Jenkerson 1998). The best performance is on a seafloor which distributes the vibrator's forces.

Initial deep water tests were conducted in the Gulf of Mexico using a vibrator with an energy output approximately equivalent to a 1,000 in^3 (16.4 liter) airgun. Despite limitations of low frequency energy, good definition of reflectors down to three seconds indicated that the system was viable (Haldorsen et al. 1985). In 1996, a comparison between the marine vibrator and the airgun data indicated that the marine vibrator data contained more frequency content above 30 Hz and less frequency content below 10 Hz than the airgun data, but overall the data were comparable. Marine vibrator production rates were slightly lower than those of the airgun, but by the end of the survey, the technical downtime of the marine vibrator was similar to the airgun (Johnson et al. 1997). However, this technology has not been tested in the Arctic environment.

IVI continued to further develop the system into the early 2000s, but they are no longer actively marketing the product because there is no client base for the system. The significant expense to retrofit the marine exploration companies' ships to support marine vibrators is not offset by reduced operation costs or better data quality. IVI presently has marine vibrator systems that could be used for seismic data collection, but they would require renovation prior to deployment, which could take three months to a year (Elmo Christensen, Vice President IVI personal communications with Jana Lage 11/09/10, 12/17/10). This tool cannot replace all airgun surveys but has the potential to replace airguns for certain geologic prospects in certain environments.

Electric

Petroleum Geo-Services (PGS) began developing an electro-mechanical marine vibrator in the late 1990s. The original system consists of two transducers: the lower frequency (6 to 20 Hz) "Subtone" source and the higher frequency (20 to 100 Hz) "Triton" source (Tenghamn 2005, 2006). Each vibrator is composed of a flextensional shell that surrounds an electrical coil, a magnetic circuit and a spring element. The sound in the water column is generated by a current in the coil, which causes the spring elements and shell to vibrate. Mechanical resonances from the shell and spring elements allow very efficient, high power generation (Spence et al. 2007; Tenghamn 2005, 2006). The source tow-depth, generally between 5 and 25 m (16 to 82 ft) below the sea surface, is selected depending on the frequency and enhancement from the surface reflection which, to a certain degree, directs the acoustic signal downwards.

The reduction of the overall sound level and specifically the frequencies above 100 Hz, which are beyond the useful seismic range, is a major advantage of the system. Another advantage is the reduction of acoustic power in comparison with conventional seismic sources, which occurs because the net source energy is spread over a long period of time (Tenghamn 2005, 2006).

During the early period of development, the system proved the concept that it worked as a source for seismic data. However, unreliability prevented it from becoming a commercial system. PGS spent 2006 and 2007 conducting a feasibility study to improve reliability and testing a newly developed prototype.

After that work, PGS developed three additional systems that are currently being tested. This tool cannot replace all airgun surveys but has the potential to replace airguns for certain geologic prospects in certain environments. PGS does not have a commercial system available for data collection at this time. They project that, if funds were available, it would take two to four years to fully develop and test a system for commercial use (Rune Tenghamn, VP Innovation and Business Development PGS, personal communication to Jana Lage 11/09/10).

2.3.5.2 Low-frequency Acoustic Source (patented)

Originally designed as a ship sound simulator for the Norwegian Navy, the low level acoustic combustion source (LACS) is being promoted as an alternative source for seismic acquisition (Weilgart 2010). The LACS system is a combustion engine with a cylinder, spark plug, two pistons, two lids, and a shock absorber. It creates an acoustic pulse when two pistons push lids vertically in opposite directions; one wave reflects from the sea surface and combines with the downward moving wave. There is no bubble noise from this system as all air is vented and released at the surface, not into the underwater environment. The absence of bubble noise allows the system to produce long sequences of acoustic pulses at a rate of 11 shots per second; this allows the signal energy to be built up in time with a lower amount of energy put into the water (Askeland et al. 2007, 2009).

There are two LACS systems advertised as under development. The first system is not fully proven, and the second has not been built. The LACS 4A has a diameter of 400 mm (16 in), a height of 600 mm (24 in), and a weight of approximately 100 kg (220 pounds) in air. Field test results of the LACS 4A system demonstrate that the system is capable of accurately imaging shallow sediments (~230 m [755 ft]) within a fjord environment (Askeland et al. 2008, 2009). It is reported that this system is suitable for shallow penetration towed-streamer seismic surveys or vertical seismic profiling (Askeland et al. 2008). Since there have been only a few tests conducted in a fjord environment, this system requires additional testing in various environments to determine if it is ready to replace currently used subbottom profiling systems.

The second system, the LACS 8A, theoretically has the potential to compete with a conventional deep penetration airgun seismic array. The weight is 400 kg (882 pounds), and the diameter is 800 mm (31.5 in). Several LACS units may be operated together to provide an increased pulse pressure (Bjørge Naxys AS 2010). This system currently does not exist, and the project is presently on hold. It would take at least 18 months to build and field test one of these systems if money became available to do so (Jens Abrahamsen, Managing Director Bjørge Naxys personal communication to Jana Lage 12/2/10). At this time, it is difficult to compare this system with an airgun array or project its capabilities since it has not been built and tested.

2.3.5.3 Deep-Towed Acoustics/Geophysics System

The U.S. Navy developed a deep-towed acoustics/geophysics system (DTAGS) to better characterize the geoacoustic properties of abyssal plain and other deep-water sediments. The system was tested and modified in the early 1990s and used in various locations around the world until it was lost at sea in 1997 (Gettrust et al. 1991, Wood et al. 2003).

The second generation DTAGS is based on the original design but with more modern electronics. The source is extremely flexible, allowing for changes in waveform and decrease in sound level to produce a source amplitude, waveform, and frequency to suit specific requirements (Wood et al. 2003, Wood 2010).

The DTAGS is towed behind a survey vessel usually at a level of 100 m above the seafloor and a vessel speed of two knots; it can operate at full ocean depths (6,000 m). A 450 meter, 48 channel streamer array is towed behind the source to record the reflected signals. DTAGS can also be configured with an aluminum landing plate, which transmits the acoustic energy directly into the seafloor. With this configuration, vertical bottom founded hydrophone arrays are used to receive reflections (Breland 2010).

Proximity of the acoustic source to the seafloor is an advantage of the DTAGS system. The system has a limit of 1 km penetration in most marine sediments (Wood et al. 2003). It has been used very successfully to map out gas hydrates in the Gulf of Mexico (Wood et al. 2008), Canadian Pacific (Wood et al. 2002, Wood and Gettrust 2000) and Blake Ridge (Wood and Gettrust 2000).

There is only one DTAGS in existence at this time. While it has imaged shallow sediments and gas hydrate environments extremely well, the current tool design could not replace a deep penetration airgun array for oil and gas exploration at this time - DTAGS was not designed for this purpose. There is no physical limitation to designing a resonant cavity source to simulate the frequency band of airguns. At this time, it is difficult to compare this system with an airgun array or project its capabilities since it has not been built and tested.

The strength of the high frequency system is the ability to tow the source near the seafloor. While it may be technically feasible to create a system with frequencies comparable to that of an airgun, they system is a cabled, deep-tow, which is not a realistic replacement for airguns. The deep tow configuration is not conducive to multi-streamer exploration seismic surveys.

2.3.5.4 Low Frequency Passive Seismic Methods for Exploration

Low frequency passive seismic methods utilize microseisms, which are faint Earth tremors caused by the natural sounds of the earth, to image the subsurface. A typical survey consists of highly sensitive receivers (usually broadband seismometers) placed in the area of interest to collect data over a period of time. Upon completion of the survey, the data are analyzed and filtered to remove all non-natural sounds, which is most efficiently completed using an automated process (Hanssen and Bussat 2008).

All of the current methods use one of following three sources of natural sounds: natural seismicity, ocean waves, or microseism surface waves.

Natural seismicity uses the Earth's own movements as a source of energy. Two techniques have been developed to utilize this energy source:

Daylight Imaging (DLI) uses the local seismicity of an area to produce reflection seismic profiles, similar to those recorded in active seismic surveys (Claerbout 1968). As in active reflection seismic operations, geophones are deployed; the target can be imaged using regularly-spaced 2D line geometry (Hohl and Mateeva 2006, Draganov et al. 2009).

Local Earthquake Tomography (LET) also uses local seismicity of a region to map on the reservoir scale (Kapotas et al. 2003). However, it is used to calculate the velocity structure of the subsurface in 3D by analyzing each earthquake on multiple receivers and generating ray paths instead of cross-correlating the recorded signals.

Ocean waves are used as a sound source for the Sea Floor Compliance technique. The method requires that Ocean Bottom Seismometer stations with highly-sensitive, broadband seismometers and differential or absolute pressure gauges be installed in water several hundred meters deep.

Ambient-Noise (Surface-Wave) Tomography [AN(SW)T] uses low frequency (between 0.1 and 1 Hz) ambient noise records to estimate shear wave velocities and structural information about the Earth. This technique requires the use of broadband seismometers to record the low frequency surface waves, which can penetrate to depths of several kilometers (Bensen et al. 2007, 2008). AN(SW)T can be used in areas where seismic data are difficult to collect or in environmentally sensitive areas. While this technology is new and still in need of further testing, the lateral resolution at several kilometer depths may reach a few hundred meters and the resolution may be better than gravimetric or magnetic data, which is promising for oil and gas exploration (Bussat and Kugler 2009).

Surface-wave amplitudes is a one-dimensional (1D) method that images the geological structure of the sub-surface by analyzing passive acoustic data that have not been geophysically processed. The transformation of incoming micro-seismic surface-waves, scattered at vertical discontinuities, into body waves may produce these data, but the process is not well understood (Gorbatikov et al. 2008).

Low-Frequency Spectroscopy (LFS) is also known as Low Frequency Passive Seismic (LFPS) or Hydrocarbon Microtremor Analysis (HyMAS) tests for an indication of subsurface hydrocarbon accumulation using spectral signatures gathered from the ambient seismic wave field recorded by broadband seismometers. However, this methodology is highly dependent on the ability to process out all anthropogenic noise and topography (Hanssen and Bussat 2008). This method is still in the early stage of development and has not been confirmed in the field during any studies (Ali et al. 2007, Al-Faraj 2007).

The most successful use of low frequency passive micro-seismic data has been on land where it is easier to isolate the extraneous noise from the natural signal. The technique is also promising in the marine environment. To ensure success of a marine survey: (1) it is imperative that the recording instruments are in proper contact with the substrate (the natural signal may not be accurately recorded in unconsolidated material) and (2) the increase in both anthropogenic and naturally produced noise in the marine environment is correctly filtered so that it does not mask the signal of interest.

Like the CSEM technique that is discussed in Section 2.3.2, passive seismic surveys cannot replace active seismic acquisition because the data do not match the quality of the data collected by more traditional methods. However, passive acoustic data have the potential to enhance oil recovery at a better resolution than magnetic or gravimetric methods (Bussat and Kugler 2009), especially in areas that are environmentally sensitive or where active seismic operations are difficult.

2.3.5.5 Quieting Mitigation Technologies in Development

Industry and the public sector have actively investigated the use of technology-based mitigation measures to reduce anthropogenic noise and thus potentially reduce the impacts of current methods of hydrocarbon data collection. Some of these technologies are not yet available and may not work in all circumstances.

Airgun Silencer

One such measure, an airgun silencer, which has acoustically absorptive foam rubber on metal plates mounted radially around the airgun, has demonstrated 0 to 6 dB reductions at frequencies above and 0 to 3 dB reductions at frequencies below 700 Hz. This system has been tested only on low pressure airguns and is not a viable mitigation tool because it needs to be replaced after 100 shots (Spence et al. 2007). Other tests are being conducted to attenuate unwanted high frequency energy without affecting the frequencies of interest.

Airgun Design

Another mitigation measure in development is optimizing the design of the airgun to reduce unwanted energy through array, source, and receiver design optimization in both the inline and horizontal plane of interest (Weilgart 2009). There are other tests to lower source levels through better pairing of source and receiver characteristics or better system gains.

Bubble Curtain

Bubble curtains generally consist of a rubber hose or metal pipe with holes to allow air passage and a connector hose attached to an air compressor. They have successfully been tested and used in conjunction with pile driving and at construction sites to frighten away fish and decrease the noise level emitted into the surrounding water (Würsig et al. 2000, Sexton 2007, Reyff 2009). They have also been used as standalone units or with light and sound to deflect fish away from dams or keep them out of specific areas (Weiser 2010, Pegg, M. 2005).

The use of bubbles as a mitigation for seismic noise has also been pursued. During an initial test of the concept, the sound source was flanked by two bubble screens; it demonstrated that bubble curtains were capable of attenuating seismic energy up to 28 dB at 80 Hz while stationary in a lake. This two-bubble curtain configuration was field tested from a moving vessel in Venezuela and Aruba where a 12 dB suppression of low frequency sound and a decrease in the sound level of laterally projecting sound was documented (Sixma 1996, Sixma and Stubbs 1998). A different study in the Gulf of Mexico tested an "acoustic blanket" of bubbles as a method to suppress multiple reflections in the seismic data. The results of the acoustic blanket study determined that suppression of multiples was not practical using the current technology. However, the acoustic blanket measurably suppressed tube waves in boreholes and has the capability of blocking out thruster noises from a laying vessel during an OBC survey, which would allow closer proximity of the shooting vessel and increase productivity (Ross et al. 2004, 2005).

A recent study "Methods to Reduce Lateral Noise Propagation from Seismic Exploration Vessels" was conducted by Stress Engineering Services Inc. under the BSEE Technology Assessment & Research Program. The first phase of the project was spent researching, developing concepts for noise reduction, and evaluating the following three concepts: (1) an air bubble curtain; (2) focusing arrays to create a narrower footprint; and (3) decreasing noise by redesigning airguns. The air bubble curtain was selected as the most promising alternative, which led to more refined studies the second year (Ayers et al. 2009). A rigorous 3D acoustic analysis of the preferred bubble curtain design, including shallow-water seafloor effects and sound attenuation within the bubble curtain, was conducted during the second phase of the study. Results of the model indicated that the bubble curtains performed poorly at reducing sound levels and are not viable for mitigation of lateral noise propagation during seismic operations from a moving vessel (Ayers et al. 2010).

2.3.5.6 Fiber Optic Receivers

Fiber optic receivers incorporate optical fibers to transmit the received acoustic signal as light. They are most frequently used in the petroleum industry for seismic Permanent Reservoir Monitoring, a four-dimensional (4D) reservoir evaluation application. The optical receivers are permanently placed on the seafloor, ensuring consistency and repeatability of the 4D surveys, better signal to noise ratios, and quality of subsequently collected data. Fiber optic systems are not new and have proven to be highly reliable.

Fiber optic receivers are more sensitive than standard receivers, which allows for smaller airgun arrays to be used. While these receivers offer a benefit to the environment through a decrease in airgun noise, this technology is not presently available for towed-streamer surveys.

Fiber optic receivers have not been used in the Alaska OCS due to the lack of large scale offshore production requiring 4D monitoring. This technology is associated with production and therefore is not analyzed further in this document.

2.4 Alternatives Considered in the EIS

The federal actions considered in this EIS are the issuance of G&G permits and ancillary activity notice approvals by BOEM for the Beaufort and Chukchi seas and the issuance of ITAs under the MMPA for G&G surveys, ancillary activities, and exploratory drilling activities in the Beaufort and Chukchi seas by NMFS. ITAs could be issued for these activities in either federal or State of Alaska waters. Given the widespread presence of several species of marine mammals in the Beaufort and Chukchi seas and the nature of oil and gas exploration activities, it is likely that some amount of seismic and exploratory drilling activities may result in the disturbance of marine mammals through sound, discharge of pollutants, and/or the physical presence of vessels. Because of the potential for these activities to "take" marine mammals, oil and gas operators may choose to apply for an ITA.

Sections 101(a)(5)(A) and (D) of the MMPA direct NMFS to allow, upon request, the incidental, but not intentional, taking of small numbers of marine mammals of a species or population stock by U.S. citizens who engage in a specified activity (other than commercial fishing) within a specified geographical region if certain findings are made and either regulations are issued or, if the taking is limited to harassment, a notice of proposed authorization is provided to the public for review. Authorization for incidental taking shall be granted if NMFS finds that the taking will have a negligible impact on the affected species or stock(s) and will not have an unmitigable adverse impact on the availability of the species or stock(s) for taking for subsistence uses. NMFS must also prescribe: the permissible methods of taking pursuant to the activity; other means of effecting the "least practicable adverse impact" on the affected species or stock and its habitat and on the availability of such species or stock for subsistence uses; and requirements pertaining to the monitoring and reporting of such taking.

The approach taken in identifying alternatives considered by NMFS and BOEM in this EIS involved four major components:

1) Evaluating alternative concepts suggested during the scoping period (such as using alternative technologies to airguns for seismic surveys);
2) Reviewing potential alternatives in the context of NMFS and BOEM's regulatory requirements;
3) Assessing potential levels of seismic exploration and exploratory drilling activities, and a suite of Standard Mitigation Measures; and
4) Identifying a range of potential Additional Mitigation Measures that need further analysis and may be applied to alternatives pursuant to the MMPA ITA process and the BOEM OCS Lands Act permitting processes.

2.4.1 Review of Multiple Exploration Activities

Past ITAs have been issued for individual G&G surveys, ancillary activities, and exploratory drilling projects in the Arctic Seas. These authorizations have been in the form of Incidental Harassment Authorizations (IHA) issued for periods of no more than one year at a time. One purpose of this EIS is to analyze effects from multiple oil and gas industry exploration activities with regard to marine mammals and subsistence hunting, assess the potential effects of authorizing takes from concurrent activities, and analyze whether the standard mitigation and monitoring measures stipulated in the past are appropriate for current and reasonably foreseeable oil and gas activities. Additional mitigation measures to address potential marine mammal or subsistence impacts from the activities have been suggested by the public or other agencies and the potential effectiveness of these measures will also be analyzed.

For planning purposes, NMFS and BOEM can project a reasonable level of exploration activities in the near term based upon current leases, upcoming lease sales, and industry's stated needs for exploring those leases. Although the levels of activities can be estimated, the particular strategy used by a company regarding where and when to explore for resources may change depending on what a company found during previous exploration activities, as well as changes in technology. Furthermore, outside forces (i.e. the price of oil) and politics may affect the oil and gas market and play a role in how much effort is applied to exploration in the Arctic. Therefore, predicting and planning for levels of activity over a longer period of time (i.e. three or more years in the future) can be difficult. In order to help predict the level of exploration activities for a given year, communications for upcoming G&G and exploratory drilling activities are ongoing between NMFS, BOEM, and industry throughout the year; but NMFS and BOEM are officially notified of the specific planned activities upon receipt of an application for an ITA, G&G permit, or ancillary notice, which may be submitted just several months prior to the activity taking place. Therefore, while NMFS and BOEM can estimate the level of proposed activity on an annual basis, there is some uncertainty.

2.4.2 Review of Mitigation Measures

The evaluation of measures intended to reduce adverse impacts to marine mammals and other protected resources and to ensure that there will be no unmitigable adverse impact on the availability of marine mammals for subsistence uses are the main foci of this document and are key components of the development of alternatives. Mitigation measures directed at protecting subsistence uses include measures incorporated into previous ITAs, many of which were developed over a number of years through the annual negotiation of a CAA between offshore oil and gas operators and the AEWC. Mitigation measures are currently categorized in the action alternatives in three different ways:

1) **Required Standard Mitigation Measures** – These measures, which are required in all five of the action alternatives, are those that NMFS deemed appropriate to *require* in MMPA authorizations. These measures (e.g. shutdown zones, certain time/area closures to protect known subsistence uses) have been used consistently in past permits and authorizations.

2) **Additional Mitigation Measures** – These measures, which are evaluated *but not required* in all five action alternatives, may or may not be required for future activities depending on the outcome of the MMPA authorization processes (or other environmental compliance processes). These measures are intended to include other reasonable potential mitigation measures, such as those that have been required or considered in the past or recommended by the public, which may or may not have been required or considered in the past.

3) **Alternatives 5 and 6** – These two alternatives are characterized by additional specific mitigation measures associated with time/area closures or alternative technologies that are intended to minimize impacts to marine mammals and subsistence uses.

In Chapter 4, all of the mitigation measures currently categorized as described above are comprehensively evaluated in the context of the manner and degree in which the measure is likely to reduce adverse impacts to marine mammals, likely effectiveness, and practicability of implementation of the measures. This analysis, which also includes consideration of public comments received on previous proposed ITAs, the scoping period of this EIS, and on the 2011 Draft EIS, is needed in order to better assess the programmatic appropriateness of each measure (i.e., based on the generalized expectations for a given year of projected activities) and to inform decisions of whether the measure should:

a) Be considered a Standard Mitigation Measure (i.e., required in every ITA for a given activity type);

b) Never be required; or

c) Be included in the Additional Mitigation Measure category, which means that the measure will be considered for inclusion as a requirement through future regulatory or authorization processes during which more specific information is known.

All Additional Mitigation Measures ultimately identified in the Final EIS for a particular activity type will be further evaluated for potential required inclusion for any specific proposed activity through the MMPA process (and potentially other environmental compliance processes) using the additional detail that will be available once applicants have determined the specific activities that they propose to conduct in a given year and submitted their applications. These measures will be further evaluated using this more specific information to determine the degree to which the measure is likely to reduce impacts to marine mammals or subsistence uses based on the proposed specified activity, the likely effectiveness of the measure, and the practicability of the measure. Some of the types of more specific information that will be used to make the decision of whether to require a given measure include:

- The timeframe, duration, and location of the proposed activity and the spatiotemporal overlap with marine mammal distribution and subsistence hunts of marine mammals;
- The specific characteristics of the sound sources used in the proposed activity;

- The availability and cost of the resources needed to carry out the measure;
- The timeframe, duration, and locations of other activities expected in the same season; and
- New information related to the likely success of the measure (from reports from previous years).

In this EIS, NMFS and BOEM present and assess a reasonable range of G&G, ancillary, and exploratory drilling activities expected to occur, as well as a reasonable range of measures intended to reduce adverse impacts on the human environment, in order to accurately assess the potential consequences of issuing ITAs under the MMPA and permits under the OCS Lands Act. Based upon past lease sales, the timing of the future scheduled lease sales in the 2012-2017 Five Year Program for the Arctic OCS, G&G permits, ancillary activity notices, exploration drilling activities, and requests for ITAs, NMFS and BOEM have determined a reasonable range and level of activities for which permits and authorizations may be requested in the foreseeable future. While the level of activity proposed may vary from one year to the next, the structure of the action alternatives represents a reasonable range of exploration activities for which permits and authorizations may be requested.

2.4.3 Activity Definitions

The following discussion and table provide explanation and definitions for what is meant by the different types of activities considered in each of the action alternatives in this EIS. In determining the potential level of activity in each alternative, NMFS and BOEM reviewed the following information: results of recent federal and state lease sales; the timing of the future scheduled lease sales in the 2012-2017 Five Year Program for the Arctic OCS; and recent industry plans for both seismic surveys and exploratory drilling programs in the Beaufort and Chukchi seas. Additionally, NMFS and BOEM considered the logistical and technological limitations of conducting different levels of exploration activities when developing the potential activity levels for each alternative.

Table 2.4 outlines what each type of survey or drilling program entails. The definitions for the various programs include number of source and support vessels, types of sound sources used, time periods when the activity could occur (i.e. open-water season only, ice-covered season only, etc.), number of days of active operations, and size of the program activity area. Surveys or drilling programs could be conducted by a single company or companies working together using the same vessels and equipment. These definitions provide an overview of the components of each type of activity, and there may be slight variations in how a particular activity is conducted from what is outlined in Table 2.4.

For analysis in this EIS, one "program" entails however many surveys or exploration wells a particular company is planning for that season under a given EP. Each "program" would use only one source vessel (or two source vessels working in tandem, e.g. OBC surveys) or drilling unit (i.e. drillship, jackup rig, SDC, etc.) to conduct the program and would not survey multiple sites or drill multiple wells concurrently. Survey vessels and drilling units are generally self-contained, with the crew living aboard the vessel. For surveys in the Beaufort Sea, support operations would likely occur out of West Dock or Oliktok Dock near Prudhoe Bay. Chukchi Sea surveys could be supported either from Wainwright or Nome. Helicopters stationed at either Barrow (for operations in either the Beaufort Sea or Chukchi Sea) or Deadhorse (for operations in the Beaufort Sea) would provide emergency or search-and-rescue support, as needed.

Site clearance and shallow hazards survey programs are contemplated in each action alternative and may also include ice gouge and strudel scour surveys and are often referred to as marine survey programs by oil and gas industry operators. The ice gouge and strudel scour surveys often span several seasons of data collection separate from the typical site clearance survey and do not involve the use of airguns but do involve the use of smaller, higher-frequency sound sources, such as multibeam echosounders and sub-bottom profilers. The area of a site clearance and shallow hazards survey, which is tied to a lease plan, is typically determined by the number of potential, future drill sites in the area. Table 2.4 outlines the typical types of sound sources used in these programs.

Table 2.4 Activity Definitions

Activity/Program	# of source vessels	# of support vessels	Type of Energy/Sound Sources Used	# of Days Activities Could Occur in a Season	Months During Which the Activity Could Occur	Extent of the Activity Area and/or # of Wells to be Drilled
2D/3D Open Water Towed Streamer Seismic Survey	1 Source/ Receiver Vessel	• 1 support vessel • 1 vessel for monitoring	• Source array typically consists of one or more sub-arrays of 6-8 airgun sources each • Individual airgun size: 5-1,500 in^3 (0.081-24.58 liter) • Airgun array range from 1,800-5,000 in^3 (29.50-81.94 liter)	30-90	July – November	85-110 line miles per day
Ocean-bottom cable or node survey (Beaufort Sea only)	2 (working in tandem)	• 2 vessels for layout/pickup • 1 recording vessel • 2 small support vessels	• Source array on each vessel typically consists of two sub-arrays of 4 airgun sources each • Individual airgun size: 70-150 in^3 • Airgun array range from 440-880 in^3	30-90	July – October	10 by 20 mile area
In-ice seismic survey	1 Source/ Receiver vessel	• 1 icebreaker • 1 support vessel (possibly)	Same as 2D/3D seismic survey	60-90	Late September – December	Approximately 75 line miles (120 km) per day
CSEM Survey	1	• 1 source and layout vessel	0.5-10 Hertz electromagnetic signal	60	July – November	unknown
Site Clearance and High-Resolution Shallow Hazard Surveys	1 Source/ Receiver vessel	• 1 vessel for monitoring, as needed	• Four, 10 in^3 (0.16 liter) airguns • Multi-beam echosounders • Sub-bottom profilers • Side-scan sonars	45-90 days	July – November	46 line miles per day
On-ice Vibroseis Seismic Survey (Beaufort Sea only)	4 wheeled vibrators	• 2 marking vehicles • Bulldozer	Continuously driven piston (wheeled vibrators)	30-90 days	January – May	15-40 linear miles per day

Activity/Program	# of source vessels	# of support vessels	Type of Energy/Sound Sources Used	# of Days Activities Could Occur in a Season	Months During Which the Activity Could Occur	Extent of the Activity Area and/or # of Wells to be Drilled
Exploratory Drilling Program (from a drillship)	1 drillship	• 2 icebreakers • 1 anchor handler • 1 oil spill response barge • 1 oil spill response tug • 1 tank vessel for spill storage • 3 support vessels • Aircraft for crew changes	Drill	40 days per well (dependent on well depth)	July – October	25 mile (40 km) radius around the well; 2-4 wells per season
Exploratory Drilling Program (from a jackup rig)	1 jackup rig	• 2 icebreakers • 2 oil spill response vessels (each with two workboats) • 1 oil spill response tug • 1 tank vessel for spill storage • 3 support vessels • Aircraft for crew changes	Drill	40 days per well (dependent on well depth)	July – October	25 mile (40 km) radius around the well 2-4 wells per season

The following alternatives are summarized in Table 2.5.

2.4.4 Alternative 1 – No Action

NEPA's implementing regulations require that the No Action Alternative be evaluated. Under the No Action Alternative, NMFS would not issue any ITAs under the MMPA for seismic surveys or exploratory drilling in the Beaufort and Chukchi seas, and BOEM would not issue G&G permits or authorize ancillary activities in the Beaufort and Chukchi seas. If companies proceeded to operate in this area without MMPA authorizations, any takes of marine mammals would occur in violation of the MMPA.

2.4.5 Alternative 2 – Authorization for Level 1 Exploration Activity

Alternative 2 is defined for analytical purposes as the following:

2.4.5.1 Level of Activity

- Up to **four** 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to **three** 2D/3D seismic or CSEM surveys in the Chukchi Sea per year, with up to **one** of that total number of surveys in each sea done in-ice with ice breaking if necessary.
- Up to **three** site clearance and high resolution shallow hazards survey programs in the Beaufort Sea and up to **three** site clearance and high resolution shallow hazards survey programs in the Chukchi Sea per year.
- **One** on-ice seismic survey in the Beaufort Sea per year.
- **One** exploratory drilling program in the Beaufort Sea and **one** exploratory drilling program in the Chukchi Sea per year. In the Beaufort Sea, the exploratory drilling program could occur in either federal or State waters[2].

2.4.5.2 Mitigation

- Including *required* Standard Mitigation Measures (described in Section 2.4.10) that are part of every action alternative.
- Including a full analysis of a wide range of Additional Mitigation Measures (described in Section 2.4.11) that *could potentially* be required through the MMPA process and could vary by alternative (i.e. some might be different based on level and/or type of activity in a given year)

2.4.5.3 Assumptions

Seismic work in the Arctic has traditionally been conducted in open water (ice-free) months (July through November), although this analysis addresses the possibility of one survey utilizing an icebreaker and potentially continuing through mid-December. Seismic surveys are also conducted on-ice in areas where there is bottom fast ice in the winter. These surveys generally occur from January through May. Each survey takes between 30 and 90 days, depending on ice conditions, weather, equipment operations, size of area to be surveyed, timing of subsistence hunts, etc. Because of the limited time period of open water, it is likely that concurrent surveys would be conducted in the same general time frame and may overlap in time, but will not overlap in space (i.e. within a minimum of approximately 24 km [15 mi] of each independent survey operation) for reasons regarding data integrity. It is assumed for analytical purposes

---

[2] There are currently no State of Alaska leases in the Chukchi Sea. Therefore, exploratory drilling programs (in addition to seismic surveys) are not contemplated in State of Alaska waters in the Chukchi Sea in this EIS.

that at least one of the authorized 2D/3D seismic surveys in the Beaufort Sea and one in the Chukchi Sea would utilize an ice breaker.

Exploratory activities (including deep penetration seismic, site clearance and high resolution shallow hazards, and exploratory drilling) in the next three years are expected to be concentrated in areas of purchased leases. Exploratory activities in other areas of the U.S. Arctic Ocean may also occur, especially related to any sales in the Arctic OCS scheduled in BOEM's next Five-Year OCS Leasing Plan. In the U.S. Beaufort Sea, the two primary areas of interest for exploration are nearshore in Camden Bay and Harrison Bay. In the U.S. Chukchi Sea, the areas of interest are all well offshore in the lease areas, particularly around drill sites from the late 1980s, including Shell's Burger, Crackerjack, and Shoebill prospects; ConocoPhillips' Klondike prospect; and Statoil's leases in the northeast part of the Lease Sale 193 area (see Figure 1.3).

2.4.6 Alternative 3 – Authorization for Level 2 Exploration Activity

Alternative 3 is defined for analytical purposes as the following:

2.4.6.1 Level of Activity

- Up to **six** 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to **five** 2D/3D seismic or CSEM surveys in the Chukchi Sea per year, with up to **one** of that total number of surveys in each sea done in-ice with ice breaking if necessary.
- Up to **five** site clearance and high resolution shallow hazards survey programs in the Beaufort Sea and up to **five** site clearance and high resolution shallow hazards survey programs in the Chukchi Sea per year.
- **One** on-ice seismic survey in the Beaufort Sea per year.
- Up to **two** exploratory drilling programs in the Beaufort Sea and up to **two** exploratory drilling programs in the Chukchi Sea per year. In the Beaufort Sea, exploratory drilling programs could occur in either federal or State waters.

2.4.6.2 Mitigation

- Including *required* Standard Mitigation Measures (described in Section 2.4.10) that are part of every action alternative.
- Including a full analysis of a wide range of Additional Mitigation Measures (described in Section 2.4.11) that *could potentially* be required through the MMPA process and could vary by alternative (i.e. some might be different based on level and/or type of activity in a given year).

Assumptions for the analysis of Alternative 3 would be the same as those listed for Alternative 2.

2.4.7 Alternative 4 – Authorization for Level 3 Exploration Activity[3]

Alternative 4 is defined for analytical purposes as the following:

2.4.7.1 Level of Activity

- Up to **six** 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to **five** 2D/3D seismic or CSEM surveys in the Chukchi Sea per year, with up to **one** of that total number of surveys in each sea done in-ice with ice breaking if necessary.

[3] This alternative is new and was not included in the 2011 Draft EIS.

- Up to **five** site clearance and high resolution shallow hazards survey programs in the Beaufort Sea and up to **five** site clearance and high resolution shallow hazards survey programs in the Chukchi Sea per year.
- **One** on-ice seismic survey in the Beaufort Sea per year.
- Up to **four** exploratory drilling programs in the Beaufort Sea and up to **four** exploratory drilling programs in the Chukchi Sea per year. In the Beaufort Sea, exploratory drilling programs could occur in either federal or State waters.

2.4.7.2 Mitigation

- Including *required* Standard Mitigation Measures (described in Section 2.4.10) that are part of every action alternative.
- Including a full analysis of a wide range of Additional Mitigation Measures (described in Section 2.4.11) that *could potentially* be required through the MMPA process and could vary by alternative (i.e. some might be different based on level and/or type of activity in a given year).

Assumptions for the analysis of Alternative 4 would be the same as those listed for Alternative 2.

2.4.8 Alternative 5[4] – Authorization for Level 3 Exploration Activity With Additional Required Time/Area Closures

Alternative 5 is defined for analytical purposes as the following:

2.4.8.1 Level of Activity

- Up to **six** 2D/3D seismic or CSEM surveys in the Beaufort Sea and up to **five** 2D/3D seismic or CSEM surveys in the Chukchi Sea per year, with up to **one** of that total number of surveys in each sea done in-ice with ice breaking if necessary.
- Up to **five** site clearance and high resolution shallow hazards survey programs in the Beaufort Sea and up to **five** site clearance and high resolution shallow hazards survey programs in the Chukchi Sea per year.
- **One** on-ice seismic survey in the Beaufort Sea per year.
- Up to **four** exploratory drilling programs in the Beaufort Sea and up to **four** exploratory drilling programs in the Chukchi Sea per year. In the Beaufort Sea, exploratory drilling programs could occur in either federal or State waters.

2.4.8.2 Mitigation

- Including *required* Standard Mitigation Measures (described in Section 2.4.10) that are part of every action alternative.
- Including *required* time/area closures for specific areas important to biological productivity, life history functions for specific species of concern, and subsistence activities. Activities would not be permitted to occur in any of the areas listed here during the specific time/area closure periods identified. Additionally, buffer zones around these time/area closures could potentially be included. Buffer zones would require that activities emitting pulsed sounds would need to

[4] This alternative was previously identified as Alternative 4 in the 2011 Draft EIS. Some modifications to the required time/area closures have been made to this alternative since publication of the 2011 Draft EIS, as noted below.

operate far enough away from these closure areas so that sounds at 160 dB re 1 µPa rms do not propagate into the area or that activities emitting continuous sounds would need to operate far enough away from these closure areas so that sounds at 120 dB re 1 µPa rms do not propagate into the area. These areas are shown on Figures 3.2-25 and 3.2-26, and are described in detail in Chapter 3, Sections 3.2.3 and 3.2.4, and under additional mitigation measures described in Appendix A[5]:

- Kaktovik and Cross Island[6] – An area of importance for fall subsistence bowhead whale hunting
    - Bowhead whale subsistence hunting: late August – mid-September
    - Except for emergencies or human/navigation safety, oil and gas exploration operations shall not occur off Kaktovik or Cross Island or the designated buffer zones from August 25 to the close of the fall bowhead whale hunt in Kaktovik and on Cross Island.
- Barrow Canyon, the Western Beaufort Sea, and the Shelf Break of the Beaufort Sea – An area of high biological productivity; a feeding area for bowhead and beluga whales; fall subsistence bowhead whale hunting area.
    - Bowhead whales: September – October
    - Beluga whales: mid-July – late September
    - Except for emergencies or human/navigation safety, oil and gas exploration operations shall not occur within the Barrow Canyon area or the designated buffer zones from August 25 to the close of the fall bowhead whale hunt in Barrow.
- Hanna Shoal[7] – An area of high biological productivity (benthic organisms); a feeding area for various marine mammals (walrus and bearded seals).
    - Walrus: July – August (USGS 2011)
    - Bearded Seals: September – October (Clarke et al. 2011a)

---

[5] In the 2011 Draft EIS, Camden Bay was included as one of the potential time/area closure locations that would be required under this alternative because of its importance as a feeding area for bowhead whales and important location for subsistence hunters to actively hunt the species. After further review of the most recent data and literature, other areas of the Beaufort Sea, such as the Barrow Canyon and Western Beaufort Sea area (from Pt. Barrow to Smith Bay) appear to be more important feeding areas for bowhead whales than does the Camden Bay area (Clarke et al. 2011b, c, d). Additionally, hunters from Kaktovik do not venture into Camden Bay to hunt whales but rather stay in close proximity to the community. For these reasons, Camden Bay is no longer considered as a time/area location in this EIS. Additional information on the importance of the various locations for certain biological and life history functions and for subsistence hunts is contained in Chapter 3.

[6] This time/area closure has been added since publication of the 2011 Draft EIS. The area just east of Kaktovik has been identified as a feeding area for bowhead whales in the fall. Additionally, the waters just off Kaktovik and Cross Island are important fall bowhead whale subsistence hunting areas by the communities of Kaktovik and Nuiqsut.

[7] Gray whales have been removed as a reason for designating Hanna Shoal as a time/area closure location. While gray whales were consistently seen feeding in that area in September and October in the late 1980s and early 1990s (Clarke and Moore 2002), gray whale sightings in Hanna Shoal have been very infrequent since aerial surveys recommenced in 2008, and the area probably should not be considered a current gray whale feeding area (Clarke et al. in prep.).

    - Except for emergencies or human/navigation safety, oil and gas exploration operations shall not occur within the Hanna Shoal area or the designated buffer zones from July 1 – August 30.

  - Kasegaluk Lagoon – An important habitat for beluga whales (feeding, molting, calving) and spotted seals; subsistence beluga whale hunting area.
    - Beluga whales: June – mid-July
    - Subsistence (Kasegaluk Lagoon beluga whale hunting): mid-June – mid-July
    - Spotted seals: August – October
    - Except for emergencies or human/navigation safety, oil and gas exploration operations shall not occur within Kasegaluk Lagoon or the designated buffer zones from June 1 – July 15.

  - Ledyard Bay – An important habitat for spectacled eiders and the northern edge of important habitat for gray whales
    - Except for emergencies, human/navigation safety, or deployment of scientific devices, oil and gas exploration operations shall not occur within the Ledyard Bay Critical Habitat Unit or the designated buffer zones between July 1 and November 15.
    - To the maximum extent practicable, aircraft supporting seismic operations shall avoid operating below 1,500 ft (457 m) over the Unit between July 1 and November 15.

- Including a full analysis of a wide range of Additional Mitigation Measures (described in Section 2.4.11) that *could potentially* be required through the MMPA process and could vary by alternative (i.e. some might be different based on level and/or type of activity in a given year). The time/area closures that are described in this section that are optional for Alternatives 2, 3, 4, and 6 would not be optional but rather required under Alternative 5.

Assumptions for the analysis of Alternative 5 would be the same as those listed for Alternative 2.

2.4.9 Alternative 6[8] – Authorization for Level 3 Exploration Activity With Use of Alternative Technologies

Alternative 6 is defined for analytical purposes as the following:

2.4.9.1 Level of Activity

- Up to **six** surveys (utilizing either airguns or an alternative technology, as described below) in the Beaufort Sea and up to **five** surveys (utilizing either airguns or an alternative technology, as described below) in the Chukchi Sea per year, with up to **one** of that total number of surveys in each sea done in-ice with ice breaking if necessary.
- Up to **five** site clearance and high resolution shallow hazards survey programs in the Beaufort Sea and up to **five** site clearance and high resolution shallow hazards survey programs in the Chukchi Sea per year.
- **One** on-ice seismic survey in the Beaufort Sea per year.

[8] This alternative was previously identified as Alternative 5 in the 2011 Draft EIS.

- For exploratory drilling programs, any level up to the maximum contemplated in this EIS, as the technology only relates to seismic surveys. In the Beaufort Sea, exploratory drilling programs could occur in either federal or State waters.

2.4.9.2 Mitigation

- Including *required* Standard Mitigation Measures (described in Section 2.4.10) that are part of every action alternative.
- Including a full analysis of a wide range of Additional Mitigation Measures (described in Section 2.4.11) that *could potentially* be required through the MMPA process and could vary by alternative (i.e. some might be different based on level and/or type of activity in a given year), potentially including new mitigations developed to apply to new technologies.
- Including specific additional measures that focus on the use of alternative technologies that have the potential to augment or replace traditional airgun-based seismic exploration activities.

Assumptions for the analysis of Alternative 6 would be the same as those listed for Alternative 2.

2.4.10 Standard Mitigation Measures

The mitigation measures (and the identified mitigation monitoring needed to support them) listed below are planned for inclusion as a requirement under every ITA issued for the type of activity identified. Full descriptions of these measures are contained in Appendix A.

a) Detection-based measures intended to reduce near-source acoustic exposures and impacts on marine mammals within a given distance of the source

2D/3D Seismic Surveys, Including In-ice Seismic; Site Clearance and High Resolution Shallow Hazards Surveys

- Establishment and execution of 180 dB shutdown/power down radius for cetaceans and 190 dB shutdown/power down radius for ice seals, respectively.
- Specified ramp-up procedures for airgun arrays.
- Protected Species Observers (PSOs; formerly referred to as Marine Mammal Observers [MMOs]) required on all seismic source vessels and icebreakers, as well as on dedicated monitoring vessels.

On-ice Seismic Surveys

- All activities must be conducted at least 152 m (500 ft) from any observed ringed seal lair.
- No energy source may be placed over a ringed seal lair.

Exploratory Drilling Activities

- PSOs required on all drill ships and ice management vessels.

b) Non-detection-based measures intended to more broadly lessen the severity of acoustic impacts on marine mammals or reduce overall numbers taken by acoustic source

This measure would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- Specified flight altitudes for all support aircraft except for take-off, landing, and emergency situations.

c) Measures intended to reduce/lessen non-acoustic impacts on marine mammals

These measures would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice surveys, CSEM surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- Specified procedures for changing vessel speed and/or direction to avoid collisions with marine mammals.

d) Measures intended to ensure no unmitigable adverse impact to subsistence uses

These measures would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice surveys, CSEM surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- Shutdown of activities occurring in specific areas of the Beaufort Sea corresponding to the start and conclusion of the fall bowhead whale hunts in Nuiqsut (Cross Island) and Kaktovik beginning on August 25.
- Establishment and utilization of Communication Centers in subsistence communities when oil and gas exploration activities and marine mammal subsistence hunts will occur at the same time to address potential interference with marine mammal hunts on a real-time basis throughout the season.
- Required flight altitudes and paths for all support aircraft in areas where subsistence occurs, except during take-off, landing, and emergency situations.

2.4.11 Additional Mitigation Measures

The mitigation measures (and mitigation monitoring needed to support them) listed below will be evaluated in Chapter 4, which could lead to some of these measures becoming Standard Mitigation Measures in the Final EIS. In the future, these Additional Mitigation Measures will be evaluated in the context of each specifically described activity to determine whether they should be required by NMFS in a specific ITA or by BOEM in a specific G&G permit or ancillary activity notice approval to make the necessary findings under the MMPA or the OCS Lands Act. In short, these measures may, or may not, be incorporated in future permits and authorizations, depending on the specific activity and the analysis conducted pursuant to the MMPA and the OCS Lands Act. Full descriptions of these measures are contained in Appendix A.

a) Detection-based measures intended to reduce near-array acoustic exposures and impacts on marine mammals within a given distance of the source

2D/3D Seismic and In-ice Surveys; Site Clearance and High Resolution Shallow Hazards Surveys; Exploratory Drilling Activities

- Prior to conducting the authorized survey, the seismic array operator shall conduct sound source verification tests for their airgun array configurations in the area in which the survey is proposed to occur.
- All PSOs shall be provided with and use appropriate night-vision devices (e.g. Forward Looking Infrared [FLIR] imaging devices, 360° thermal imaging devices), Big Eyes, and reticulated and/or laser range finding binoculars in order to detect marine mammals within the exclusion zones.
- Operators shall limit seismic airgun operations in situations of low visibility when the entire safety radius cannot be observed (e.g., nighttime or bad weather).

- Seismic operators shall use passive (or active) acoustic monitoring systems, in addition to visual monitoring, to detect marine mammals approaching or within the exclusion zone and trigger the shutdown of airguns.
- Enhancement of monitoring protocols and mitigation shutdown zones to minimize impacts in specific biologic situations (e.g. expansion of shutdown zone to 120 dB or 160 dB when cow/calf groups and feeding or resting aggregations are detected, respectively).

b) Non-detection-based measures intended to more broadly lessen the severity of acoustic impacts on marine mammals or reduce overall numbers taken by acoustic source

These measures would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- Temporal/spatial limitations to minimize impacts in particular important habitats, including Kaktovik and Cross Island, Barrow Canyon/Western Beaufort Sea, Hanna Shoal, the shelf break of the Beaufort Sea, Kasegaluk Lagoon, and Ledyard Bay.
- Restriction of number of surveys (of same level of detail) that can be conducted in the same area in a given amount of time (i.e. to avoid needless collection of identical data).

2D/3D Seismic, including in-ice surveys ONLY

- Separate seismic surveys are prohibited from operating within 145 km (90 mi) of one another.

c) Measures intended to reduce/lessen non-acoustic impacts on marine mammals

These measures would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice seismic, CSEM surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- Vessel and aircraft avoidance of concentrations of groups of ice seals by 0.8 km (0.5 mi).
- Specified shipping or transit routes to avoid important habitat in areas where marine mammals may occur in high densities.

Exploratory Drilling Activities ONLY

- Requirements to ensure reduced, limited, or zero discharge of any or all of the specific discharge streams identified with potential impacts to marine mammals or marine mammal prey or habitat.
- Operators are required to recycle drilling muds.

On-ice Seismic Surveys

- Use trained seal-lair sniffing dogs for areas with water deeper than 3 m (9.8 ft) depth contour to locate seal structures under snow in the work area and camp site before initiation of activities.
- Use trained seal-lair sniffing dogs to survey the ice road and establish a route where no seal structures are present.

d) Measures intended to ensure no unmitigable adverse impact to subsistence uses

These measures would be required for all activities that occur during the open-water season and in-ice (i.e. 2D/3D seismic, including in-ice surveys, CSEM surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities).

- No transit of exploration vessels into the Chukchi Sea prior to July 15 or until the beluga hunt is completed at Point Lay.
- Vessels transiting east of Bullen Point to the Canadian border should remain at least 8 km (5 mi) offshore during transit along the coast, provided ice and sea conditions allow.
- Shutdown of exploration activities in the Beaufort Sea for the Nuiqsut (Cross Island) and Kaktovik bowhead whale hunts based on real-time reporting of whale presence and hunting activity rather than a fixed date.
- Shutdown of exploration activities in the Beaufort Sea for the Barrow bowhead whale hunts from Pitt Point on the east side of Smith Bay to a location about half way between Barrow and Peard Bay from September 15 to the close of the fall bowhead whale hunt in Barrow.
- Shutdown of exploration activities in the Chukchi Sea for the Barrow (the area circumscribed from the mouth of Tuapaktushak Creek due north to the coastal zone boundary, to Cape Halkett due east to the coastal zone boundary) and Wainwright (the area circumscribed from Point Franklin due south to the coastal zone boundary, to the Kuk River mouth due west to the coastal zone boundary) bowhead whale hunts based on real-time reporting of whale presence and hunting activity rather than a fixed date.
- Shutdown of exploration activities in the Chukchi Sea for the Point Hope and Point Lay bowhead whale hunts based on real-time reporting of whale presence and hunting activity rather than a fixed date.
- Transit restrictions into the Chukchi Sea modified to allow offshore travel under certain conditions (e.g. 32 km [20 mi] from the coast) if beluga whale, fall bowhead whale (Barrow and Wainwright), and other marine mammal hunts would not be affected.

Exploratory Drilling Activities ONLY

- For exploratory drilling operations in the Beaufort Sea west of Cross Island, no drilling equipment or related vessels used for at-sea oil and gas operations shall be moved onsite at any location outside the barrier islands west of Cross Island until the close of the bowhead whale hunt in Barrow.

2.4.12 Marine Mammal Monitoring Programs and Reporting Requirements

2.4.12.1 Monitoring Requirements

The MMPA and NMFS' implementing regulations require that an applicant conduct monitoring of marine mammals in the designated activity area. According to 50 CFR § 216.108(c), the monitoring program must, if appropriate, document the effects (including acoustic effects) on marine mammals and document or estimate the actual level of take as a result of the activity. Additionally, the program should increase the knowledge of the affected species and/or increase knowledge of the anticipated impacts on marine mammal populations.

Monitoring plans are submitted as part of the MMPA ITA application. NMFS reviews the monitoring plans prior to issuing ITAs to ensure they meet the goals stated above. If an activity may affect the availability of a marine mammal species or stock for taking for subsistence uses, the proposed monitoring plan must be independently peer-reviewed prior to issuance of the ITA (16 U.S.C. 1371(a)(5)(D) and 50 CFR § 216.108(d)).

There are two different types of monitoring that are most often included in monitoring plans submitted as part of MMPA ITA applications. The first type is what NMFS often refers to as mitigation monitoring. Mitigation monitoring is used to detect and localize marine mammals so that mitigation measures, which ensure that the activity is being conducted in a way to effect the least practicable adverse impact on marine mammals, their habitat, and on their availability for subsistence uses, may be implemented (e.g. monitoring the area immediately adjacent to an activity to ensure there are no marine mammals about to enter the 180- or 190-dB exclusion zones). The second type of monitoring relates to the applicant's specific statutory responsibility to monitor marine mammals in order to document the potential effects and level of take resulting from the applicant's action and to increase knowledge of the species (e.g. use of regional aerial surveys to assess changes in distribution).

Mitigation monitoring will be assessed along with the associated mitigation it accompanies, as described above and in Appendix A and analyzed in Chapter 4. The second type of monitoring described above will be further discussed in Chapter 5 through the following:

- A more detailed description of the goals of the required monitoring.
- A description/summary of the types of monitoring that have been required in the past and the nature of the data that has been collected.
- A discussion of the different methods/structure for peer-review used to date, including their comparative success, and discussion of any recommended means of improving the peer-review process.
- A discussion of different methods/frameworks that NMFS could potentially use for:
    - Identifying specific existing data gaps that can potentially be addressed through monitoring; and
    - Prioritizing monitoring needs in advance to inform would-be applicants and management decisions/recommendations.

2.4.12.2 Reporting Requirements

The following reports are planned to be included as requirements under every ITA; additional reporting requirements that may be considered and required are discussed in Chapter 5.

- 90-day Report: A draft report will be submitted to the Director, Office of Protected Resources, NMFS, within 90 days after the end of any activity authorized under an ITA in the Arctic Seas. Additional reporting measurements may be required through the MMPA or ESA processes and may be revised from year to year through the adaptive management process, however, at a minimum the report will describe in detail: (i) the operations that were conducted; (ii) the results of the acoustical measurements to verify the safety radii (if required); (iii) the methods, results, and interpretation pertaining to all monitoring tasks; (iv) the results of that year's shipboard marine mammal monitoring; (v) a summary of the dates and locations of operations, including summaries of mitigation measures that were implemented (e.g. power-downs, shutdowns, and ramp-up delays); (vi) marine mammal sightings (species, numbers, dates, times and locations; age/size/gender, environmental correlates, activities, associated seismic survey activities); (vii) estimates of the amount and nature of potential take (exposure) of marine mammals (by species) by harassment or in other ways to industry sounds; (viii) an analysis of the effects of operations (e.g. on sighting rates, sighting distances, behaviors, movement patterns of marine mammals); (ix) an analysis of factors influencing detectability of marine mammals; and (x) summaries of communications with hunters and potential effects on subsistence uses.
- The draft 90-day report will be subject to review and comment by NMFS. Any recommendations made by NMFS must be addressed in the final report prior to acceptance by NMFS. The draft report will be considered the final report for this activity under the Authorization if NMFS has not provided comments and recommendations within 90 days of receipt of the draft report.
- As described in Chapter 5, NMFS plans to engage industry applicants, scientists, and stakeholders in the development of a comprehensive monitoring plan designed to better understand the combined impacts of multiple oil and gas exploration activities in the Arctic. This

comprehensive plan may result in monitoring requirements intended to contribute to a broader understanding of industry impacts, beyond those of one activity alone, and may necessitate coordination between multiple companies in a given year to produce an integrated report. NMFS will work with companies through the MMPA process, and any additional requirements of this nature would be coordinated in advance and outlined in individual MMPA authorizations.

- When Field Source Verification is required, the distances to the various isopleths are to be reported to NMFS within five days of completing the measurements. In addition to reporting the radii of specific regulatory concern, distances to other sound isopleths down to 120 dB rms (if measurable) will be reported in increments of 10 dB.
- NMFS will make the final reports available to the public on the NMFS Office of Protected Resources website.

In recent years, the Alaska offices of NMFS, BOEM/BSEE, and the USFWS have held weekly monitoring and mitigation meetings while seismic surveys and exploratory drilling activities have been underway. Industry operators attended those meetings on a weekly or bi-weekly basis and provided real-time data on marine mammal observations and any interactions and mitigation measures taken. While not required in the MMPA ITAs, these meetings have proved to be extremely helpful in providing an avenue for immediate feedback to operators, and some changes in location or timing of activities to reduce potential impacts to protected species have been implemented as a result of the meetings. As a result of the usefulness of these meetings, they are likely to continue into the future.

2.5 Alternatives Considered but Dismissed From Further Evaluation

Comments received during the scoping process have suggested features that should be incorporated into project alternatives (Table 2.1). Many of these have been incorporated into the alternatives considered for analysis in this EIS (Section 2.4). However, others have been dismissed from further consideration after careful review. These are described in the following sections:

2.5.1 Permanent Closures of Areas

Through the scoping process, a suggestion was put forward that certain areas of the Beaufort and Chukchi seas should be permanently closed to oil and gas leasing due to environmental sensitivity. The appropriate mechanism for considering exclusion of areas from leasing is when BOEM requests public comments on its Five Year OCS Oil and Gas Leasing Program and later when considering lease sales as described at the leasing stage of the OCS Lands Act. During the Five-Year Program stage, the public is afforded the opportunity to make recommendations regarding the size, timing, and location of proposed lease sales for the next five years. At the lease sale stage, BOEM invites the public to make comments regarding a specific sale and potential exclusions.

The President of the United States can place a moratorium on an area or the U.S. Congress can permanently close an area. The current alternatives in this EIS consider a wide array of geographic restrictions that could be used, alone or in combination, to mitigate impacts to different resources in the context of the specific activity that is being permitted.

Applicants come to NMFS requesting take authorization for specified activities. The MMPA states that if NMFS finds that the specified activity itself, or with the implementation of mitigation and monitoring measures, will have a negligible impact on affected marine mammal species or stocks and will not have an unmitigable adverse impact on the availability of affected marine mammal species or stocks for taking for subsistence uses, NMFS *shall issue* the requested ITA. NMFS is required to make these decisions on an application-specific basis, and there is no mechanism in Section 101(a)(5) to preemptively permanently close an area to all oil and gas activity.

NEPA does not preclude the consideration of alternatives that the lead agency(s) cannot implement or enforce, however, nor does it require the consideration of alternatives that do not meet the purpose and need of the EIS. In this case, NMFS is using this EIS to inform decisions of whether to issue ITAs pursuant to Section 101(a)(5) of the MMPA, and the analysis of a permanent closure alternative does not add value, especially considering the broad array of geographic restrictions that are considered within the action alternatives carried forward for analysis. In this case, BOEM is using this EIS to inform decisions on issuing G&G permits and authorizing ancillary activities. The analysis of a permanent closure alternative does not add value, especially considering the broad array of geographic restrictions that are considered within the action alternatives.

As noted above, NMFS and BOEM may, and do in the alternatives carried forward, consider temporary restrictions, such as time/area closures (see Alternative 4) and other mitigation measures to avoid or minimize adverse effects on marine mammals, other marine resources, and subsistence harvest activities through their respective authorities.

2.5.2 Caps on Levels of Activities and /or Noise

During the scoping period, commenters suggested that there should be a cap established to limit the total number of oil and gas seismic and exploratory drilling activities that may occur in the EIS project area on a per season basis. The alternatives carried forward for analysis in this EIS include a range of exploration activities at different activity levels. While these separate activity level alternatives do not function as "caps," they do serve as the maximum annual level of activities for which NEPA coverage under this EIS exists for NMFS' and BOEM's issuance of ITAs and permits, respectively, in a given year. If the agencies receive additional requests for authorizations and permits for such activities beyond the level analyzed in this PEIS or within the alternative selected in an ensuing Record of Decision, NMFS and BOEM would need to conduct additional NEPA analyses before making a final determination on those requests.

There is little, if any, quantitative data upon which BOEM or NMFS could justify designating a particular activity-level cap. The impacts of sound exposure on marine mammals can vary greatly depending upon context (i.e. where, when, and how the activities and marine mammals overlap) and the likely impacts from a particular combination of multiple activities can vary even more depending on the context of each activity, which is not known prior to the submittal of applications. This EIS will specifically analyze the likely effects of individual oil and gas activities in different particular contexts (e.g. in marine mammal feeding areas, during subsistence hunts), further generally analyze the likely impacts of multiple activities, including a qualitative assessment of how specific contextual factors would affect the multiple activity analysis, and analyze the implementation of mitigation measures intended to minimize environmental impacts from both individual activities and multiple activities occurring at once (e.g. minimum distances between seismic vessels), all of which will be used in the context of specific industry requests to support NMFS' and BOEM's decisions in a given season. NMFS will also continue to require monitoring that contributes to the understanding of marine mammal responses to both individual and multiple activities, which is then used to better inform future decisions.

An OCS lease authorizes a lessee to engage only in "*ancillary activities*" that receive further environmental review to determine if they will cause any harm to the environment and are only approved if the activity does not cause "*undue or serious harm or damage to the human, marine, or coastal environment*" (30 CFR Parts 550.105, 550.202, and 550.209; see also 43 U.S.C. 1340[c} approval required prior to exploration]. The U.S. Supreme Court has recognized that "*[u]nder OCSLA's plain language, the purchase of a lease entails no right to proceed with full exploration, development, or production. . .; the lessee acquires only a priority in submitting plans to conduct these activities*" (*Secretary of the Interior v. California*, 464 U.S. 312, 339 [1984]).

BOEM has the statutory authority to make a decision on exploratory drilling activities. NMFS does not authorize the exploration activities, but rather authorizes the take of marine mammals incidental to specified activities. As discussed above, NMFS must consider every application and shall issue the ITA if the requisite findings are made.

Similarly, a commenter recommended that this EIS include an alternative wherein BOEM and NMFS use a phased, adaptive approach for increasing oil and gas activities in the Beaufort and Chukchi seas or issue permits and authorizations in alternating years for each sea (e.g. only issue permits and authorizations for the Beaufort Sea in odd numbered years and only issue permits and authorizations for the Chukchi Sea in even numbered years). The information in the paragraphs immediately above supports our decision not to carry these alternatives forward for consideration (i.e. there are no data to support such a decision and NMFS must consider every application and shall issue the ITA if the requisite findings are made). Additionally, there are little to no data to support an analysis of such alternatives.

Separately, a commenter suggested that a sound cap or sound budget that limits the total amount of noise (from oil and gas exploration sounds, as well as other sounds that are not part of the proposed action) allowed per season should be considered as an alternative. The factors discussed in the paragraphs above (activity level caps) apply to this recommendation as well. Additionally, there are insufficient data to support a cumulative noise cap as the current understanding of the likely impacts from noise and ability to quantify those impacts are generally limited to observed responses to a single sound source. Existing data support the identification of received levels above which particular species might be expected to respond in a particular manner that NMFS would consider a take (either injury or behavioral harassment), and it is possible, within the context of the area and expected ensonification around one sound source, to use those levels to evaluate the scope of likely effects *in advance* and develop measures intended to minimize impacts or avoid injury. There is information showing generally (mostly for overlap in space and time between low frequency sound sources and low-frequency hearing specialists) that the higher the noise level in a given area, the higher the likelihood that it will interfere, to some degree, with a marine mammal's ability to communicate with conspecifics or collect other important environmental information (which supports the general goal of reducing noise, which is explored both in mitigation measures and alternatives in this EIS). However, there is no specific information regarding at what level or over what period of time an elevated overall background noise will trigger any specific significant impacts to marine mammal health or fitness, which would make the designation of a noise cap an arbitrary and unsupportable action. Additionally, the soundscape will vary based on bathymetry, the sound speed profile of the water, and where any contributing sources are located in relationship to one another in space and time, which means that it would be very difficult to predict and then establish a "noise cap" in advance with any accuracy in the absence of the details of proposed activities. Last, even if justified, this recommendation would be very difficult (if not impossible) to effectively implement since other entities conducting activities that do not require an MMPA authorization (which would also be contributing to the soundscape) have no responsibility either to indicate their future plans or report their prior sound production, which would be necessary for the budget "accounting."

In Chapter 4, NMFS will consider the combined noise impacts from multiple surveys. Similarly, in the cumulative impact analysis, NMFS will consider the potential noise (and other types of) impacts from other known activities occurring in the EIS project area. This information will be analyzed on a qualitative basis and potentially in the development of mitigation or monitoring measures contained in this EIS. Additionally, NMFS and BOEM are aware of several ongoing scientific efforts to better quantify different aspects of potential cumulative impacts in the Arctic (e.g. the Cumulative Effects of Anthropogenic Sound on Marine Mammals Workshop sponsored by British Petroleum [BP] and the NOAA Sound Mapping Working Group) and any applicable available preliminary or final products will be considered in the EIS, as appropriate. While NMFS will consider the potential impacts from exposure over time to multiple sound sources in this document, a "budget" implies a quantitative management of total sound that cannot currently be supported by the science.

2.5.3 Duplicative Surveys

A question was raised as to why restrictions could not be placed on companies that are repeating seismic surveys in the same geographic area. Based upon the OCS Lands Act and applicable regulations (30 CFR Parts 550 and 551), BOEM does not have the discretion to require companies to share proprietary data, combine seismic programs, change lease terms, or prevent companies from acquiring data in the same geographic area. The agency does not have the authority to deny seismic permits simply on the grounds that they are duplicative – meaning the acquisition of the exact same data using the exact same equipment and technology in the exact same location. Continuing improvements in seismic survey technology, operations, and data processing could provide better quality data, which would support better decisions and higher drilling success rates (i.e., fewer unsuccessful wells or “dry holes”). To improve data quality and imaging in the same area, surveys have been shot, for example, in different orientations, using different cable lengths, using new wide azimuth techniques, or using multi-component sensors. Some improvements resulted in deeper imaging, others in better imaging. Also, all seismic surveys are not the same, even when the exact equipment and technology is being used. Variances in the use of the exact same equipment and technology provide different data sets that have the potential to produce information to assist in subsequent exploration.

However, NMFS and BOEM are both committed to supporting the reduction of unnecessary sound in the water.

2.5.4 Zero Discharge

Through the scoping process, a suggestion was put forward that “zero discharge” practices should be implemented to eliminate discharges of waste into the marine environment. Part of the impetus for making this suggestion was the fact that Norway, in cases, implements zero discharge standards. An additional basis for this particular recommendation was a specific voluntary ”zero discharge” proposal by one oil and gas operator (i.e. Shell Oil) to manage five specific waste streams within its lease blocks near Camden Bay in the Beaufort Sea by:

1) collecting sanitary waste, bilge water, ballast water, and domestic waste (i.e. gray water) on the drillship, and subsequently transporting those waste materials for disposal out of the activity area; and

2) collecting and disposing of drilling fluids and drill cuttings after the well casing is set in the top hole and the riser is installed at an offsite location.

However, oil and gas exploration activities generate a wide range of waste streams in addition to those associated with the current “zero discharge” proposal put forth by Shell Oil.

The Beaufort and Chukchi NPDES general permits issued by the EPA regulate discharges of drilling fluids and drill cuttings; deck drainage; sanitary wastes; domestic wastes; uncontaminated ballast water; bilge water; desalination unit wastes; blowout preventer fluid; boiler blowdown; fire control system test water; non-contact cooling water; excess cement slurry; and muds, cuttings, and cement at seafloor. The general permits include effluent limitations and monitoring requirements specific to each of the discharges, with additional restrictions for the discharge of drilling fluids and drill cuttings, including no discharge starting on August 25 until fall bowhead whale hunting activities have been completed by the communities of Nuiqsut and Kaktovik in the Beaufort Sea.

The Beaufort and Chukchi general permits also require environmental monitoring programs conducted at each drill site location before, during, and after drilling activities. The general permits also include numerous seasonal and area restrictions.

Under the MMPA, NMFS has the authority to require the implementation of mitigation measures to effect the least practicable adverse impact to marine mammals and their habitat and to ensure that there is no unmitigable adverse impact to the subsistence uses of these species. NMFS will consider as additional mitigation measures, within the action alternatives carried forward for analysis, the reduction, limitation, or elimination of the discharge of specific wastes that may potentially impact marine mammals or marine mammal habitat. NMFS does not have the authority to require mitigation measures that limit discharge streams for which there is no science supporting the link to impacts to marine mammals or their habitat. Again, NEPA does not preclude the consideration of alternatives that the lead agency(s) cannot implement or enforce, however, nor does it require the consideration of alternatives that do not meet the purpose and need of this EIS. NMFS does not intend to include an alternative that includes zero discharge of all waste streams, as it will not add value to this analysis. Rather, the EIS will analyze the limitation (zero discharge or reduced discharge) of the subset of discharge streams associated with impacts to marine mammals or their habitat in the Additional Mitigation section. The mitigation analysis looks at how the limitation will reduce potential adverse impacts to marine mammals and their habitat or to subsistence uses of marine mammals, the effectiveness of the measure, and the practicability for applicant implementation. This analysis/approach will more effectively support NMFS' purpose and need.

2.5.5 Level of Exploratory Drilling Programs Commensurate with the Number of Lease Holders in the Beaufort and Chukchi Seas

An alternative representing a high level of exploration activity (i.e., equal to the number of lease holders in the Alaskan Beaufort and Chukchi Seas) was considered but eliminated from further analysis. As per the CEQ regulations (40 CFR 1502.14), it was the intent of NMFS and BOEM to consider a range of reasonable alternatives to the proposal. CEQ guidance on this regulation states:

> "40 CFR Section 1502.14 requires the EIS to examine all reasonable alternatives to the proposal. In determining the scope of alternatives to be considered, the emphasis is on what is "reasonable" rather than on whether the proponent or applicant likes or is itself capable of carrying out a particular alternative. Reasonable alternatives include those that are practical or feasible from the technical and economic standpoint and using common sense, rather than simply desirable from the standpoint of the applicant" (CEQ, *Forty Most Asked Questions Concerning NEPA Regulations,* Quest. 2a, March 23, 1981).

Speaking to this concern during the commenting period on the December 2011 Draft EIS, oil and gas industry representatives encouraged NMFS to consider a broad range of exploration scenarios. The industry representatives expressed concern that with so many existing leases, the maximum development alternative at the time—a total of four exploration projects, two in the Beaufort Sea and two in the Chukchi Sea—was too limiting.

There are currently 183 leases in the Beaufort Sea and 487 leases in the Chukchi Sea, for a total of 670 leases. There are 11 lessees/owners of these leases. The intention with the range of alternatives analyzed in the EIS is not to limit the amount of exploration and development but rather to address realistic scenarios. The extreme case would be to analyze a total of 670 Arctic exploration projects (one for each lease), but this is unrealistic given the logistical and technological limitations for such an undertaking—it would challenge common sense. On the other hand, the possibility of analyzing an alternative that allows for one exploration program per lease holder, for a total of 11 concurrently operating exploration projects, does bear a closer look.

Each exploration project in the Arctic requires extensive commitment of resources and personnel. Recent projects permitted in the Chukchi Sea have required up to five support vessels in addition to the drillship itself: at least one ice management vessel, an anchor handler vessel, two supply ships, and possibly a shallow water landing craft. Drilling operations would also be attended by a number of spill response vessels, some that would remain with the drillship and some that would simply be available to respond as needed. In addition to vessel support, each drilling project would require fixed wing air support to transport personnel from the shore base to the nearest regional jet service and helicopter support for multiple weekly runs to rotate crews and transport supplies.

There are limitations to the numbers of drill rigs/drill ships, icebreakers, oil-spill response vessels, and other support equipment generally available to support Arctic drilling operations. For example, there are currently only four drilling rigs ready to operate in the Arctic. Further, there are minimum timelines to consider in terms of permitting and regulatory process. Shell is the only lessee/operator currently permitted by DOI to begin exploratory drilling in the Beaufort Sea and Chukchi Sea Planning Areas. Even if Shell discovers commercial quantities of oil in 2013, potentially increasing interest in Arctic exploration, it is very unlikely that more than eight drilling programs (as analyzed under Alternative 4) would be operational in the time frame of this EIS. Such a scenario would require more resources than are currently available and is not reasonably foreseeable. Therefore, an alternative representing a higher level of activity (more than 8 programs) will not be analyzed further in this EIS. However, the absence of an alternative analyzing a higher level of activity does not limit the number of possible drilling programs. Should a higher level of activity be proposed at some point in the future, further NEPA analysis would be developed to analyze those requests.

2.6 Comparison of Impacts

Table 2.6 presents a summary of impacts to all resources from Alternative 1 through Alternative 6. Summary impact conclusions are identified in the table for each resource. The methodology for determining the level of impact is discussed in Chapter 4, Section 4.1.3.

Table 2.5 Summary of Alternatives

Element	Alternative 1 – No Action	Alternative 2	Alternative 3	Alternative 4	Alternative 5	Alternative 6
Level of Activity	No ITAs issued; No G&G permits or ancillary activity notices issued	Up to four 2D/3D seismic or CSEM surveys in the Beaufort Sea (Beaufort) and up to three 2D/3D seismic or CSEM surveys in the Chukchi Sea (Chukchi) per year. Up to one of the total number of surveys in each sea done in-ice with ice breaking if necessary.	Up to six 2D/3D seismic or CSEM surveys in the Beaufort and up to five 2D/3D seismic or CSEM surveys in the Chukchi per year. Up to one of the total number of surveys in each sea done in-ice with ice breaking if necessary	Up to six 2D/3D seismic or CSEM surveys in the Beaufort and up to five 2D/3D seismic or CSEM surveys in the Chukchi per year. Up to one of the total number of surveys in each sea done in-ice with ice breaking if necessary	Same as Alternative 3	Same as Alternative 3
		Up to three site clearance and high resolution shallow hazards survey programs in the Beaufort and up to three site clearance and high resolution shallow hazards survey programs in the Chukchi per year.	Up to five site clearance and high resolution shallow hazards survey programs in the Beaufort and up to five site clearance and high resolution shallow hazards survey programs in the Chukchi per year	Up to five site clearance and high resolution shallow hazards survey programs in the Beaufort and up to five site clearance and high resolution shallow hazards survey programs in the Chukchi per year	Same as Alternative 3	Same as Alternative 3
		One on-ice seismic survey in the Beaufort per year.	Same as Alternative 2	Same as Alternative 2	Same as Alternative 2	Same as Alternative 2
		One exploratory drilling program in the Beaufort and one exploratory drilling program in the Chukchi per year.	Up to two exploratory drilling programs in the Beaufort and up to two exploratory drilling programs in the Chukchi per year.	Up to four exploratory drilling programs in the Beaufort and up to four exploratory drilling programs in the Chukchi per year.	Same as Alternative 4	Any level up to the maximum contemplated in this EIS, as the technology only relates to seismic surveys
Required Standard Mitigation Measures	None needed	Full range of those measures described in Section 2.4.9 for consideration as needed.	Same as Alternative 2	Same as Alternative 2	Same as Alternative 2	Same as Alternative 2
Additional Mitigation Measures	None needed	Full range of those measures described in Section 2.4.10 for consideration as needed.	Same as Alternative 2	Same as Alternative 2	Same as Alternative 2	Same as Alternative 2
					Additional required time/area closures for: • Barrow Canyon/ Western Beaufort Sea • Shelf Break of the Beaufort Sea • Hannah Shoal • Kasegaluk Lagoon • Ledyard Bay	Additional Mitigation Measures that focus on the use of alternative technologies that have the potential to augment or replace traditional airgun-based seismic exploration activities.

Table 2.6 Comparison of Impacts

Impact Topic	Alternative 1- No Action Alternative	Alternative 2- Authorization for Level 1 Exploration Activity	Alternative 3- Authorization for Level 2 Exploration Activity	Alternative 4- Authorization for Level 3 Exploration Activity	Alternative 5- Authorization for Level 3 Exploration Activity with Additional Required Time/Area Closures	Alternative 6- Authorization for Level 3 Exploration Activity with Use of Alternative Technologies
PHYSICAL ENVIRONMENT						
Physical Oceanography	No effect	Minor impacts from deposition of materials during exploratory drilling, construction of artificial island, ice-breaking, and on-ice seismic surveys.	Same types of impacts as Alternative 2, intensity and extent of the impact would be doubled, level of impact still minor.	Same types of impacts as Alternative 2, intensity and extent of the impact would be doubled for exploratory drilling activities, level of impact still minor.	Same as Alternative 4	Same as Alternative 4
Climate	No effect	Impacts cannot be measured on a project-level basis.	Impacts cannot be measured on a project-level basis.	Impacts cannot be measured on a project-level basis.	Same as Alternative 4	Same as Alternative 4
Air Quality	No effect	Negligible to minor impacts due to emissions from survey vessels and from emissions of CO_2e from drilling programs.	Minor impacts due to emissions from survey vessels and from emissions of CO_2e from drilling programs.	Moderate impacts due to emissions from survey vessels and from emissions of CO_2e from drilling programs.	Same as Alternative 4	Same as Alternative 4
Acoustics	No effect	Moderate impacts from sound of exploration activities.	Moderate, although the number of exploration programs is increased from Alternative 2, the same types of noise-generating sources are to be used.	Moderate, although the number of exploration programs is increased from Alternative 2, the same types of noise-generating sources are to be used.	Same as Alternative 4	Same as Alternative 4
Water Quality	No effect	Impacts reduced to negligible by mitigation measures.	Impacts reduced to negligible by mitigation measures.	Impacts reduced to negligible by mitigation measures.	Same as Alternative 4	Same as Alternative 4
Environmental Contaminants and Ecosystem Functions	No effect	Negligible impacts, they could be medium intensity but would be local and temporary.	Minor impacts due to the greater level of activity increasing the potential volume of contaminants introduced to the project area.	Minor impacts due to the greater level of activity increasing the potential volume of contaminants introduced to the project area.	Same as Alternative 4	Same as Alternative 4
BIOLOGICAL ENVIRONMENT						
Lower Trophic Levels	No effect	Negligible impacts from disturbance of habitat and displacement of organisms from drilling, sediment sampling, ship anchoring, or platform installation; toxicity due to production discharge; increased productivity due to ice breaking. Introduction of invasive species from ship traffic could cause moderate impacts.	Negligible impacts, the increased levels of activity would not generate different types or level of impacts. Introduction of invasive species from ship traffic could cause moderate impacts.	Negligible impacts, the increased levels of activity would not generate different types or level of impacts. Introduction of invasive species from ship traffic could cause moderate impacts.	Same as Alternative 2, the time/area closures would not affect lower trophic levels.	Same as Alternative 2, the use of alternative technologies would not affect lower trophic levels.
Fish/Essential Fish Habitat	No effect	Minor impacts, small scale and temporary only.	Minor impacts, increased activities would not change the impact level.	Minor impacts, increased activities would not change the impact level.	Minor impacts. The time/area closures would reduce the impacts to lower than Alternative 2.	Negligible impacts. The use of alternative technologies may reduce any impact.
Marine and Coastal Birds	No effect	Negligible to minor impacts, depending on species ESA status, from temporary and localized disturbance, injury/mortality, and changes in habitat.	Negligible to minor impacts, depending on the species ESA status, increased activities would not change the impact level.	Moderate impacts from the increased level of activity.	Same as Alternative 4	Same as Alternative 4

Impact Topic	Alternative 1- No Action Alternative	Alternative 2- Authorization for Level 1 Exploration Activity	Alternative 3- Authorization for Level 2 Exploration Activity	Alternative 4- Authorization for Level 3 Exploration Activity	Alternative 5- Authorization for Level 3 Exploration Activity with Additional Required Time/Area Closures	Alternative 6- Authorization for Level 3 Exploration Activity with Use of Alternative Technologies
Marine Mammals: Bowhead Whales	No effect	Moderate impacts from noise disturbance, possible ship strikes, or habitat degradation.	Moderate impacts from noise disturbance, possible ship strikes, or habitat degradation.	Moderate to major impacts from noise disturbance, possible ship strikes, or habitat degradation.	Moderate impacts, as the Time/Area closures could reduce adverse impacts in particular times and locations.	Moderate to major impacts. Despite possible localized mitigating capabilities of alternative technologies the impact level would not change.
Marine Mammals: Beluga Whales	No effect	Moderate impacts from noise disturbance, possible ship strikes, or habitat degradation.	Moderate impacts from noise disturbance, possible ship strikes, or habitat degradation.	Moderate impacts from noise disturbance, possible ship strikes, or habitat degradation.	Minor to moderate impacts. The effects on beluga whales would be similar to Alternative 4 but may occur in different times and places.	Moderate impacts. Although the gradual introduction of these alternative technologies could eventually reduce the amount of seismic noise introduced into the marine environment, alternative technologies would not completely replace the existing technology, so moderate impacts would remain.
Marine Mammals: Other Cetaceans	No effect	Minor impacts from temporary, local disturbance.	Minor to moderate impacts from temporary, local disturbance. Increased activities would not change the impact level.	Minor to moderate impacts from temporary, local disturbance. Increased activities would not change the impact level.	Minor to moderate impacts. Although the time/area closures could reduce adverse impacts in particular times and locations, the overall exploration effort may not be reduced, but, rather, redistributed and possibly concentrated in other areas, so the impact would not change.	Minor to moderate impacts. Alternative technologies could reduce the extent to localized areas on a small scale; it is not currently possible to assess potential behavioral reactions and determine if intensity level would change as a result.
Marine Mammals: Ice Seals	No effect	Minor impacts from temporary localized disturbance.	Minor to moderate impacts from temporary localized disturbance. Increased activities would not change the impact level.	Minor to moderate impacts from temporary localized disturbance. Increased activities would not change the impact level.	Minor impacts, as the time/area closures could reduce potentially adverse effects on seals in those areas.	Minor to moderate impact. Alternative technologies would presumably reduce the amount of noise introduced but would still use marine vessels which are at least as important for disturbance to seals in the water.
Marine Mammals: Pacific Walrus	No effect	Minor impacts from disturbance, risk of injury or mortality, and changes in habitat in the Chukchi Sea. No impact from activities in the Beaufort Sea as they are uncommon there.	Minor impacts from disturbance, risk of injury or mortality, and changes in habitat in the Chukchi Sea. Despite the increased activity, there would be no increase in the impact level. No impact from activities in the Beaufort Sea as they are uncommon there.	Minor impacts from disturbance, risk of injury or mortality, and changes in habitat in the Chukchi Sea. Despite the increased activity, there would be no increase in the impact level. No impact from activities in the Beaufort Sea as they are uncommon there.	Minor impacts, although time/area closures would reduce potentially adverse effects on walrus in those areas. No impact from activities in the Beaufort Sea as they are uncommon there.	Minor impacts. Alternative seismic technologies for in-ice surveys would likely still require the use of ice and would therefore have similar disturbance effects on walrus as those technologies currently in use. No impact from activities in the Beaufort Sea as they are uncommon there.
Marine Mammals: Polar Bears	No effect	Minor impacts from temporary localized disturbance.	Minor impacts from temporary localized disturbance. Despite the increased activity, there would be no increase in the impact level.	Minor impacts from temporary localized disturbance. Despite the increased activity, there would be no increase in the impact level.	Minor impacts. The time/area closures may protect ice seals, a primary food source for polar bears.	Minor impacts. Alternative technologies would presumably reduce the amount of noise introduced but would still use marine vessels which are at least as important for disturbance to polar bears in the water.
Terrestrial Mammals	No effect	Minor impacts from temporary localized disturbance, risk of vehicle strikes, and habitat alternations.	Minor impacts. Despite the increased activity, there would be no increase in the impact level.	Minor impacts. Despite the increased activity, there would be no increase in the impact level.	Minor impacts. The time/area closures would not affect terrestrial mammals.	Minor impacts. The use of alternative technologies would not affect terrestrial mammals.
SOCIAL ENVIRONMENT						
Socioeconomics	Minor adverse impact from unrealized local employment and tax revenue.	Minor beneficial impact from temporary rise in regional personal income and employment rates.	Minor beneficial impact. Despite the increased activity, there would be no increase in the impact level because the increases in income and employment rates are not more than 5 percent.	Minor beneficial impact. Despite the increased activity, there would be no increase in the impact level because the increases in income and employment rates are not more than 5 percent.	Minor beneficial impact. The time/area closures could reduce total local employment rates and personal income so the positive impact would be less than Alternative 2.	Minor beneficial impact. The alternative technologies could result in additional costs from lost productivity so the positive impact would be less than Alternative 2.
Subsistence	No effect	Negligible to minor impacts from disturbance, depending on the species.	Negligible to moderate impacts from disturbance, depending on the species. Even with the increased activities, the impacts to subsistence resources and harvest would be similar in type, intensity, and duration, but would occur in more locations.	Negligible to moderate impacts from disturbance, depending on the species. Even with the increased activities, the impacts to subsistence resources and harvest would be similar in type, intensity, and duration, but would occur in more locations.	Negligible to minor impacts from disturbance, depending on the species. Impacts would be slightly reduced because of the required time/area closures that would be applied in all circumstances instead of being considered as additional mitigation measures.	Negligible to moderate impacts from disturbance, depending on the species. The effectiveness of these alternative technologies to reduce adverse impacts to subsistence uses is unknown. If alternative technologies reduce disturbance to marine mammals, that would reduce impacts to subsistence users.

Impact Topic	Alternative 1- No Action Alternative	Alternative 2- Authorization for Level 1 Exploration Activity	Alternative 3- Authorization for Level 2 Exploration Activity	Alternative 4- Authorization for Level 3 Exploration Activity	Alternative 5- Authorization for Level 3 Exploration Activity with Additional Required Time/Area Closures	Alternative 6- Authorization for Level 3 Exploration Activity with Use of Alternative Technologies
Public Health	No effect	Negligible impacts, both beneficial and adverse, from changes to: • Diet and nutrition • Contamination • Safety • Acculturative stress • Economic impacts • Health care services	Negligible impacts, both beneficial and adverse, from changes to: • Diet and nutrition • Contamination • Safety • Acculturative stress • Economic impacts • Health care services Despite the increased activity, there would be no increase in the impact level.	Negligible impacts, both beneficial and adverse, from changes to: • Diet and nutrition • Contamination • Safety • Acculturative stress • Economic impacts • Health care services Despite the increased activity, there would be no increase in the impact level.	Negligible impacts, both beneficial and adverse. If the time/area closures improve the likelihood of maintaining a strong subsistence harvest, there will also be resulting benefits to public health. If the closures allow hunters to complete their hunts with less travel time, it will benefit safety. However, these benefits do not affect the overall impact criteria rating, as it is are already negligible.	Negligible impacts, both beneficial and adverse. The alternative technologies may reduce disturbance to marine mammals, which could reduce adverse impacts to subsistence users. However, the effectiveness of the alternative technologies in reducing adverse impacts to subsistence uses is unknown, and thus the benefits are theoretical. Therefore, the impact rating remains the same. If the alternative technologies are demonstrated to be effective, they would benefit public health.
Cultural Resources	No effect	Negligible impact.	Negligible impact.	Negligible impact.	Minor impact. The time/area closures would not affect cultural resources.	Minor impact. The alternative technologies would not affect cultural resources.
Land and Water Ownership, Use, and Management	Major adverse impacts from loss of opportunity to explore for oil and gas.	Moderate impacts to land and water use from activity in new areas and potential long-term development. Negligible impacts to land and water ownership and management as no changes in management or ownership would occur.	Moderate impacts to land and water use from possible conflict between subsistence use and seismic surveys, changes in industrial, transportation, and commercial land use and management. Slightly higher possibility of new facilities and infrastructure, higher levels of air and vessel traffic, and commercial activity associated with survey support. Minor impacts to land and water management - as activities increase, the possibility for conflicts with borough offshore development policies goes up as well. Negligible impacts to land and water ownership as no changes in ownership would occur.	Moderate impacts to land and water use from possible conflict between subsistence use and seismic surveys, changes in industrial, transportation, and commercial land use and management. Slightly higher possibility of new facilities and infrastructure, higher levels of air and vessel traffic, and commercial activity associated with survey support. Minor impacts to land and water management - as activities increase, the possibility for conflicts with borough offshore development policies goes up as well. Negligible impacts to land and water ownership as no changes in ownership would occur.	Moderate impacts to land and water use. As time/area closures are implemented, the likelihood of conflicts decreases because the closures would lessen the exposure of subsistence species to seismic activities and exploratory drilling at critical locations and during critical seasons of the year. Time/area closures would shorten the timeframe available for oil and gas exploration activities and potentially impede exploration activity. As a result, there may be a reduction in transportation and commercial uses during certain times of the year. Minor impacts to land and water management. Constraining exploration to certain times and locations may result in more moderate state and federal resource development goals, while promoting management practices to protect the human, marine and coastal environments, and improve consistency with North Slope Borough and Northwest Arctic Borough comprehensive plans and Land Management Regulations. Therefore, because these techniques reflect balanced management and do not prohibit resource development, no inconsistencies or changes in federal or state land or water management are anticipated. Negligible impacts to land and water ownership as no changes in ownership would occur.	Moderate impacts to land and water use from activity in new areas and potential long-term development. Minor impacts to land and water management. Negligible impacts to land and water ownership as no changes in ownership would occur.
Transportation	No effect	Negligible (aircraft and vehicle) to minor (vessel) impacts from increased traffic.	Minor to moderate impacts from increased traffic.	Minor to moderate impacts from increased traffic.	Minor to moderate impacts from increased traffic. The time/area closures would limit the amount of aircraft overflights in these areas.	Minor to moderate impacts from increased traffic. It is assumed that these new alternative technologies would require the same levels of aircraft and surface and vessel support as under Alternative 3, and, therefore, the impacts are expected to be similar.
Recreation and Tourism	No effect	Minor impacts from temporary and local effects on recreational setting.	Minor impacts from temporary and local effects on recreational setting. The increased levels of activity would not generate different types or level of impacts.	Minor impacts from temporary and local effects on recreational setting. The increased levels of activity would not generate different types or level of impacts.	Minor impacts from temporary and local effects on recreational setting. If the time/area closures benefit marine mammals, they would also benefit recreation and tourism based on wildlife viewing.	Minor impacts from temporary and local effects on recreational setting. The alternative technologies would not affect recreation or tourism.
Visual Resources	No effect	Moderate impacts from high contrast of drill sites and associated activities.	Moderate impacts from high contrast of drill sites and associated activities.	Moderate impacts from high contrast of drill sites and associated activities.	Same as Alternative 3.	Same as Alternative 3.

Impact Topic	Alternative 1- No Action Alternative	Alternative 2- Authorization for Level 1 Exploration Activity	Alternative 3- Authorization for Level 2 Exploration Activity	Alternative 4- Authorization for Level 3 Exploration Activity	Alternative 5- Authorization for Level 3 Exploration Activity with Additional Required Time/Area Closures	Alternative 6- Authorization for Level 3 Exploration Activity with Use of Alternative Technologies
Environmental Justice	No effect	Minor adverse impacts from disruption of subsistence activities and potential contamination of subsistence food. Minor beneficial impacts from local employment opportunities.	Minor adverse impacts from disruption of subsistence activities and contamination of subsistence food. Minor beneficial impacts from local employment opportunities.	Minor adverse impacts from disruption of subsistence activities and contamination of subsistence food. Minor beneficial impacts from local employment opportunities.	Minor impacts. With the time/area closures, the impacts to subsistence activities could be further minimized but would remain minor.	Minor impacts. With the alternative technologies, the impacts to subsistence foods and human health could be further minimized but would remain minor.

3.0 AFFECTED ENVIRONMENT

This chapter describes the physical, biological, and social resources that are affected by the issuance of ITAs by NMFS or the authorization of G&G permits and authorization of ancillary activities in the U.S. Beaufort and Chukchi seas by BOEM. The objective of this section is to describe baseline conditions for the analysis of direct and indirect effects of the alternatives and the cumulative effects analysis presented in Chapter 4 of this document.

The following descriptions of the affected environment have been compiled from several other sources, including NMFS and BOEM documents. In many cases, the original documents are referenced and the pertinent information has been summarized. In other cases, pertinent sections of documents have been reproduced from the original. All source documents are cited in the text with full references in Chapter 7 of this document.

3.1 Physical Environment

3.1.1 Physical Oceanography

3.1.1.1 Water Depth and General Circulation

The Beaufort and Chukchi seas are the northernmost seas bordering Alaska. The Beaufort and Chukchi seas are parts of the Arctic Ocean, but both are linked, atmospherically and oceanographically, to the Pacific Ocean. The atmospheric connection involves the Aleutian Low, which affects regional meteorological conditions. The oceanographic link is via the Bering Strait, which draws relatively warm nutrient-rich water into the Arctic Ocean from the Bering Sea (Weingartner and Danielson 2010).

The Beaufort Sea is a semi-enclosed basin with a narrow continental shelf extending 30 to 80 kilometers (km) (19 to 50 miles [mi]) from the coast (Figure 3.1-1) (Chu et al. 1999). The Alaskan coast of the Beaufort Sea is about 600 km (373 mi) in length, reaching from the Canadian border in the east, to the Chukchi Sea at Point Barrow in the west. The continental shelf of the Beaufort Sea is relatively shallow, with an average water depth of about 37 m (121 feet [ft]). Bottom depths on the shelf increase gradually to a depth of about 80 m (262 ft), then increase rapidly along the shelf break and continental slope to a maximum depth of around 3,800 m (12,467 ft) (Figure 3.1-2) (Weingartner 2008, Greenberg et al. 1981). Numerous narrow and low relief barrier islands within 1.6 to 32 km (1 to 20 mi) of the coast influence nearshore processes in the Beaufort Sea (Brown et al. 2010).

The shallow continental shelf waters of the Beaufort Sea are subjected to seasonally varying conditions, such as heating, cooling, wind stress, ice formation and melting, and terrestrial freshwater input. Seasonal variations in the temperature and salinity of the continental shelf waters are large (Chu et al. 1999). Such physical and chemical gradients influence the productivity and trophic structure of the Beaufort Sea shelf. Freshwater discharge from the Mackenzie River, along with numerous smaller rivers and streams distributed along the coast, create an environment that is estuarine in character, especially in late spring and summer. In addition, coastal erosion and river discharge are responsible for introducing high concentrations of suspended sediment and associated terrestrial organic carbon into the near shore zone. These terrestrial inputs of organic carbon, identifiable on the basis of isotopic composition, are important to the functioning of the Beaufort Sea shelf ecosystem (Dunton et al. 2006).

The Chukchi Sea is predominantly a shallow sea with a mean depth of 40 to 50 m (131 to 164 ft). Gentle mounds and shallow troughs characterize the seafloor morphology of the Chukchi Sea (Chu et al. 1999). The Chukchi Sea shelf is approximately 500 km (311 mi) wide and extends roughly 800 km (497 mi) northward from the Bering Strait to the continental shelf break (Weingartner 2008). Beyond the shelf break, water depths increase quickly beyond 1,000 m (3,281 ft). The western edge of the Chukchi Sea shelf extends to Herald Canyon, and the eastern edge is defined by Barrow Canyon (Pickart and Stossmeiser 2008), which separates the Beaufort and Chukchi seas.

Mean northward flow of relatively warm nutrient-rich water through the Bering Strait occurs due to the Pacific-Arctic pressure gradient (Weingartner and Danielson 2010). This pressure gradient propels Bering Strait water through the Chukchi Sea along three principal pathways that are associated with distinct bathymetric features: Herald Valley; the Central Channel; and Barrow Canyon (Figure 3.1-3). This northward flow opposes the prevailing winds, which are from the northeast (Weingartner and Danielson 2010). The northward flows of relatively warm nutrient-rich water through the Bering Strait are largely responsible for the ecological characteristics of the Chukchi shelf, including its ability to support large and diverse marine mammal populations (Springer et al. 1996).

3.1.1.2 Currents, Upwelling and Eddies

Beaufort Sea

Three oceanic geographic regions influence the movement of Beaufort Sea waters: 1) Pacific waters that flow from the Chukchi Sea shelf through the Barrow Canyon; 2) the offshore boundary of the Beaufort Sea shelf and slope; and 3) the Mackenzie shelf (Weingartner 2008).

Pacific Ocean waters that exit the Chukchi shelf through Barrow Canyon comprise the first regime (Mountain et al. 1976, Weingartner 2008). Some of this outflow continues eastward along the Beaufort shelf break and contributes to thermohaline stratification in the Canada Basin (Mountain et al. 1976, Weingartner 2008), while some of the water exiting the Barrow Canyon appears to spread offshore (Shimada et al. 2001).

The second oceanic regime includes the outer shelf and continental slope. Along the outer shelf and continental slope, the Beaufort undercurrent, or shelf break jet, carries Bering Sea water from the Chukchi Sea between late spring and early fall; from mid-fall to mid-spring, warmer, saltier Atlantic Water upwelled from greater depths is transported by the Beaufort undercurrent jet (Pickart 2004, Weingartner 2008, Nikolopoulos et al. 2009). The jet configuration changes seasonally. From late spring to early fall, the subsurface jet carries Bering Sea water, and from mid-fall to mid-spring upwelled Atlantic water is transported by the Beaufort undercurrent jet (Pickart 2004). Wind-driven upwelling is occasionally strong enough to push the undercurrent onto the shelf (Weingartner 2008, Pickart et al. 2011). This flow along the Beaufort Sea slope appears to be highly unstable, and it is therefore likely to be a source for the numerous eddies that extend into the Canada Basin (Shimada et al. 2001, Weingartner 2008).

The Mackenzie shelf forms the eastern boundary of the Alaska Beaufort Sea shelf and also characterizes the third oceanic regime that influences Beaufort Sea waters. Although there are few measurements in this area, it appears that discharge from the Mackenzie River influences the eastern Alaskan Beaufort Sea, and that northeast winds may occasionally force Mackenzie waters onto the Alaska Beaufort Sea shelf (Weingartner 2008).

Winds, river water, and sea ice influence circulation in the Beaufort Sea (Weingartner et al. 2009). During a brief period in the spring when the river stage increases rapidly as the snow pack melts, river water overfloods the ice and creates a freshwater lens (Dickens et al. 2011). Currents during the open water period (July to mid-October) correlate with local winds, whereas during the landfast ice period, underlying shelf waters are separated from surface stresses, such as wind (Weingartner et al. 2009). Nearshore currents are weak when landfast ice is present, and strengthen during the open water period (Weingartner 2008). Potter and Weingartner (2010) found that along-shore winds accounted for approximately 75 percent of the along-shore surface current variance and that winds accompanying strong storms lead to rapid turnover of Beaufort Sea shelf waters.

Prevailing northeasterly winds contribute to onshore and westward flow of sea ice onto the shelf, which promotes upwelling of sub-surface waters along the shelfbreak (Weingartner 2008, Weingartner et al.

2009). During the open-water season, mid-water currents may be greater than 20 cm/s (0.4 knots), but during the landfast ice period (mid-October through June) the mid-water currents are generally less than 10 cm/s (0.2 knots). Tidal currents in the Beaufort Sea shelf area are relatively weak, at less than 3 cm/s (0.06 knots) (Weingartner et al. 2009). Rates of cross-shore flows are also usually small, at less than 3 cm/s (0.06 knots), but freshwater inputs from numerous rivers in the area are responsible for greater rates of cross-shore flow during the spring (Weingartner et al. 2009).

Chukchi Sea

Circulation through the Chukchi Sea is primarily influenced by topography, while variability in flow is primarily wind driven (Weingartner et al. 2005). Mean flow through the Chukchi Sea is generally northward against the prevailing northeasterly winds (Weingartner 2008). Herald Canyon and Barrow Canyon influence the northward flow of Pacific waters (Pickart et al. 2011), and Hanna Shoal diverts central shelf water northeastward toward the continental slope and eastward along the southern edge of the shoal (Figure 3.1-3) (Weingartner et al. 2005, Weingartner et al. 2011).

Pacific water flowing through the Bering Strait crosses the Chukchi Sea by three main pathways: 1) a western branch flows northwestward through Herald Canyon; 2) a second branch flows across the Central Channel shelf; and 3) a third branch flows northeastward along the Alaska coast toward Barrow Canyon and the junction of the Chukchi and Beaufort shelves (Weingartner 2008). During summer, the third branch includes the northward extension of the Alaska Coastal Current, which merges with eastward flowing water from the central shelf within Barrow Canyon (Weingartner 2008, Woodgate et al. 2005). Pacific water flowing through Herald and Barrow Canyons contributes to a boundary current that flows east into the Beaufort Sea (Pickart and Stossmeister 2008) (Figure 3.1-3).

During the spring and fall, the Siberian Coastal Current carries water from the Siberian coast into the Chukchi Sea. The Siberian Coastal Current moves offshore near the Bering Strait, mixes with Bering Strait water, and then flows through Herald Canyon and across the central Chukchi shelf. This process is seasonal, occurring during the spring and fall, as the Siberian Coastal Current is absent or weak during winter (Weingartner 2008, Weingartner et al. 2011).

Mean current speeds are greatest within Herald Canyon and Barrow Canyon (~25 cm/s or 0.5 knots), moderate in the central channel (~10 cm/s or 0.2 knots), and generally much slower (less than 5 cm/s or 0.1 knots) elsewhere on the shelf (Weingartner et al. 2005, Weingartner 2008). Maximum current speeds of ~100 cm/s (about 2 knots) have been recorded in Barrow Canyon, while maximum flow rates of up to 50 cm/s (1 knot) have been recorded elsewhere (Weingartner et al. 2011).

Wind strongly influences current flow and flow variability. Wind magnitude and variability are highest in fall and winter and lowest in summer (Weingartner 2008). Flow through Long Strait and Barrow Canyon correlate well with local winds, whereas flow through Herald Canyon does not (Woodgate et al. 2005).

3.1.1.3 Temperature and Salinity

Beaufort Sea

Throughout the summer, temperature increases and salinity decreases due to surface warming and associated ice melting and freshwater input from rivers to the Beaufort Sea. The sea surface temperature increases to a maximum value near 8 °C, and the sea surface salinity decreases to a minimum value below 20 practical salinity units (psu) (Chu et al. 1999). During summer, profiles of temperature and salinity in the Beaufort Sea show a multilayer structure, with a shallow layer of warm low-salinity water overlying cooler saltier deep layers. A rapid (one to two weeks) collapse to the freezing point (~-1.7 °C) occurs in autumn (usually in early October), after which temperatures remain near-freezing until late June or early July. At that time, temperatures slowly increase and reach 0 °C by late July. During summer, salinity varies from 14 to 32 psu, with the lowest salinities observed immediately following the decay of the landfast ice. After the ice forms in October, salinities increase and attain values of 34 to 35 psu by

January due to the expulsion of salt from growing sea ice. Thereafter, salinities remain relatively constant through winter and spring before slowly starting to decrease in June. Following the removal of ice and the first significant wind-mixing event, salinities decrease rapidly in nearshore areas as a result of low-salinity ice meltwater and freshwater input from rivers (Weingartner et al. 2009). During winter, temperature decreases and salinity increases as freezing expels brine from sea ice (Weingartner et al. 2009).

Chukchi Sea

Temperature and salinity in the Chukchi Sea vary seasonally and are influenced by sea ice formation and melting. During winter (January to May), shelf waters cool to the freezing point, and salinity in the water increases during sea ice formation. Salinities decrease as ice melts and Bering Sea water moves onto the shelf during spring and summer (Weingartner 2008, Woodgate et al. 2005, Weingartner et al. 2011).

During the spring season (May to July) warm water (above 0 °C) appears in the southern Chukchi Sea due to the gradual increase of solar radiation and warm water advected through the eastern Bering Strait (Chu et al. 1999). During the summer season (July to August), the deep water can still be cold (0 to 3 °C), depending upon location on the shelf. However, surface water temperatures can be above 9 °C in the southern Chukchi Sea. During the fall season, the surface water temperatures of the southern Chukchi Sea cools but still remains relatively warm (2 to 6 °C).

During the winter season (November to April), radiative cooling makes the whole Chukchi Sea surface temperature fall below 0°C (Chu et al. 1999).

Water properties also vary regionally across the Chukchi Sea. The eastern Chukchi is influenced by the warmer, fresher waters of the Alaskan Coastal Current and eastern Bering Strait (Woodgate et al. 2005). The largest seasonal variability in temperature and salinity occurs in the eastern Chukchi, where variations in ice cover modify the shelf waters (Woodgate et al. 2005). The western Chukchi, influenced by Anadyr waters from south of the Bering Strait, is generally colder and saltier than the eastern Chukchi (Weingartner 2008). Waters in Herald Valley include flow from the Bering Strait and cold salty water formed in winter on the Chukchi shelf near Wrangel Island (Weingartner 2008). These water masses mix with one another as they flow out of the Herald Valley and create a new water mass (Figure 3.1-3) (Pickart et al. 2011, Weingartner 2008).

3.1.1.4 Tides and Water Levels

Beaufort Sea

Recent tide gauge observations at Barrow show coastal water levels are driven primarily by the wind stress and barometric pressure changes from the passage of storm centers and frontal passages (Gill et al. 2011). Storm surge on the coast and coastal water level withdrawal can be significant (about 1 m [3.3 ft] amplitude; Gill et al. 2011). Highest montly sea levels generally occur in August and lowest monthly mean sea levels generally occur in March. Winds from the west are associated with positive surges, and winds from the east are associated with negative surges.

In the Beaufort Sea, tides propagate from west to east along the coast. Tidal ranges in the Beaufort Sea are relatively small, ranging from 0.3 to 0.7 m (1 to 2 ft), depending on location (VanderZwaag and Lamson 1990). Although tides do not seem to exert an important influence on the oceanography of the Beaufort Sea shelf, they may play an important role in sea ice dynamics. Storm surges influence coastal erosion, and may influence the time at which landfast ice breaks away from the shore (MBC 2003).

Anecdotal observations suggest that wind speed and direction may drastically influence water levels along the Beaufort Sea coast. In a Northstar public meeting, Thomas Napageak described the interaction between wind and water levels as follows: *"…you don't get…high tides [storm surges] on a northeast wind…. But when we've got the southwesterly wind, that's when the tide [water level] comes up."*

(Napageak, in Dames and Moore, 1996). Frank Long, Jr., described how a rising tide or storm surge can force water over the top of sea ice and flood river drainages: *"If there's enough water that comes in, it'll bring the ice up, plus water will be flowing…up over the edge."* (Long, in Dames and Moore 1996). An example of a negative storm surge also was observed by Nuiqsut whaling captains who reported that in 1977, the water drained out of a bay near Oliktok Point and then came back in (Dames and Moore 1996).

Chukchi Sea

Tides are small in the Chukchi Sea, and the tidal range is generally less than 0.3 m (1 ft). Tidal currents are largest on the western side of the Chukchi and near Wrangel Island, ranging up to 5 cm/s (0.1 knots) (Woodgate et al. 2005). Storm surges are both positive and negative. Winds from the west are associated with positive surges, and winds from the east are associated with negative surges. In late fall, the lack of sea ice increases the open-water area, enhancing water transport and increasing wave height (Lynch and Brunner 2007).

3.1.1.5 Stream and River Discharge

Beaufort Sea

Freshwater input from the Mackenzie River, the Colville River, and numerous other rivers affects a range of physical and chemical parameters in the Beaufort Sea (Weingartner et al. 2009).

With the exception of the Mackenzie River, these rivers usually do not flow year-round. Flow is minimal or absent throughout the winter. Stream flow begins in late May or early June as a rapid flood event that can inundate extremely large areas in a matter of days (MMS 2008). During the spring flood, river waters flow under landfast ice in narrow (1 to 2 m [3 to 7 ft]), highly stratified plumes. The plumes can spread 20 km (12 mi) or more offshore and transport large quantities of fresh water, sediments, and associated nutrients to offshore waters (Weingartner et al. 2009). Most streams continue to flow throughout the summer but at rates much lower than during the spring flood event (Weingartner et al. 2009, Weingartner 2008).

Chukchi Sea

The Kivalina, Kobuk, Kokolik, Kukpowruk, Kukpuk, Noatak, Utukok, Pitmegea, and Wulik Rivers flow into the Chukchi Sea. There are also numerous other small streams and inlets (several unnamed) that feed the Chukchi Sea on the U.S. side. These rivers, streams, and inlets have local effects on the salinity, temperature, and nutrient concentrations of the receiving waters. Discharges from the Red Dog Mine, a large zinc hardrock mine, flow into tributaries of the Wulik River, which discharges into the Chukchi Sea. These discharges are treated to remove dissolved metals. The treatment of the discharged water has improved the water quality downstream of the mine so that now the Red Dog Creek supports a population of spawning and rearing Arctic Grayling and Dolly Varden.

3.1.2 Sea Ice

3.1.2.1 Ice Dynamics

Sea ice, formed by the freezing of sea water, is a dominant feature of the Arctic environment. Annual formation and decay of sea ice influence the oceanography and dynamics of the Beaufort and Chukchi seas, impacting the physical, biological, and cultural aspects of life in this region. Sea ice generally reaches its maximum extent in March and minimum extent in September.

Ice cover consists of drifting pack ice over the middle and outer shelf and landfast ice on the inner shelf (Weingartner 2008). Landfast ice usually starts to form in October and can extend 20 to 40 km (12 to 25 mi) offshore. Stamukhi, or grounded ice, forms along the seaward edge of the landfast ice. It may help protect the inner shelf from forces exerted by pack ice (Weingartner et al. 2009).

Sea ice covers the Beaufort shelf for about nine months of the year (MBC 2003). In recent years, the Alaska Beaufort Sea shelf has been ice-free from late-July through early October (Weingartner 2008). Sea ice formation in the Chukchi Sea begins in mid-October near Wrangel Island, while the central Chukchi may remain ice free through early November. By December, the entire region is generally ice-covered (Woodgate et al. 2005).

Iñupiat hunters in Barrow describe three basic sea-ice zones: 1) *Tuvag* is the innermost zone of landfast ice, which consists of first-year ice mixed with varying amounts of multi-year ice; 2) *Uiñiq* includes the open lead, or flaw lead, and the ice fragments moving within it, which is a very dynamic area where seal and whale hunting occur; and 3) S*arri* is the outer realm of pack ice comprised of fast and varying currents and shifting sea ice (George et al. 2004).

3.1.2.2 Landfast Ice

Landfast ice is, by definition, stationary. It is contiguous with the land and strongly associated with the 20 m (66 ft) isobath, where it coincides with grounded ridges of ice (Eicken et al. 2006). Coastline and bathymetry are the primary determinants of landfast ice extent (Mahoney et al. 2007a). Most landfast ice is floating and held in place by non-floating landfast ice. Tide cracks commonly form in landfast ice along northern Alaska beaches in response to sea level fluctuations affecting the floating ice (Mahoney et al. 2007b).

A combination of processes lead to the formation patterns of landfast ice (Eicken et al. 2006). Wind and current patterns during fall and winter are critical to ice formation (George et al. 2004). Landfast ice generally starts forming in October, and, at its maximum extent in March and April, covers roughly 25 percent of the Beaufort shelf area (Weingartner 2008, Mahoney et al. 2007a). Formation of landfast ice is a complex process, and the landfast ice may form, break up, and reform several times before becoming stable (Eicken et al. 2006, Mahoney et al. 2007b).

The ice retreats with the onset of spring in May and June (Eicken et al. 2006). Timing of the ice retreat correlates with increasing temperature and atmospheric changes (Mahoney et al. 2007a). Areas of open water (e.g. polynyas and leads), act as heat sinks for solar radiation and allow for increased wind and wave action, which destabilizes landfast ice (Mahoney et al. 2007a).

The landfast ice is important to the biology, economy, and cultures of the Arctic. It is used by various seal species, polar bears, and Arctic fox, is critical to Iñupiat hunting, and has been used as a platform for transportation in nearshore areas (George et al. 2004, Eicken et al. 2006).

3.1.2.3 Stamukhi

The stamukhi ice zone lies seaward of the landfast ice and is characterized by pressure ridges, leads, and polynyas (large areas of open water) resulting from interactions between relatively stable landfast-ice and mobile pack-ice. In the Chukchi Sea, the most intense ridging occurs in waters from 15 to 40 m (49 to 131 ft) deep, while moderate ridging extends seaward and shoreward of these regions (MMS 2007a). In the Beaufort Sea, ridges occur at depths ranging from 18 to 25 m (59 to 82 ft) (Mahoney et al. 2007a). Grounded ridges help to stabilize the seaward edge of the landfast-ice zone. Extensive sea-ice rafting may occur in areas adjacent to pressure ridges, and ice thicknesses of two to four times the sheet thickness may be found within a few hundred meters of the ridge. Shear ridges are straighter, usually have one vertical side, and are composed of ice pieces that range in size from a few centimeters to several meters. The outer edge of the stamukhi zone advances seaward during the ice season (MMS 2007a).

3.1.2.4 Pack Ice and Ice Gouges

During winter, movement in the pack ice zone of the Beaufort Sea generally is small and tends to occur only during strong wind events of several days' duration. The long-term direction of ice movement tends to be from east to west, however, there may be short-term perturbations from this general trend due to variable weather (MMS 2008).

The seabed of the Alaskan Beaufort Sea shows evidence of modification by ice keels, which gouge the seafloor. The keels of sea-ice pressure ridges cut through seafloor sediments to form 'V' shaped incisions called gouges, also referred to as scours. Gouging is associated with ice keels driven by forces from the associated ice pack. An OCS study commissioned by MMS (2006-059) noted that ice gouges occur almost everywhere in the Arctic, from shore to water depths of at least 40 m (131 ft) (Palmer and Niedoroda 2005 cited in MMS 2006-059). Most ice gouges are less than 0.5 m (2 ft) deep, but the deepest gouges exceed 2 m (7 ft) in depth (NRC 2011). It should be noted, however, that maximum ice gouge depths are not indicative of maximum ice keel penetration depths due to the preferential infill of ice gouges during sediment redistribution events (Barnes and Reimnitz 1979). One study of ice gouging in the Alaskan Beaufort Sea showed that the maximum number of gouges occur in the 20 to 30 m (66 to 99 ft) water-depth range (Machemehl and Jo 1989). Earlier work by Weeks *et al*. (1983) found no relationship between ice gouge density and water depth in deeper water but reported the presence of relatively fewer gouges along shallower segments in the lagoons between Smith Bay in the west to near Camden Bay in the east (Weeks et al. 1983 in MMS 2006-059). In contrast, data from 5,329 gouges in the Canadian Beaufort Sea from 1974 to 1990 showed a decreasing density of gouges in deeper water (from about 1.5 gouges/km in about 8 m to about 0.22 gouges/km in 30 m of water) (Chayes et al. 2006 in MMS 2006-059). There are a variety of potential explanations for the differences in reported ice gouge density distributions across water depth, but the resolution of such discrepancies is outside the scope of this report. Ice gouges are considered important by pipeline engineers involved in the design and burial of Arctic offshore pipelines (Machemehl and Jo 1989). Because a great amount of force (on the order of 100 meganewtons) is required to cut a deep ice gouge, it is impractical to design a pipeline to withstand such force (Palmer and Niedoroda 2005 as cited in MMS 2006).

3.1.2.5 Leads and Polynyas

Polynyas are semi-permanent areas of open water that can be up to thousands of square kilometers in size (ACIA 2005). There are generally two types of polynyas: persistent polynyas that form off of south and west facing coasts, and north coast polynyas that form along north facing coasts (Stringer and Groves 1991). The frequency with which polynyas change from ice-covered to open water and vice-versa is influenced by wind, currents, and solar warming (Stringer and Groves 1991).

Leads are open channels, or lanes of water that form between large pieces of ice as a result of forces generated by winds and /or currents. Flaw leads occur along landfast ice when winds separate drift ice from fast ice (ACIA 2005). Pack ice shifting north is the simplest way for a lead to form along the landfast ice edge. Leads formed this way are generally narrow and short lived. Leads most commonly open along the boundary between landfast ice and pack ice. Pack ice moving parallel to landfast ice may generate leads well inside of the pack ice boundary (Eicken et al. 2006).

Spatial patterns of lead occurrence and size are consistent between years in the eastern Chukchi and the central Beaufort seas. The number of leads and mean size of leads are greater in the eastern Chukchi and off the Mackenzie Delta than in the central Beaufort Sea. Prevailing easterly winds usually force ice offshore in these areas and create recurring leads and polynyas along the landfast ice. Linear leads are prevalent in winter, while patches of open water are more common in late May or early June (Eicken et al. 2006).

Ice conditions to the west of Point Barrow are more dynamic than to the east, with leads radiating out of Point Barrow (Eicken et al. 2006). Point Barrow juts out into the Beaufort and Chukchi Seas, forming an obstacle to westward drifting Beaufort Sea pack ice (Mahoney et al. 2007a). As a result, the area to the west of Point Barrow in the Chukchi Sea is dominated by a semi-permanent polyna or flaw zone (Norton and Gaylord 2004). Grounded ice on Hanna Shoal also creates a series of leads. Ice movement is more stagnant in the eastern Beaufort, and winter breakouts are more common in the western Beaufort and eastern Chukchi (Eicken et al. 2006).

Leads and polynyas are important habitat for several seal species, polar bears, and migrating bowhead and beluga whales. Iñupiat hunters rely on these leads and open water for spring whaling of bowheads from April to June (Norton and Gaylord 2004).

3.1.2.6 Changes in Sea Ice

Arctic sea ice is changing in extent, thickness, distribution, age, and timing of melt. Analysis of long-term data sets show substantial decreases in both extent (area of ocean covered by ice) and thickness of sea ice cover during the past 30 years. Sea ice extent, the primary measure by which Arctic ice conditions are judged, has been monitored using satellite imagery since 1979. The annual maximum extent (March) and minimum extent (September) are the measures used for interannual comparisons (Perovich et al. 2012). The September 2012 minimum ice extent was the second lowest since 1979 (Perovich et al. 2012; see Figure 2.1). The summers of 2007 to 2012 experienced the six lowest minimums in the satellite record; nine of the ten lowest minimums occurred during the last decade (NSIDC 2011b, Perovich et al. 2012). The March 2010 ice extent was four percent lower than the 1979 to 2000 average. A time series of anomalies in sea ice extent (1979 to 2009) reveals both interannual variability and general decreasing trends. March ice extent decreased at a rate of 2.7 percent per decade, while September extent decreased 13 percent per decade (Perovich et al. 2012, NSIDC 2011b).

Sea ice age is another indicator of ice cover and changes. Following the record summer melt of 2007, there was a record low amount of multiyear ice (ice that has survived at least one summer melt season) in March 2008. Multiyear ice increased modestly in 2009 and 2010. Despite this, 2010 had the third lowest March multiyear ice extent since 1980. Most of the 2-3 year old ice remained in the central Arctic due to atmospheric patterns in the winter of 2010. Although some older ice from north of the Canadian Archipelago moved into the Beaufort and Chukchi seas, it did not survive the summer melt period (Perovich et al. 2010).

Loss of multiyear ice is considered a key factor in ice thinning and retreat in the Beaufort and Chukchi shelves. Ice older than five years decreased by an estimated 56 percent from 1982 to 2007 (Stroeve et al. 2008). Analysis of a satellite-derived record of sea ice age for 1980 through March 2011 shows a particularly extensive loss of the oldest ice types. The fraction of multiyear sea ice in March decreased from about 75 percent in the mid 1980s to 45 percent in 2011, while the proportion of the oldest ice declined from 50 percent of the multiyear ice pack to 10 percent (Maslanik et al. 2011). Multiyear ice (as detected by satellite) was studied in the winters from 1979-2011. The extent and area are declining at rates of -15.1 percent and -17.2 percent per decade, respectively. A record low value occurred in 2008 followed by higher values in 2009, 2010, and 2011 (Comiso 2011). The Beaufort and Chukchi seas have experienced reductions of overall mean thickness of level ice due to the replacement of multi-year by first-year ice over large areas (Shirawasa et al. 2009).

The landfast ice season has shortened since the 1970s, with coastlines being ice-free over a month earlier for the Beaufort Sea and two weeks earlier for some areas of the Chukchi Sea (Mahoney et al. 2012). Landfast ice has also been less stable in recent years, with break-offs at the beach occurring as late as January and February, or near to the beach in March. Lack of multiyear ice and decreased pressure ridges decrease stability and increase the likelihood of early break-offs and break-up events (George et al. 2004).

Iñupiat hunters have described these changes to the landfast ice, including thinning ice, changing pressure ridge patterns, and the loss of multiyear ice. These changes affect the ability to haul large whales onto the ice during spring whaling (Gearheard et al. 2006).

3.1.3 Geology

This section presents brief summaries of the regional geologic setting, stratigraphy and petroleum resources of northern Alaska, exploration history of the Alaska North Slope region, potential targets of undiscovered oil and gas resources in the Arctic Alaska offshore, and Arctic Alaska seafloor features. The Alaska Outer Continental Shelf lies north of the petroleum-resource rich Alaska North Slope where the large Prudhoe Bay oil-field was discovered in 1968 by Atlantic Richfield. The surface and subsurface geology of the Alaska North Slope is very complex and has been studied extensively by numerous workers within federal and state agencies, academia, and the oil and gas industry over the last 50 years. Limited exploration has occurred on federal lands within the Alaska Outer Continental Shelf (OCS) region that includes the Beaufort Sea and Chukchi Sea along the northwest coast of Alaska between Kotzebue and Barrow. The rocks under the Beaufort and Chukchi seas of the Arctic Ocean within the Alaska OCS are interpreted by examination of rocks exposed at surface, those encountered during exploration activities onshore north of the Brooks Range the south, from the 35 exploration wells drilled in Alaska OCS waters and from wells drilled near-shore within State of Alaska waters, within three miles of the coastline. The onshore and near-shore surface and subsurface rocks have been grouped into the Arctic Alaska Petroleum Province by numerous previous workers. The Arctic Alaska Petroleum Province is also referred as the Northern Alaska Province. These workers speculate that a large portion of conventionally recoverable oil and gas in Alaska OCS federal off-shore waters (Beaufort and Chukchi seas of the Arctic Ocean) occur in rocks similar in age and composition to those found within the Arctic Alaska Petroleum Province (Houseknecht and Bird 2006, Bird 2001). In the early 1990s the Northstar (Seal Island) field was discovered and is recognized as the first petroleum producing field from Arctic Alaska federal offshore lands. The Northstar field lies within both State of Alaska and federal waters north of Prudhoe Bay.

For planning purposes the following terms, as defined in *Undiscovered Oil and Gas Resources, Alaska Federal Offshore-As of 2006* (Minerals Management Service 2006b), are utilized by stakeholders when describing physiographic and geologic features and economic assessments of petroleum resources. MMS 2006a *Common Assessment Terms* is quoted below for brevity:

- ***Prospect*** **-** an untested geologic feature having the potential for trapping and accumulating hydrocarbons.
- ***Pool*** – a subsurface accumulation of liquid or gaseous hydrocarbons, typically within a single stratigraphic interval, that is hydraulically separated from any other hydrocarbon accumulation.
- ***Field*** **-** a pool or grouping of related pools, sufficiently large to be economically producible.
- ***Play*** – a family of geologically related prospects, having similar hydrocarbon source, reservoir, and trapping mechanism.
- ***Basin*** – a large downwarped region serving as a center of sediment deposition. It can contain numerous geologic plays.
- ***Province*** – a large area or region unified geologically by a single dominant structural element or a number of contiguous elements. A province can be defined to contain a single basin or may contain several related or similar basins.
- ***Planning Area*** – an administrative subdivision of an offshore area used as the initial basis for considering blocks to be offered for lease in the Department of Interior offshore oil and gas leasing program.
- ***Undiscovered, technically recoverable resources (UTRR)*** – focus on geologic attributes. The resource potential is estimated without being constrained by economic considerations, such as the existence of transportation infrastructure to take the resources to market. The only constraint is

that conventional recovery techniques are assumed. The reported resources are those that would be produced at the surface, but estimates of recovery efficiency are based on current, known techniques. Ranges of values imply that some improvement in efficiency is considered, but dramatic improvements from unknown future techniques are not included.

3.1.3.1 Regional Physiography

The Arctic Alaska offshore region is divided into five distinct physiographic features (Figure 3.1-14). The boundaries of the features are delineated by geology, geography, water depth, and bathymetric surface relief of seafloor morphology. From east to west they include the Beaufort Shelf, the Canada Basin-Beaufort Shelf, the Chukchi Borderland, the Chukchi Shelf, and the Hope Basin. The Canada Basin-Beaufort Slope lies north of the Beaufort Shelf where its border with the Beaufort Shelf is recognized by sharp break in bathymetric slope that extends north and is expressed as a deep-water abyssal plain. This abyssal plain increases in depth northward and is ice-covered throughout much of the year. North of the Chukchi Shelf and west of the Canada Basin-Beaufort Slope is the Chukchi Borderland. The Chukchi Borderland is composed of submarine ridges and basins that trend north-south with water depths greater than 1,000 m (3,281 ft). Along the sub-sea boundaries of the features marked by sharp breaks in slope morphology, gravity-driven slope failures indicate that the most historically active seafloor features are gravity-driven slope failures (Grantz et al. 1994).

The Beaufort Sea area of the Alaska continental shelf is approximately 100 km (60 mi) wide, with water depths ranging from 10 to 200 m (30 to 660 ft). The Beaufort Shelf contains many barrier islands and shoals that are generated from sediment deposition at river mouths. The barrier islands and shoals origins are considered erosional remnants of coastal plain sediments, and constructional islands. The constructional islands are eventually overridden by storm surges, and migrate landward and to the west due to longshore marine currents.

The Chukchi Sea area is an approximately 600-km (400-mi) wide shallow embayment of the Arctic Ocean. The floor of the Chukchi Sea is a broad, northerly inclined, continental shelf in water depths generally less than 61 m (200 ft). Two shoals, the Hanna and Herald, lie within the Chukchi Sea (MMS 2006a). These shoals rise above the surrounding seafloor to approximately 20 m (66 ft) below sea level. In the Barrow and Hanna submarine canyons, water depths range from 50 to 200 m (160 to 660 ft) (MMS 2008).

The Hope Basin is bounded on the west by the U.S.-Russia maritime boundary and to the east by the northwest coastline of Alaska south of Point Hope into Kotzebue Sound, continuing southward along the northwestern coast of the Seward Peninsula near the Bering Strait. The Hope Basin province includes the easternmost part of the larger South Chukchi-Hope basin that extends 483 km (290 mi) west into Russian waters (MMS 2006a, Gautier and Klett 2010, Gautier et al. 2009). The Chukchi Borderlands is bounded on the south by the Chukchi Shelf, on the west by the Arlis Plateau, and on the east by the Northwind Ridge that separates the borderlands from the abyssal plain of the Canada Basin (Figure 3.1-14).

3.1.3.2 Regional Geologic Setting

The following summary of the geologic setting of north and northwest Alaska is based on previous work conducted by Alaska Department of Natural Resources (ADNR) (2009), Bird (2001), Gautier et al. (2009), Gautier and Klett (2010), Grantz et al. (1994), Houseknecht and Bird (2006), MMS (2006a, 2006b, 2008), Sherwood (1998, 2006), and Sherwood et al. (1996, 2001). Rocks within the continental shelves beneath the Beaufort and Chukchi Seas are recognized as direct geological extensions of rocks found onshore and near-shore in northern Alaska. Northern Alaska is a geologically complex region that over the last 400 million years (my) has undergone periods of tectonic plate collisions, continental rifting, regional uplift, and episodes of major erosion and sedimentary deposition. The principle geologic features of northern Alaska are presented in Figure 3.1-14. The Devonian age Chukchi and Arctic platforms are the oldest geologic features of the Arctic Alaska Petroleum Province and are recognized as remnants of a stable continental margin that existed in Northern Alaska some 345 to 395 million years before present [myBP].

The stable continental margin continued to exist through early Mesozoic time (about 200 myBP). The Chukchi and Arctic platforms are separated by the Hanna Trough that straddles the U.S.-Russia maritime boundary and extends from Point Lay northward to the North Chukchi Basin and straddles the U.S.–Russia maritime boundary. The Hanna Trough is a structural depression characterized by extensional normal faulting that received thick accumulation of sediments during Mississippian time (310 to 345 myBP) and into the early Mesozoic (Houseknecht and Bird 2006). The Barrow Arch is recognized as the expression of the onset of continental rifting (spreading apart) during the Late Jurassic through Early Cretaceous time (100 myBP). The trace of the Barrow Arch roughly parallels the northern Alaska coastline from Prudhoe Bay west past Point Barrow and continues to the northwest extending to the North Chukchi Basin (Figure 3.1-14). During this period of continental rifting, tectonic uplift dominated to the north of the Barrow Arch, whereas south of the arch, deposition of sediments continued into Cretaceous time. The oceanic Canada Basin and associated passive margin resulted from the development of the Barrow Arch (Houseknecht and Bird 2006). Also during this time of rifting along the southern margin of the Arctic and Chukchi platforms, a volcanic arc-continent collision perpetrated the creation of the Brooks Range, the adjacent Colville foreland basin, and the Herald Arch. The Herald Arch begins at the west end of the Brooks Range just south of Point Hope and extends northward to Cape Lisburne and continues west toward the North Chukchi Basin. The Herald Arch separates the Hope Basin to the south from the Chukchi Shelf on the north (Figure 3.1-14).

With continued uplift of the Brooks Range came deposition of sediments to the north onto the coastal plain during Early Cretaceous through Tertiary time (145 to 2 myBP). During Tertiary time convergent deformation events created the fold-and thrust belt of rocks that extends northward from the Brooks Range and is referred as the Foothills Belt (Houseknecht and Bird 2006, ADNR 2009, Bird 2001, Grantz et al. 1994).

3.1.3.3 Stratigraphy and Petroleum Resources

Geoscientists believe that a large portion of the undiscovered, technically recoverable oil and gas in Alaska OCS federal offshore waters will be found in the Beaufort and Chukchi seas of the Arctic Ocean. The Beaufort and Chukchi seas are predicted to contain 89 percent of the oil and 79 percent of the gas resources of the Alaska OCS. The Beaufort and Chukchi seas are estimated in the mean case to contain more than 23 billion barrels of oil and over 104 trillion cubic feet of gas (MMS 2006b).

Northern and Arctic Alaska

Evidence from surface outcrops, exploration drilling, and geophysical assessments have identified four major geologic sequences of rocks north of the Brooks Range, each having a unique structural setting, sediment source area, and depositional environment. These rock sequences extend north and northwest beneath the Beaufort and Chukchi shelves and are geologically important in the Arctic Alaska Petroleum Province. The four major rock sequences from oldest to youngest are the Franklinian, Ellesmerian, Beaufortian, and Brookian. The stratigraphic record of rocks within the Arctic Alaska Petroleum Province includes Precambrian age rocks (more than 600 myBP). The Precambrian age rocks have undergone intense periods of temperature and pressure changes that erase the potential of hosting economic quantities of petroleum hydrocarbons. Rocks within Northern Alaska with a potential for petroleum accumulation have ages of 310 to 345 myBP (Mississippian) and younger (Bird 2001, Houseknecht and Bird 2006).

The pre-Mississippian age Franklinian sequence consists of fractured carbonate, argillite, quartzite, volcanic, and granitic rocks that represents the stable continental platform before Devonian time (345 to 395 myBP). The Franklinian sequence was deformed, uplifted, and eroded during Cambrian (500 to

600 myBP) through Devonian time. Following the uplifting event, the Franklinian high was eroded and was the northerly source of sediments for the Ellesmerian sequence. The Franklinian rocks have undergone burial and metamorphism. This characteristic has given the Franklinian sequence rocks limited petroleum potential and they are considered to be the economic basement rocks of the Arctic Alaska Petroleum Province (ADNR 2009, Houseknecht and Bird 2006).

The Ellesmerian sequence consists of marine carbonates and quartz- and chert-rich clastic rocks and is the most important sequence geologically in terms of petroleum production. The Ellesmerian sequence rocks were deposited over a 150 my period during the Mississippian through Early Jurassic time (approximately 195 myBP). The Ivishak Formation is an alluvial fan-delta complex that was deposited within the Ellesmerian sequence in Permo-Triassic time (200 to 300 myBP) and forms the reservoir for the giant Prudhoe Bay Oil Field that has produced over 12 billion barrels of oil (ADNR 2009). Continental shelf deposits of the Ellesmerian accumulated on a south-facing passive margin of the Arctic Platform (Houseknecht and Bird 2006). To the west, thick accumulations of Ellesmerian strata were deposited into the Hanna Trough. On the Chukchi Platform beyond the trough, Ellesmerian sediments are rare and when present have very limited thickness. Although the Ellesmerian sequence contains both petroleum source and reservoir rocks, petroleum was not generated in the source rocks, which lie near the top of the sequence, until they were buried by Beaufortian and Brookian deposits (Houseknecht and Bird 2006).

The Jurassic and Lower Cretaceous age (approximately 150 to 100 myBP) Beaufortian sequence is associated with uplift and faulting within the Barrow Arch. This sequence is also referred as the Beaufortian Rift sequence. Uplift and faulting of the Franklinian and Ellesmerian sequences resulted in normal fault blocks consisting of horst (highlands) and graben (basin) structures. The grabens were filled with sediments from nearby locally uplifted or block-faulted Ellesmerian and Franklinian sequences forming the Beaufortian Rift sequence. During this period of geologic time the Barrow Arch formed along the northern reaches of the Beaufort Coast. The Beaufortian sequence consists of fine-grained sediments (mudstones and siltstones) that contain petroleum source and reservoir rocks. Uplift and erosion along the Barrow Arch created a regional erosion boundary referred to as the Lower Cretaceous Unconformity or LCU. The LCU helped create secondary porosity in potential reservoir rocks and an associated migration conduit to transport oil and gas from source rocks. Some of the largest oil accumulations in Northern Alaska are attributed to the LCU. The large spatial erosional activity attributed to the LCU is geologically significant by helping to create secondary porosity in potential reservoir rocks and creating a conduit for the migration of oil and gas into these enhanced porosity reservoirs (ADNR 2009). Evidence of this geologically significant erosion event is provided by three prolific oil producing formations within the Ellesmerian sequence, the Kuparuk A Sandstones, and the Ivishak and Kekiktuk formations, all three of which lie directly below the LCU (ADNR 2009). Cretaceous age fine-grained sediments that overlie the unconformity act as a seal, thereby creating structural and stratigraphic traps (Houseknecht and Bird 2006).

Cretaceous and Tertiary age deposits that originated from erosion of the Brooks Range high are assigned to the Brookian sequence. These sediments were shed from the Brooks Range during latest Cretaceous and Paleocene time (60 to 70 myBP), filling the Colville foreland basin and trough, and continued seaward eventually topping the Barrow Arch and extending beyond the coastline onto Alaska's continental margin. Throughout the North Slope basin the Brookian sequence rocks host large petroleum accumulations. The Brookian sequence consists of marine mudstone (Hue Shale); deep marine sequences of mudstone and sandstone (Torok, Seabee, and Canning Formations); and shallow-marine to nonmarine sandstone, mudstone, and conglomerate (Nanushuk, Tuluvak, Prince Creek, Schrader Bluff, and Sagavanirktok Formations). The non-marine sediments all contain amounts of coal-bearing strata intertwined within the host rocks (Houseknecht and Bird 2006). The Hue Shale contains organic-rich beds that are important oil source rocks. The Brookian sequence mudstones may contain gas source rocks. The marine and nonmarine sandstone reservoir rocks with documented oil and gas accumulations occur within both structural and stratigraphic traps within the Brookian sequence (Houseknecht and Bird

2006). Documented oil and gas accumulations and fields within the Brookian sequence include West Sak, Schrader Bluff, Ugnu, Flaxman Island, and Badami. One known field of the Brookian sequence is recognized in the OCS, the Hammerhead accumulation (ADNR 2009).

The Quaternary age unconsolidated sediments of the Gubik Formation exposed onshore on the Alaska North Slope unconformably overlie low indurated sediments of the upper Brookian sequence. The Gubik formation sediments consist of sand and gravel deposits derived by erosional activity within the last million years from both the Brookian sequence and the present day Brooks Range (ADNR 2009).

<u>Hope Basin</u>

The Hope Basin is disconnected from rocks found within onshore Alaska north of the Brooks Range and the Arctic offshore north of the Herald Arch. The Hope Basin lacks most of the key geological attributes that are found in northern Alaska which are favorable to creation of petroleum deposits. In U.S. waters, the Hope Basin is filled with Cenozoic age (up to 65 myBP) rocks with characteristics that suggest gas is the dominant resource (Sherwood 1998). Cretaceous age (65 to 145 myBP) rocks with potential oil attributes may lie within the Hope Basin in Russian waters (Sherwood 1998, Gautier and Klett 2010). Outcrops surrounding Hope Basin indicate that basin fill consists of Eocene age (34 to 56 myBP) volcanics, volcaniclastics, conglomerates and sandstones, which are overlain by Oligocene age (24 to 34 myBP) shallow-marine to nonmarine sandstones, siltstones, and conglomerates (MMS 2006a). The Hope Basin also includes the smaller local Kotzebue basin. The two basins are separated within the planning area by the Kotzebue Arch. The Tertiary aged (65 to 2 myBP) divergent Hope and Kotzebue basins are recognized to be related to right-lateral movement along the Kobuk fault zone recognized onshore in northwest Alaska. Basin development likely began in the early Tertiary (MMS 2006a).

3.1.3.4 Exploration and Production

<u>Petroleum Plays</u>

A total of 14 individual petroleum plays are identified for the Beaufort Sea offshore region. Plays in the Beaufort Sea target specific stratigraphic units. Of the 14 individual plays, nine are targeting strata within the Brookian sequence of rocks. Of the remaining five plays, one is targeting Beaufortian Rift sequence rocks, and another is targeting Upper Ellesmerian sequence rocks. The remaining three plays are targeting undeformed pre-Mississippian basement rocks, Endicott Formation rocks, and Lisburne Formation rocks (MMS 2006a).

The Chukchi Sea region is underlain by five distinct basins that are varyingly deformed by complex faulting and folding. The structural complexity of the faulting and folding has formed a large number of petroleum prospects that are mappable using only conventional 2D seismic data. Rocks equivalent to oil source sequences recognized in northern Alaska have been encountered during exploratory drilling (MMS 2006a). A total of 29 individual plays are identified for the Chukchi Sea offshore region. Plays in the Chukchi Sea target both specific stratigraphic units and structural features. Of the 29 individual plays, 14 are targeting strata within Brookian sequence rocks, three are targeting strata within Beaufortian Rift sequence rocks, and one is targeting the Herald Arch thrust structure. Of the remaining 11 plays, one is targeting strata within Franklinian sequence rocks, two are targeting Endicott Formation rocks, two are targeting Sadlerochit Group rocks, and one is targeting Lisburne Formation rocks. The five remaining plays are targeting Tertiary age strata within an area where the Chukchi Shelf and Hope Basin converge (MMS 2006a).

Hope and Kotzebue basins contain faulted structures and stratigraphic traps as potential targets. A total of 4 individual plays are identified for the Hope Basin. These plays are predominantly gas pools with a minor fraction containing mixtures of oil and gas (MMS 2006a).

Exploration History

Arctic Alaska

Oil seeps were first discovered in the Cape Simpson area near the northernmost tip of Alaska by the U.S. Geological Survey in 1917. Based on the presence of these seeps, President Warren Harding established the Naval Petroleum Reserve No. 4 in 1923. The Naval Petroleum Reserve No. 4 was later renamed the National Petroleum Reserve-Alaska (NPR-A). NPR-A consists of approximately 23 million acres situated within the west central portion of northern Alaska. The onset of World War II prompted the first publicly funded exploration program in the NPR-A from 1944 to 1953 (Sherwood et al. 1996). As a result of the drilling from 1944 to 1953, small oil fields were discovered at Umiat, Simpson, and Fish Creek and gas fields were discovered at Gubik, South Barrow, Meade, Square Lake, Oumalik, and Wolf Creek. Following passage of Alaska statehood in 1959, exploration was focused on State of Alaska lands situated between the NPR-A and the Arctic National Wildlife Refuge (ANWR) to the east. Following the initial lease sale of State of Alaska lands in 1964 and 1965, came the 1968 discovery of the Prudhoe Bay field, the largest oil field ever found in North America at that time (Sherwood et al 1996). The Prudhoe Bay discovery lead to other oil fields being discovered including Kuparuk (1969), West Sak (1969), Milne Point (1970), Flaxman Island (1975), Point Thomson (1977), and Sag Delta-Duck Island (1978), later called the Endicott field (MMS 2006a).

The 1973 embargo of the United States by the Organization of Petroleum-Exporting Countries (OPEC) drove federally funded exploration of NPR-A in 1975. Exploration in NPR-A continued for seven years and led to discoveries of small oil and gas fields at East Barrow and Walakpa. South Barrow, East Barrow, and Walakpa gas fields near the community of Barrow are being utilized for local consumption. Since the 1990s, petroleum accumulations discovered in stratigraphic traps have been developed including the Alpine pool in the Colville River unit and Lookout and Sparks discoveries in NPR-A that tap sandstones of the Beaufortian sequence. The Badami unit, the Tarn and Meltwater pools in the Kuparuk River Unit, and Nanukq pool in the Colville River unit tap sandstones in the Brookian sequence. The Tabasco pool in the Kuparuk River unit taps channel sandstones in the Brookian sequence (Houseknecht and Bird 2006). In 2003 and 2004, two new field units were formed, the Oooguruk and Nikaitchuq, with wells testing positive for oil.

Beaufort Shelf

A total of 30 exploratory OCS wells have been drilled on the Beaufort Shelf since the first Federal OCS leases were offered in 1979. Many more wells have been drilled in the nearshore Beaufort Sea under the jurisdiction of the State of Alaska. Locations of the OCS exploration wells drilled in the Beaufort Shelf region are presented in Figure 3.1-13. The wells were drilled in the Beaufort Sea between 1981 and 2003, resulting in the discovery of several commercial and subcommercial pools of oil. The Mississippian age Kekiktuk formation of the Endicott Group hosts oil at Tern Island (Liberty field). The Permo-Triassic age Ivishak Formation hosts oil at Seal Island (Northstar field). Cenozoic age Brookian sequence rocks host oil at the Hammerhead and Kuvlum wells. Two wells drilled into Salerochit sands at the Sandpiper prospect encountered significant quantities of gas and condensate (MMS 2006a). The Sagavanirktok River formation penetrated in the Phoenix and Antares wells hosted minor amounts of oil. The Salerochit Group of rocks penetrated in the Mukluk and Mars wells also hosted minor amounts of oil. Cenozoic age sands penetrated by the Galahad well hosted minor amounts of gas and an oil show. Brookian sandstone sequence penetrated by the McCovey well showed oil in core samples (MMS 2006a).

Chukchi Shelf

A total of five exploratory wells have been drilled on the Chukchi Shelf since the first OCS leases were offered in 1988. The locations of the exploration wells drilled in the Chukchi Shelf region are presented in Figure 3.1-13. The wells were drilled between 1989 and 1991, resulting in the discovery of hydrocarbons in four of the wells (Burger, Klondike, Crackerjack, and Popcorn).

The Klondike well was drilled to investigate Sadlerochit-equivalent rocks beneath a Jurassic age erosional surface on the east flank of the Chukchi platform. The Sadlerochit equivalent rocks are within a shale facies, and no reservoir rock was discovered. However, oil hosted in Brookian sequence rocks near the base of the Torok Formation was encountered in the Klondike well (MMS 2006a). The Burger well was drilled to investigate Beaufortian Rift sequence rocks equivalent to the Kuparuk Formation in the Wainwright Dome on the east flank of the Hanna Trough. The Burger well discovered a pool of gas within a 32.5 m (107 ft) thick Kuparuk-equivalent Beaufortian Rift sequence sandstone. The Popcorn well drilled into Sadlerochit-equivalent and older rocks on a faulted uplift block along an extension of the Barrow Arch that separates North Chukchi and Colville basins. The Popcorn test well failed because no reservoir rock was encountered. However, oil shows were found in sandstones of the Torok Formation and within the Permian and Pennsylvanian age carbonate rocks of the Lisburne Group. The Crackerjack well investigated Sadlerochit-equivalent rocks in a stratigraphic trap on the flank of a horst. The test well was deemed unsuccessful because no porous reservoir was encountered. However, sandstones at the base of the Early Cretaceous age Torok Formation appeared in geophysical electric logs to contain an oil pay zone. Sandstones of the Nanushuk Group also hosted minor oil shows in the Crackerjack test well (MMS 2006a).

Hope Basin

A total of two onshore exploration wells were drilled in the Hope and Kotzebue basins in 1975. The Cape Espenberg well and Nimiuk Point well were drilled on State of Alaska lands on the south and north flanks, respectively, of Kotzebue basin. No oil or gas shows were discovered in Tertiary age sediments penetrated by these two wells. Eocene and Miocene age stages of faulting caused structural deformation in Hope basin. Deformed Mesozoic and Paleozoic age rocks of the Brookian-Chukotkan mountain belt exposed on Wrangel Island (Russia) and on Cape Lisburne (Alaska) make up the basement for sediments in the northern parts of Hope basin. Cretaceous age igneous and sedimentary rocks like those exposed in the northern Yukon-Koyukuk province of Alaska form the basement for sediments in the eastern portion of the Kotzebue basin. The estimated maximum thickness of sediment fill in both Hope and Kotzebue basins is approximately 5,500 m (18,000 ft) (MMS 2006a).

Petroleum Production

Houseknecht and Bird (2006) succinctly summarize the petroleum production history of the Alaska North Slope:

> *Approximately 15 billion barrels of oil has been produced from the Arctic Alaska Petroleum Province and proven reserves are estimated at more than 7 billion barrels of oil and 35 trillion cubic feet of gas. Most oil production is from Ellesmerian reservoirs, consisting of Mississippian through Triassic marine carbonate and marine to nonmarine siliciclastic deposits that accumulated on the shelf of a passive continental margin. Lesser production has been from Beaufortian reservoirs, consisting of Jurassic through Early Cretaceous marine siliciclastic deposits associated with the rift opening of the Canada Basin, and from Brookian reservoirs, consisting of Cretaceous through Tertiary marine to nonmarine siliciclastic strata deposited as wedges of sediment shed from the Brooks Range orogenic belt. Most production is from structural and combination structural-stratigraphic traps, although several recent oil discoveries are in purely stratigraphic traps.*

3.1.3.5 Seafloor Features

Within the Beaufort Sea and Chukchi Sea regions, active dynamic surficial processes occur along the surface of the seafloor. Most of the available information regarding these processes reflects the voluminous amount of studies that have been conducted within the Beaufort Sea region making it one of the most studied shelves in the world. The most recent studies for the Beaufort and Chukchi seas have been for the oil and gas industry.

Permafrost

The occurrence and extent of permafrost onshore Alaska is well documented and understood, however, the occurrence and extent of permafrost offshore is not well known. Permafrost is defined as rock or soil that has exhibited temperatures below 0°Centigrade continuously for 2 or more years. Onshore Northern Alaska permafrost extends to depths of 660 m (2,165 ft). Permafrost in sediments off-shore was first recognized in 1972 beneath the Beaufort Sea off the McKenzie River Delta. Off-shore permafrost depths are variable due to interaction with warm marine currents and saline rich groundwater. Seafloor sediments are usually unbonded due to the salinity of the seawater. Buried sediments normally do not contain ice due to the presence of dissolved salts, confining pressure, and capillary forces. These characteristics lower the freezing point of pore water below the ambient temperature. Numerous geophysical surveys and geotechnical investigation boreholes indicate that permafrost is widespread beneath the Beaufort inner shelf, however highly irregular. Fine-grained, semi-lithified deposits of the Gubik Formation are recognized to having a direct relationship with bonding of seafloor sediments found within the Beaufort Shelf. Low permeable silts and clays of the Flaxman Member of the Gubik Formation form a barrier to the infusion of saltwater that would lower the thaw point and cause ice to melt. The depth to the surface of subsea permafrost and boundary between bonded and unbounded permafrost is highly variable. Depths to bonded permafrost have been shown to be as shallow as 10 m (33 ft) in 2 m (6.6 ft) of water. Studies have identified that the depth to subsea permafrost is variable due to different degrees of ice bonding before the region was inundated with warm water of the Holocene age (10,000 years BP) marine transgression. Other studies have speculated that the amount and distribution of subsequent thawing is probably due to the introduction of saline groundwater originating from deeper depths. These observations suggest that subsea permafrost melting is occurring from above and below (MMS 2003).

In Pleistocene times (2 myBP to 10,000 year BP) the Beaufort Shelf was exposed to the Arctic atmosphere during several lowstands of sea level. Throughout this period, bonded permafrost is thought to have formed to depths of several hundred meters beneath the exposed shelf. Pleistocene age highstands of sea level generated warm seawater and saline advection from the seawater into the underlying sediments causing the bonded permafrost to melt partially both from above by thermal heating and from below by geothermal heating. Geotechnical investigations in the Prudhoe Bay area reported that seafloor sediments are at or below the freezing point, although it is not bonded permafrost (MMS 2003).

In the Chukchi Sea, the distribution and extent of subsea permafrost is sparse or non-existent, and where present, becomes thin or absent at approximately 1 km (0.6 mi) offshore. Many workers believe that the absence of relict permafrost beneath the Chukchi Shelf may be due to the lack of significant deposits of unconsolidated sediments near surface when lowstands of sea level occurred, or to relatively warm currents moving north from the Bering Sea (MMS 2007a).

Ice Dynamics

Ice gouging and ice push are two common seafloor features. In the Beaufort Shelf region in water depths ranging between 18 and 50 m (50 to 160 ft) ice gouging is a common characteristic. Ice gouging is a significant process for sediment transport on Arctic continental shelves, especially at midshelf and innershelf water depths. In the midshelf regions of the Arctic continental shelves, ice ridges with deep keels have been observed to produce scour along the seafloor to depths of several meters. Ice gouging is mostly concentrated in water depths of 18 to 30 m (59 to 98 ft) and increase in intensity on the seaward slopes of shoals. In the area of Prudhoe and Foggy Island bays, the intensity of ice gouging is dictated by the barrier or constructed island chains that occur roughly 15 to 20 km (9 to 12 mi) from the shoreline (MMS 2003).

In the Harrison Bay region that is free of barrier islands, ice gouging is concentrated in two zones of water depths, between water depths of 10 and 20 m (33 to 66 ft). In parts of Foggy Island Bay beneath shorefast floating ice, ice gouging is very limited in extent. In other areas of shorefast floating ice, ice gouging is generally found associated with discontinuous, sparse, narrow, and shallow features (MMS 2003).

The abundance of ice-gouge in the Chukchi Sea is dependent on geographical latitude and the angle or slope of the seafloor, and decreased in abundance with increasing water depth. In deep water up to 35 m (110 ft), ice gouging in the Chukchi Sea is less concentrated and generally is wider, deeper, larger, and more linear than ice gouges in shallower water. Within the Barrow Sea Valley and Hanna Shoal regions of the Chukchi Sea, ice gouges are the dominant seafloor feature (MMS 2007a).

Throughout the Beaufort and Chukchi seas, ice-push and ice-override processes are significant methods of sediment transport and erosion. Strong winds and/or currents push blocks of ice onshore that displaces sediment into ridges farther inland. Ice-push ridges up to 2.5 m (8 ft) high and extending 100 m (330 ft) inshore have been found on some of the outer barrier islands (MMS 2003). Ridges up to 5 m (16 ft) high have been documented along the Chukchi Sea coast between Barrow and Wainwright (Mahoney et al. 2004). Throughout the Arctic coast, ice-push rubble has been identified 20 m (66 ft) inland (MMS 2003).

Strudel scour is another important process that occurs near sheltered coastal areas and river mouths. The Colville, Sagavanirktok, and Canning rivers are common locations where strudel scouring has been identified (MMS 2003). Strudel scours as deep as 6 m (20 ft) and as wide as 20 m (66 ft) have been observed near major river mouths. MMS (2003) presents a description of strudel scour developed from Reimnitz, Rodeick, and Wolf (1974) where the process *strudel scour* and feature *strudel scours/scouring* are differentiated:

> *During spring runoff, landfast sea ice is inundated by river floodwaters. Extensive areas of the fast ice near major river mouths are covered as far as 6.5 km (4 mi) from shore to depths of up to 1.5 m (4.9 ft). When the floodwater reaches holes or small cracks in the ice called strudel, it rushes through with enough force to scour the bottom to depths of several meters* (MMS 2003; Reimnitz, Rodeick, and Wolf 1974).

Sediment Transport Dynamics

In the Beaufort Sea, coast-parallel marine currents that are wind driven and strongly influenced by presence or absence of ice, are the primary sediment transport mechanisms. This sediment gets deposited along coast promontories and along barrier islands (MMS 2003). Due to the short open-water season, the annual rate of longshore sediment transport is relatively low. There are three types of shelf currents that occur in response to prevailing wind directions: inner-shelf, open-shelf, and outer shelf. Inner shelf currents generally flow to the west (MMS 2003). Open shelf currents average between 7 and 10 cm/s over the broad Bering Shelf. Outer shelf currents or Geostropic currents flow parallel to the break in shelf-slope in both easterly and westerly directions (MMS 2003). These currents transport fine-grained sediment and deposit them on the continental shelf and outer slope regions.

In the Chukchi Sea, fine-grained sediments that cover much of the continental shelf originated from the Yukon and other rivers of western Alaska were transported north by the Alaska Coastal Current. Sand and gravel concentrations tend to be higher over some of the shoals, and may be from relict submerged shoreline or residual cliff-eroded deposits. Migrating asymmetric bedform features or sand waves occur in the Chukchi in water depths ranging from 6 to 90 m (20 to 300 ft). Sand waves up to 3 m (10 ft) high generally occur in shallower water off Icy Cape and Cape Lisburne and migrate northward in response to the Alaska Coastal Current. Bedforms in deeper waters reach more than 6 m (20 ft) high and appear to migrate under the influence of westward or southward countercurrents and eddies (MMS 2007a).

Buried Channels

In the middle and inner portions of the Beaufort shelf, relicts of stream channels are buried offshore of modern river deltas. These buried stream channels generally trend north and are cut into Pleistocene age deposits and produce infill and overbank stratification features. These relict stream channels are thought to be extensions of the modern-day Canning or Sagavanirktok rivers onto the paleo-Arctic coastal plain (MMS 2003).

Buried channels are abundant in the northern and central Chukchi Sea, forming cross-cutting, generally north-trending drainage complexes. These represent successive layers of Pleistocene and Holocene sediments filling channels cut into Cretaceous bedrock, with the different channel bottom depths representing erosional baselines for different lower sea-level stands (MMS 2007a).

Shallow Gas

Shallow gas, when concentrated and under pressure by being trapped at shallow subsurface depths, typically between 100 and 1,000 m (300 and 3,000 ft), poses a drilling hazard. Numerous anomalies associated with shallow gas have been indicated on seismic profiles throughout the Beaufort Sea as isolated pockets beneath permafrost, associated with faulted strata, and as concentrations in submerged coastal plain sediments and peat deposits. Because these anomalies are avoided after being identified in shallow hazard surveys and because the gas is not an exploration target, shallow gas has not been detected in most offshore Beaufort Sea exploration wells. Free-flowing gas was encountered in one U.S. Geological Survey well in Stefansson Sound, and shallow gas has been inferred from seismic data in Harrison Bay and extensive areas of the outer shelf (MMS 2003). Shallow gas was also encountered at about 1,700 feet in the Hammerhead structure drilled in the 1980s (e.g. Unocal 1986).

Shallow gas has been mapped in the Chukchi Sea from both seismic data and water column anomalies, which probably represent gas rising from the seafloor. In the northern part of the Chukchi Sea and east-central shelf area, acoustic “wipe-out” zones representing either biogenic or thermogenic gas are found in Pleistocene sediment in buried channels, as well as in Tertiary and Cretaceous age strata. Depending on depth, trapping mechanisms, and the presence or absence of an effective seal, some gas accumulations could be overpressured (MMS 2007a). In particular, there is the potential for shallow gas along the Burger structure due to faults which extend from the deeper target zone upwards close to the seafloor (e.g. Craig and Sherwood 2004) that could act as conduits for gas migration.

3.1.4 Climate and Meteorology

3.1.4.1 Introduction

This section describes existing climate and meteorology in the project area. This information is intended, in part to establish baseline information that will provide a context for assessing climate change effects that may result from implementation of the proposed action and alternatives and, conversely, the potential effects of climate change on the proposed action and alternatives in Chapter 4 of this EIS.

3.1.4.2 Regulatory Overview

Council on Environmental Quality Draft NEPA Guidance

Currently there is no well-established guidance for considering climate change as a part of the NEPA process. NOAA and other federal agencies have begun to examine how to address climate change within their realm of responsibility, but these efforts are still in progress. The Council on Environmental Quality (CEQ) has provided draft guidance for consideration of the effects of climate change and greenhouse gas (GHG) emissions, and this approach is being followed for this analysis (CEQ 2010a). Per this draft guidance, climate change issues arise in relation to:

1) The GHG emissions effects of a proposed action and alternative actions; and

2) The relationship of climate change effects to a proposed action or alternatives, including the relationship to proposal design, environmental impacts, mitigation, and adaptation measures.

The CEQ recommends climate change and impacts of greenhouse gases from proposed projects be evaluated in NEPA documents if the proposed action is reasonably anticipated to cause direct emissions of 25,000 metric tons or more on an annual basis (CEQ 2010a).

Final Mandatory Reporting of Greenhouse Gases Rule

The Environmental Protection Agency (EPA) has issued the Final Mandatory Reporting of Greenhouse Gases Rule (EPA 2011b), which requires reporting of GHG emissions from large sources and suppliers in the United States. Section 3.1.5.2, Air Quality, provides further background on this rule.

3.1.4.3 Meteorology

The majority of the project area is located within the polar maritime subtype of the Arctic climate region, meaning that it is influenced by the Arctic Ocean (Alaska Climate Research Center 2002). The Arctic climate is characterized by high spatial variability and affected by the extreme solar radiation conditions of high latitudes. The low sun angle present in the Arctic due to its high latitude (elevation of the sun above the horizon) means that shading caused by the most minor topographic features can cause relatively major differences in local climate; heat gain during long summer days in the Arctic is still relatively small.

Weather patterns in summer are dominated by the movement of low pressure systems (cyclones) across Siberia and into the Arctic Basin (NSIDC 2011a). In the winter, solar radiation is weak or absent, and weather is dominated by the frequent occurrence of inversions (when warm air lies above a colder air layer near the surface), resulting in relatively low surface wind speeds (NSIDC 2011a).

The southwestern portion of the EIS project area, from approximately Point Hope to the southwest project terminus, is within the West Coast Climate Region (Alaska Climate Research Center 2002). This climate region is considered a transitional zone, and is influenced by the high winds, strong storms, and interannual sea ice of the Bering Sea, as well as the air masses of the Interior Climate Region to the east.

Due to the influence that proximate water bodies have on the meteorological conditions within the project area, the following meteorology discussion is separated into areas in and adjacent to the Beaufort and Chukchi seas. Specific weather stations were selected to represent existing conditions in each sub-area, including data on air temperature, precipitation, and wind. These weather stations were selected based on availability of substantial data records and their proximity to the onshore communities within the project area. Table 3.1-1 lists the weather stations analyzed for describing existing conditions in the Beaufort Sea and Chukchi Sea sub-areas. Table 3.1-2 at the end of this section provides a summary of air temperature, precipitation, and winds for the weather stations listed in Table 3.1-1 (Prokein et al. 2011).

Table 3.1-1 Weather Stations by Sea

Beaufort Sea	Chukchi Sea
Barter Island[1]	Wainwright
Deadhorse/Prudhoe Bay[2]	Cape Lisburne
Barrow[3]	Kotzebue

Notes:

1) The Barter Island station was selected due to its proximity to Kaktovik, since complete meteorological data for Kaktovik was not found to be available.
2) Deadhorse and Prudhoe Bay data are considered be to represent the same geographic location, due to their immediate proximity to one another.
3) Although Barrow is included in the Beaufort Sea category, it is also influenced by the Chukchi Sea since it is located at the boundary between the two seas.

Air Temperature

Temperatures in the region are considered relatively mild for Alaska due to the proximity of the ocean; with relatively small seasonal temperature fluctuations compared to areas further inland (Table 3.1-2).

Beaufort Sea

For the majority of the year, temperatures are below freezing. During summer months (June through September) average maximum daily temperatures are above freezing for all three stations reviewed: Barter Island, Prudhoe Bay, and Barrow. Average maximum temperatures are highest in July, ranging from approximately 45 degrees-Fahrenheit (°F) to 55 °F, while average minimum temperatures are lowest in February at around -25 °F (WRCC 2011a). Historically, extreme temperatures have been recorded as high as 82 °F in Deadhorse (August 1999) and as low as -59 °F in Barter Island (February 1950) (WRCC 2011b).

Chukchi Sea

Sub-freezing temperatures dominate for the majority of the year, and the Chukchi Sea is almost totally ice covered from early December to mid-May. A brief warm and snow-free season follows in June, July, and August. Summer high air temperatures average from 40 to 60 °F. Summer ice breakup is initiated in the eastern portion of the Chukchi and progresses westward, due to the inflow of warmer water from the Bering Sea (MMS 2007a).

Annual average temperatures typically fall between 10 °F and 22 °F. Historical extreme temperatures have been recorded as high as 85 °F in Kotzebue (July 1958) and as low as -56 °F in Wainwright (February 1964) (WRCC 2011b).

Precipitation

Beaufort Sea

During the winter, the Beaufort-Chukchi Sea region is dominated by a ridge of high pressure linking the Siberian High and high pressure over the Yukon of Canada. Rainfall usually is light during the short summers; however, heavier rainstorms occasionally occur, with the greatest amount of precipitation falling in July and August. Snow cover in the region begins between late September and early October and disappears from late May through the mid-June (MMS 2003).

Total annual precipitation recorded at the weather stations indicates that the Beaufort Coast receives an annual precipitation ranging from approximately four to six inches, while average snowfall ranges from approximately 30 to 42 inches. The amount of annual precipitation includes the melted amount of any frozen precipitation (e.g. snow, sleet) that may have fallen, in addition to any rain.

Chukchi Sea

Western-Pacific low-pressure systems, which are associated with cloudy skies, frequent precipitation, and southwesterly winds, move northeasterly through the Bering Sea into the Chukchi Sea, where they follow the northwestern Alaska coast. During the winter, the Chukchi Sea region is dominated by a ridge of high pressure linking the Siberian High and high pressure over the Yukon of Canada (MMS 2007a).

From June through August, the occurrence of low visibility in the open sea ranges from 25 to 30 percent. This value decreases toward the mainland coast (10 percent). During the central winter months, the occurrence of low visibility does not increase more than 10 to 15 percent, because snowstorms causing visibility of <1 km (0.6 mi) are infrequent (MMS 2007a).

Total annual precipitation recorded at the weather stations indicates that the Chukchi Sea coast receives an annual precipitation ranging from approximately four inches to 11 inches, while average snowfall ranges from approximately 40 to 53 inches per year. The amount of annual precipitation includes the melted amount of any frozen precipitation (e.g. snow, sleet) that may have fallen, in addition to any rain.

Wind

The communities within the project area as a whole tend to have moderate winds throughout the year, with averages ranging from approximately 11 to 13 miles per hour (mph) (Table 3.1-2). Wind speeds tend to remain relatively constant throughout the year. Of the weather stations analyzed, Cape Lisburne near the western edge of the project area experiences the highest winds, with average winds in October exceeding 16 mph (WRCC 2011a). Winds blow from the east the majority of the year at each weather station analyzed; however, seasonal variations do exist.

Beaufort Sea

For weather stations along the Beaufort Sea, onshore winds are predominantly from the east, east-northeast, and northeast, while offshore winds are chiefly from the west, west-southwest, and southwest (WRCC 2011c). The dominance of onshore winds, also known as the sea breeze effect, is more prevalent in the summer months and reaches a peak in June when snow cover over land has diminished, and the land-sea thermal gradient is the most pronounced (MMS 2007b).

The weather stations at Barter Island, Prudhoe Bay, and Barrow generally experience easterly winds, although seasonal variations do exist. These alterations include prevailing winds from the west in January, March, and December at Barter Island; from the west-southwest in January and February and the east-northeast in February, March, and July at Deadhorse; and from the east-northeast in January and December in Barrow (WRCC 2011c).

Chukchi Sea

During the winter, northerly winds prevail in the Chukchi Sea; however, wind directions vary from northwest in the western part of the sea to northeast in the eastern part of the sea. Prolonged winds can lead to extreme ice pressures and dangerous wind chills. During the summer, the Chukchi Sea experiences alternating north and south winds (MMS 2007a).

The communities of Wainwright, Point Lay, Point Hope, Kivalina, and Kotzebue generally experience winds from the east, although seasonal variations do exist, including prevailing winds from the west in July and from the south-southwest in July and August in Wainwright; from the east-northeast in October at Point Hope; and from the west in May through August at Kotzebue (WRCC 2011c).

Storms

Beaufort Sea

Weather can change abruptly in the Beaufort Sea area and has been described as unpredictable by whaling captains and residents in nearby villages (MMS 2003). In the Beaufort Sea, storms can come in from all directions but have been observed to typically come in from the north (MMS 2003). Storms and high-wind events are typically most frequent in winter and fall.

Chukchi Sea

Storms are observed more often in winter than in summer in the Chukchi Sea, with approximately six to ten storm days occurring per month. Typical storm durations range from six to 24 hours, although stormy weather has been known to last for up to 14 days. The region can experience intense storms involving high winds (gusts recorded up to 100 mph), storm surges, and intense waves causing extensive damage and coastal flooding (MMS 2007a).

Table 3.1-2 Meteorological Data Summary by Community

Parameter	Beaufort Sea			Chukchi Sea		
	Barter Island	Prudhoe Bay	Barrow	Wainwright	Cape Lisburne	Kotzebue Airport
Average Wind Speed (mph)	10.9[3]	11.9[3]	12.7[3]	11.6[3]	12.8[3]	11.5[3]
Average Daily Peak Wind Gust (mph)	N/A	22.3[6]	22.2[7]	22.2[8]	N/A	22.6[10]
Prevailing Wind Direction[1]	E[4]	E[4]	E[4]	E[4]	E[4]	E[4]
Average Air Temperature (degrees-F)	9.8[5]	11.7[6]	10.2[7]	13.6[8]	17.5[9]	21.9[10]
Average Total Precipitation (in)	6.19[5]	4.26[6]	4.63[7]	4.11[8]	11.34[9]	9.72[10]
Average Total Snowfall (in)	41.8[5]	33.1[6]	29.5[7]	N/A[8]	41.4[9]	53.0[10]
Average Days of Precipitation per Year[11]	N/A	9.9[6]	12.6[7]	12.8[8]	N/A	32.5[10]

Notes:

N/A = Data not available.

1) Indicates direction wind blows *from*.

2) Days receiving at least 0.1 inch of precipitation

3) Period of Record: 1999 – 2006

4) Period of Record: 1992 – 2002

5) Period of Record: 1949 – 1988

6) Period of Record: 1999 – 2008

7) Period of Record: 1996 – 2008

8) Period of Record: 1949 – 1969

9) Period of Record: 1954 – 1984

10) Period of Record: 1996 – 2008

11) Days receiving at least 0.1 inches of precipitation

3.1.4.4 Climate Change in the Arctic

Climate Change

As with many fields of science, the field of climate change has many uncertainties and numerous theories. Outstanding questions such as how much and at what rate warming will occur, and how such effects will globally influence precipitation, storms, and wildlife habitat, etc. still remain relatively uncertain. However, in recent years, most scientists have come to acknowledge that: 1) increasing levels of carbon dioxide (CO_2) are changing the compositions of the earth's atmosphere; 2) the major GHGs emitted by human activities remain in the atmosphere for up to centuries; and 3) increasing GHGs concentrations tend to warm the planet (EPA 2011c).

Climate in the Arctic is showing signs of rapid change; nevertheless further study is needed to better understand the changes that have been observed and their significance to the Arctic Climate Region as well as global climate change. Since climate is inherently variable, and several climate cycle systems are known to influence climate patterns in the project area, climate patterns and trends within the project area are complex with several contributing factors.

Climate Cycle Systems

The Pacific Decadal Oscillation (PDO), the Arctic Oscillation(AO), and the North Atlantic Oscillation (NAO) all represent patterns of climate variability that are believed to influence the climate patterns and trends of the project area.

The PDO is used to describe the fluctuation in northern Pacific sea surface temperatures that alternate between above normal (negative phase) and below normal (positive phase) Pacific Ocean sea surface temperatures. These cycles operate on a 20- to 30-year time scale (NOAA 2011a), and have been shown to be associated with dramatic shifts in the climate of the North Pacific around 1948 and 1976 (Bond 2011). The last major shift in the PDO occurred in 1976-77 and marked a change from cold to warm conditions in Alaskan waters (Bond 2011).

The AO is a climate cycle system that influences climate patterns in the Arctic. The AO exhibits both a negative and positive phase. The negative phase is characterized with relatively high pressure over the polar region and low pressure at mid-latitudes (about 45 degrees North); the pattern is reversed in the positive phase. In the positive phase, higher pressure at mid-latitudes drives ocean storms farther north, and changes in the circulation pattern bring wetter weather to Alaska. Frigid winter air does not extend as far into the middle of North America as it would during the negative phase of the oscillation. Weather patterns in the negative phase are in general opposite to those of the positive phase (NSIDC 2011a). Over most of the past century, the AO alternated between its positive and negative phases. Starting in the 1970s, however, the oscillation has tended to stay in the positive phase, causing lower than normal Arctic air pressure and higher than normal temperatures in much of the United States.

The NAO is a climate system that is considered the dominant mode of winter climate variability for a wide geographic area, extending from the North Atlantic region, to central North America, Europe, and Northern Asia. The NAO is a large-scale alteration of atmospheric mass that controls the strength and direction of the westerly winds and storm tracks across the North Atlantic. A positive NAO index is associated with stronger and more frequent winter storms crossing the Atlantic Ocean. The NAO has trended toward the positive phase over the past 30 years (Bell 2011), which is associated with stronger and more frequent winter storms crossing the Atlantic Ocean. The NAO is very similar to the AO with respect to timing and effects on local temperatures and precipitation (Dickson et al. 2000).

Changes in the Arctic

Climate is naturally variable, and the Arctic is no exception having experienced climatic conditions that have ranged from one extreme to the other during a period of millions of years. Fossil records indicate that during the mid-Cretacous Period (approximately 120 to 90 my ago), the Arctic region was significantly warmer than present-day conditions, and the geography, atmospheric composition, ocean currents were considerably different than current conditions (ACIA 2005).

Evidence of climate change in the past few decades, commonly referred to as global warming, has accumulated from a variety of geophysical, biological, oceanographic, atmospheric, and anthropogenic sources. Such evidence includes scientific data, as well as traditional knowledge from Alaska Native communities along the Beaufort and Chukchi seas (further described below in Section 3.3.2.6). Since much of this evidence has been derived from relatively short time periods, and climate itself is inherently variable, the recent occurrence of unusually high temperatures may not necessarily be abnormal since it could fall within the natural variability of climate patterns and fluctuations. However, with that possibility, it should be noted that evidence of climate changes in the Arctic have been identified and appear to generally agree with climate modeling scenarios of GHG warming. Such evidence suggests (NSIDC 2011a):

- Air temperatures in the Arctic are increasing at an accelerated rate;
- Year-round sea ice extent and thickness has continually decreased over the past three decades;

- Water temperatures in the Arctic Ocean have increased;
- Changes have occurred to the salinity in the Arctic Ocean;
- Rising sea levels;
- Retreating glaciers;
- Increases in terrestrial precipitation;
- Warming permafrost in Alaska; and
- Northward migration of the treeline.

Although establishing such trends in the Arctic is challenging due to the small number of monitoring stations and relatively short records of data, the following statistics for the Arctic published as part of the Arctic Climate Impact Assessment (ACIA 2010, ACIA 2005) support these trends:

- A warming trend in the Arctic of 0.16 ºF per decade compared to 0.11 ºF per decade for the globe;
- A warming trend of 0.7 ºF per decade over last four decades;
- Precipitation has increased approximately one percent per decade over the past century;
- Snow extent has declined approximately 10 percent and permafrost has warmed by almost 3.6 ºF over the past three decades;
- Arctic Sea level has risen 10 to 20 centimeters (cm) in the past 100 years;
- Annual average sea ice extent has decreased by about eight percent, and the summer sea ice extent has decreased by 15 to 20 percent over the past three decades;
- Mean annual temperatures have increased by about 3.5 to 5.5 ºF over the last five decades;
- Sea ice thickness has decreased by 42 percent since the mid-1970s; and
- Winter temperatures have increased by about 5.5 to 7 ºF over the last five decades.

Climate change in the Arctic has global implications. One reason is due to the albedo feedback. Warming (or cooling) in the Arctic affecting ice and snow cover directly affects the amount of sunlight reflected or absorbed by the earth's surface, which can produce a warmer Arctic and an accelerating decrease in ice cover over time. Such an effect has the potential to increase sea levels, alter the salinity in the Arctic Ocean, cause an increased release of methane (CH_4) into the atmosphere due to melting of permafrost, impact storm tracks, patterns of precipitation and the frequency and severity of cold-air outbreaks in middle latitudes (ACIA 2005, Serreze 2008).

Black carbon, commonly referred to as "soot," plays a large-role in short-term climate effects in the Arctic. Black carbon is produced through the burning of carbon-based fuels and affects climate by absorbing incoming and outgoing radiation and decreasing surface albedo when deposited on snow and ice (Hirdman et al. 2009). Unlike GHGs, black carbon is a short-lived pollutant with an atmospheric lifetime of days to weeks (AMAP 2011). Due to its short lifetime, regional climate effects from black carbon are correlated with regional black carbon sources and are noticed more immediately than effects from GHGs. Climate effects from black carbon are especially strong in sensitive areas such as the Arctic, resulting in earlier annual spring melting and sea ice decline (AMAP 2011). Current sources of black carbon in the Arctic are limited and include emissions from burning fossil fuels, including those from oil and gas drilling and boreal forest fires (Hirdman et al. 2009).

Concurrent with climate change is a change in ocean chemistry known as ocean acidification. This phenomenon is described in the IPCC Fourth Assessment Report (IPCC 2007a), a 2005 synthesis report by members of the Royal Society of London (Raven et al. 2005), and an ongoing BOEM-funded study (Mathis 2011). The greatest degree of ocean acidification worldwide is predicted to occur in the Arctic Ocean. This amplified scenario in the Arctic is due to the effects of increased freshwater input from melting snow and ice and from increased CO_2 uptake by the sea as a result of ice retreat (Fabry et al. 2009). Measurements in the Canada Basin of the Arctic Ocean demonstrate that over 11 years, melting sea ice forced changes in pH and the inorganic carbon equilibrium, resulting in decreased saturation of calcium carbonate in the seawater (Yamamoto-Kawai 2009). Bates et al. (2009) showed the effects of decreasing pH on the saturation states of inorganic carbonate in the Chukchi and Beaufort seas, and the interaction of carbonate states with primary productivity.

3.1.4.5 Greenhouse Gas Emissions

Gases that trap heat in the atmosphere are often called greenhouse gases (EPA 2011c). Due to this ability, GHGs are widely considered an important contributing factor in climate change. Some GHGs such as carbon dioxide (CO_2) occur naturally and are emitted to the atmosphere through natural processes and human activities. Other GHGs (e.g. fluorinated gases) are created and emitted solely through human activities. The principal GHGs that enter the atmosphere because of human activities are:

Carbon Dioxide (CO_2) – CO_2 enters the atmosphere through the burning of fossil fuels (oil, natural gas, and coal), solid waste, trees and wood products, and also as a result of other chemical reactions (e.g. manufacture of cement). CO_2 is also removed from the atmosphere when it is absorbed by plants as part of the biological carbon cycle (EPA 2011d).

Methane (CH_4) – CH_4 is emitted during the production and transport of coal, natural gas, and oil. CH_4 emissions also result from livestock and other agricultural practices and by the decay of organic waste in municipal solid waste landfills (EPA 2011c).

Nitrous Oxide (N_2O) – N_2O is emitted during agricultural and industrial activities, as well as during combustion of fossil fuels and solid waste (EPA 2011d).

Fluorinated gases – Hydrofluorocarbons, perfluorocarbons, and sulfur hexafluoride are synthetic, powerful GHGs that are emitted from a variety of industrial processes. Fluorinated gases are sometimes used as substitutes for ozone-depleting substances. These gases are typically emitted in smaller quantities, but because they are potent GHGs, they are sometimes referred to as “High Global Warming Potential” gases (EPA 2011d).

These particular gases are covered under the United Nations Framework Convention on Climate Change, an international agreement that requires participating countries to develop and periodically submit an inventory of greenhouse gas emissions (EPA 2011e).

In 2005, activities in Alaska were estimated to contribute 52.1 million metric tons (MMt) of gross[1] CO_2e, accounting for approximately 0.7 percent of the total US gross GHG emissions. From 1990 to 2000, GHG emissions from activities in Alaska were estimated to increase by approximately 13 percent which is on par with the national total, which rose by approximately 14 percent over the same period. The main source of Alaska’s GHG emissions is residential, commercial, and industrial fuel use followed by the transportation sector. In 2010, the fossil fuel industry was estimated to produce approximately 2.9 MMt of CO_2e, representing approximately 5.2 percent of the state’s CO_2e emissions. Approximately 2.4 MMt of those emissions are attributed to the oil industry, equaling approximately 4.3 percent of the state’s total. Table 3.1-3 provides historical and estimated current GHG emissions in Alaska by sector. Current conditions are estimated as values for the year 2010 as projected as part of a study conducted in 2007 by Center for Climate Strategies (CCS 2007).

[1] Excludes emissions removed due to carbon sequestering.

3.1.5 Air Quality

Air quality is a function of the air pollutant emission sources within an area, atmospheric conditions (such as wind direction and speed), and characteristics of the area itself (topography and air shed size). Pollutants transported from outside an area can also affect its air quality. Air pollutants are emitted from both man-made (anthropogenic) and natural sources. Industrial, residential, transportation-related, and construction-related emissions are anthropogenic sources; these sources can be either ongoing or temporary. Natural sources include windblown dust, forest fires, and volcanic eruptions; these typically contribute only to temporary increases in air pollution.

Air quality in the majority of Alaska's Arctic region, including the Beaufort and Chukchi seas, is generally considered very good due to minimal human habitation and industrial development, along with the distance from population centers such as Anchorage or Fairbanks (MMS 2007c). Widely scattered air pollutant emission sources exist in the onshore coastal regions of the EIS project area, with the only major industrial complex of more concentrated emission sources being Prudhoe Bay, Kuparuk, and Endicott oil-production facilities in the North Slope Areawide Oil and Gas Lease Sale Area (North Slope area). Dust and other pollutants from combustion sources in Europe and Asia also have the potential to be transported to the Arctic, having temporary and usually seasonal effects on visibility; such effects are commonly referred to as regional (or arctic) haze. Regional haze is discussed further under the subheading Other Air Quality Evaluation Criteria in Section 3.1.5.2.

3.1.5.1 EIS Project Area

For purposes of defining existing air quality in the EIS project area, it is convenient to divide the project area into three zones: the state's seaward boundary (0 to 4.8km [0 to 3 mi]); within 40 km (25 mi) of a state's seaward boundary (i.e., 4.8 to 45 km [3 to 28 mi] from the coast); and beyond 40 km (25 mi) of the state's seaward boundary (i.e., 45 to 322 km [28 to 200 mi] from the coast). These three zones are subject to different air quality regulatory requirements and different ambient air quality background levels. Air pollutant sources located offshore are regulated under the OCS Air Regulations (discussed below).

Certain ADEC rules are also applicable to offshore areas within 40 km (25 mi) of Alaska's seaward boundary (inner OCS); the EPA applies the corresponding onshore area (COA) rules to these areas, so they are basically treated the same as onshore sources for permitting purposes. Outer OCS offshore areas (beyond 40 km [25 mi] of the State's seaward boundary) are expected to have minimal anthropogenic sources of air pollution. In December 2011, Congress moved air permitting authority for the outer OCS from EPA to BOEM; however, authority for existing permits (and any pending as of December 2011) remained with EPA. The onshore areas are regulated by EPA and ADEC, and do not fall under the OCS regulations.

Except for the areas around Prudhoe Bay, Barrow and Kotzebue are the largest communities in terms of population within the onshore areas, and would thus be expected to have the highest current air pollutant levels. In addition, Kivalina is reported to have elevated dust levels, and Nuiqsut is located adjacent to the North Slope Area which has industrial activity. The other communities in the study area (Point Hope, Point Lay, Wainwright, and Kaktovik (located within the Arctic National Wildlife Refuge [ANWR]) are assumed to have lower background levels than the industrial areas and larger communities. However, in the absence of background air quality data in these remote regions, they are conservatively included in the onshore group for air quality purposes in this EIS.

3.1.5.2 Regulatory Framework and Pollutants of Concern

Air Quality Standards

Air quality in Alaska and the inner OCS is regulated by the EPA and ADEC, while air quality in the outer OCS is regulated by BOEM (as of December 2011). The EPA has established the NAAQS, which specify maximum allowable concentrations for six principal criteria pollutants (EPA 2011f). Nonattainment areas are geographic regions where air pollutant concentrations exceed the NAAQS for a pollutant. An area is designated as unclassified when there is insufficient information to determine attainment status; these are typically areas where air pollution is not considered a problem (often rural areas), and no monitoring is conducted. The land areas adjacent to the Beaufort and Chukchi seas are unclassifiable; according to the EPA's Green Book, this means that the area "cannot be classified on the basis of available information as meeting or not meeting the national primary or secondary ambient air quality standard (EPA 2012e, 2012f)." There are no designated nonattainment areas within or near the EIS project area (ADEC 2011a).

The two main criteria air pollutants affecting Alaska are carbon monoxide (CO) and particulate matter less than 10 microns in diameter (PM_{10}). Outdoor carbon monoxide emissions come from combustion sources, such as automobiles, airplanes, and industrial engines (ADEC 2011b). Fuel combustion is also a source of particulate matter emissions. In rural communities, airborne dust (PM_{10}) can be caused by windflow over glaciers, gravel pits, vehicles on dirt roads, dry river beds, and human activity on non-vegetated land (ADEC 2011c). On the OCS, marine engines cause emissions of nitrogen oxides (NO_2) and particulate matter. Air quality standards for these pollutants, along with the other criteria pollutants, are listed below in Table 3.1-4. Primary standards have been established to protect human health, and secondary standards have been designed to protect property and natural ecosystems from the effects of air pollution.

Table 3.1-4 Federal and State Ambient Air Quality Standards

Pollutant	Averaging Period	National Standards		Alaska State Standards
		Primary	Secondary	
Ozone (O_3)	8-hour (2008 Std) 8-hour (1997 Std)	0.075 ppm 0.080 ppm	0.075 ppm 0.080 ppm	0.075 ppm
Particulate Matter equal to or	Annual	15.0 μg/m^3	15.0 μg/m^3	15 μg/m^3

Pollutant	Averaging Period	National Standards		Alaska State Standards
		Primary	Secondary	
less than 2.5 micrometers in diameter ($PM_{2.5}$)	24-hour	35 µg/m^3	35 µg/m^3	35 µg/m^3
Particulate Matter equal to or less than 10 micrometers in diameter (PM_{10})				
	24-hour	150 µg/m^3	150 µg/m^3	150 µg/m^3
Carbon Monoxide (CO)	8-hour	9 ppm (10 mg/m^3)		10 mg/m^3
	1-hour	35 ppm (40 mg/m^3)		40 mg/m^3
Nitrogen Dioxide (NO_2)	Annual	0.053 ppm (100 µg/m^3)	0.053 ppm (100 µg/m^3)	100 µg/m^3
	1-hour	0.100 ppm		0.100 ppm
Sulfur Dioxide (SO_2)	Annual	0.03 ppm (80 µg/m^3)		80 µg/m^3
	24-hour	0.14 ppm (365 µg/m^3)		365 µg/m^3
	3-hour		0.5 ppm (1300 µg/m^3)	1300 µg/m^3
	1-hour	0.075 ppm		0.075 ppm
Reduced Sulfur Compounds (as SO_2)	30-minute			50 µg/m^3
Ammonia (NH_3)	8-hour			2.1 mg/m^3
Lead (Pb)	Rolling 3-Month Average	0.15 µg/m^3	0.15 µg/m^3	0.15 µg/m^3
	Quarterly Average	1.5 µg/m^3	1.5 µg/m^3	

Notes:
µm = micrometers (for particulate diameter)
µg/m^3 = micrograms of pollutant per cubic meter of air
mg/m^3 = milligrams of pollutant per cubic meter of air
ppm = parts per million

Control of Emissions from OCS Sources

Jurisdiction for control of air emissions from stationary sources on the Arctic OCS (stationary rigs, drillship, and platforms) was the responsibility of the EPA until amendments to the Clean Air Act Section 328 were enacted on December 23, 2011 (Public Law [Pub. L.] 112-74) in the Consolidated Appropriations Act of 2012. The Arctic OCS is defined to include the Beaufort Sea and Chukchi Sea OCS Planning Areas that are adjacent to Alaska's North Slope Borough. The signing of Pub. L. 112-74 transferred authority for the control of air stationary source emissions, except for existing or pending permits, on the Arctic OCS from the EPA to BOEM. The other Alaska OCS Planning Areas remain under EPA jurisdiction by the authority granted in the Clean Air Act Section 328. However, all actions on the Alaska OCS proposed within 25 miles of shore remain subject to air quality regulations of the ADEC and may require State of Alaska permitting if within the three-mile boundary.

Control of stationary source emissions on the Alaska OCS is now regulated by BOEM, EPA, and ADEC, depending on the location and timeframe of the proposed action. For proposed exploration plans (EPs) located more than three miles offshore on the Arctic OCS, emissions are regulated by the BOEM under 30 CFR Part 550 Subpart C (BOEM Subpart C) and by the authority granted in the OCSLA Sec. 5(a)(8). Under BOEM Subpart C, no air quality permit is required. Rather, the BOEM Alaska OCS Region would be required to conduct an analytical evaluation of the air quality analysis contained in any EP for compliance with BOEM Subpart C. Emissions projected for a facility proposed for an EP on the Arctic OCS that exceed the exemption thresholds calculated under Subpart C would be required to conduct an air quality impact analysis (dispersion analysis) for comparison to the BOEM Significance Levels (SLs). Control of emission sources on the OCS by BOEM is required only when the rig, drillship, or platform is expected to cause a significant air quality effect on the nearest shore area. Should the analysis demonstrate pollutant concentrations that exceed any SL, the application of Best Available Control technology (BACT) would be required by the BOEM Alaska OCS Region. If the action proposes a permanent facility, additional analysis would be required to show the application of BACT would result in compliance with the BOEM Maximum Allowable Increases (MAIs). Additional controls would be required until the MAIs are met. An EP must demonstrate compliance with Subpart C before the EP could be "deemed submitted" by BOEM Alaska OCS Region. Any required application of BACT or other emission controls would be enforced by the BSEE Alaska Region.

National Environmental Policy Act (NEPA) Compliance

The air quality assessment required under NEPA is separate and distinct from the requirement to control stationary source emissions under BOEM Subpart C. The air quality analysis conducted for an EA or an EIS under NEPA requires an accounting and disclosure of total project emissions, namely, land, sea, and air emissions, from both temporary and permanent sources of emissions, and from both mobile and stationary sources. The air quality analysis would account for and disclose any project-related emissions that would occur under the EP. The air quality analysis would be required to demonstrate whether or not the proposed EP would cause emissions that would result in pollutant concentrations that would exceed the EPA NAAQS or otherwise cause a significant effect on air quality in the nearest communities onshore.

Other Air Quality Evaluation Criteria

Climate Change and Greenhouse Gases

Climate change is believed to be occurring as a direct consequence of emissions of GHGs from many types of sources in every nation of the world. The EPA issued the Final Mandatory Reporting of Greenhouse Gases Rule (EPA 2009a), which requires reporting of of GHGs from large sources and suppliers in the United States. The reporting is intended to collect accurate and timely emissions data to inform future policy decisions. Under the rule, suppliers of fossil fuels or industrial GHGs, manufacturers of vehicles and engines, and facilities that emit 25,000 metric tons or more per year of GHG emissions are required to submit annual reports to the EPA. In addition to the reporting rule, the EPA's Tailoring Rule requires sources that emit GHGs in quantities above certain thresholds to include such emissions in PSD and Title V permitting (EPA 2012g).

Regional Haze

Regional haze refers to haze that impairs visibility over a large area. In general, visibility is measured by the farthest distance a viewer can see a landscape or feature, which may be limited by tiny particles in the air absorbing and scattering sunlight, which in turn degrades color, contrast, and clarity of the view. Many sources produce the particulate matter that causes haze. In addition to the primary sources of particulate matter discussed above, secondary particulate matter is also formed when gaseous pollutants undergo chemical reactions with sunlight in the atmosphere. Factors such as weather and humidity further influence the formation of haze. The EPA Regional Haze Rule is designed to protect and improve visibility in National Parks and Wilderness Areas throughout the country (EPA 1999a). Class I airsheds are federally designated areas under the Clean Air Act where no degradation of visibility is allowed. Alaska has four Class I areas subject to the rule (ADEC 2011d). Denali National Park is the closest Class I area to any of the EIS project area, ranging from approximately 650 km (404 mi) southeast of Kotzebue and approximately 750 km (466 mi) south of the more industrialized Prudhoe Bay area, to well over 1,000 km (621 mi) south of some of the outer OCS region (Wilderness Net 2011). The National Park

Service (NPS) and USFWS monitor regional haze at Denali. Potential new sources of air pollution as part of this EIS are expected to have no appreciable effect at this distant Class I area, so no further description of the area is provided. In addition, monitoring data from this site are not representative of the EIS project area, although they could be used to identify specific events (such as Asian dust storms, see below) for verification purposes.

The focus of the regional haze issue in Alaska is primarily on visibility degradation within the Arctic region. Arctic haze and Asian dust events are the primary areas of concern, both identified as being the result of international transport of pollutants into Alaska (ADEC 2002). Arctic haze is defined as "diffuse bands of tropospheric aerosol occurring northward of about 70° latitude and at altitudes of up to 9,000 meters (29,528 ft). These layers are hundreds to thousands of kilometers wide and 1-3 km (0.6-1.9 mi) thick" (ADEC 2002). Coal burning and metal smelting from sources in the industrial regions of Europe and Russia appear to be the primary contributors to Arctic haze. Sources in North America and the Orient only contribute a minor amount of pollution to the Arctic due to their position relative to oceans and prevailing meteorology which provide pollutant scavenging mechanisms before reaching the Arctic (ADEC 2002).

Dust storms in Mongolia and northern China also have the potential to create large dust incidents within the Arctic region. These Asian dust events typically occur in the springtime, usually April and May, and appear to have high enough loft to avoid the ocean scavenging mechanisms. Anthropogenic sources of pollution, likely associated with China's largely coal-fired economy, have also been shown to be transported concurrently with the dust events (ADEC 2002).

3.1.5.3 Existing Air Quality

Based on the physical environment, land uses, and low population density of the EIS project area, existing air quality is assumed to be generally good in all of the offshore and onshore locations, although as mentioned previously, dust emissions in even remote areas can cause localized increased particulate concentrations. The levels of some pollutants are expected to be slightly higher in the onshore areas due to increased numbers of fuel combustion sources; however these areas are still in attainment or unclassifiable of air quality standards. For the nonindustrial onshore areas, residential emission sources (diesel generators, fuel oil stoves, propane heating and/or woodstove) and mobile sources (vehicles) are expected to cause relatively low levels of combustion pollutants due to the limited population in the communities, as compared to the industrial North Slope area or the larger communities of Barrow and Kotzebue. In addition, fairly consistent winds in these areas provide adequate transport and dispersion of these localized emissions. External (international) sources of air pollution may also have an influence on air quality in the EIS project area, including temporary increases in levels of dust and combustion pollutants, which may affect visibility (Arctic haze).

Federal regulations requiring ultra-low sulfur diesel were promulgated by the EPA (EPA 2006a). These regulations are expected to benefit air quality in the EIS project area where diesel combustion is an important anthropogenic category of air pollution emissions. By June 1, 2010, all rural areas in Alaska were to have transitioned to 15 parts per million (ppm) diesel fuel for all highway, non-road, locomotive, and marine engines. By October 1, 2010, retail and wholesale purchaser-consumer transitions were to be complete; and by December 1, 2010, 15 ppm sulfur content diesel fuel was to be in retail facilities in all rural areas (ADEC 2010f). The switch to ultra-low sulfur diesel is expected to result in improved air quality, as it will reduce emissions of smoke, particulate matter, sulfur dioxide, and toxics from diesel combustion sources.

Background Data

The EIS project areas included in this discussion are in attainment (or unclassifiable) for all criteria pollutants. ADEC maintains air quality monitoring sites in some rural communities where there is concern for dust problems (ADEC 2011c, ADEC 2011d). The majority of background air quality data in northern Alaska have been collected in the North Slope area; criteria air pollutant monitoring data have been used for source permitting in the North Slope area, and for several OCS facilities (Air Sciences, Inc 2009, Environ 2010, and AECOM 2010). The dataset shown in Table 3.1-5 was compiled using maximum monitored values and should be conservatively representative of the OCS areas, including the COA areas. Therefore, it is expected that this compiled dataset is reasonably representative for the three air quality zones covered in this EIS (outer OCS, inner OCS, and onshore).

Table 3.1-5 Background Concentrations

Pollutant	Averaging Period	Measured Concentration (µg/m^3)	Percent of Air Quality Standard
PM_{10}	Annual	7.5	15.0
	24-hour	55.1	36.7
CO	8-hour	1097	11.0
	1-hour	1749	4.4

Source: Compiled from monitoring data for BPX Liberty and BPX Prudhoe Bay monitoring sites (Environ 2010).

Note:
µg/m^3 = micrograms of pollutant per cubic meter of air

There are limited background concentration data for offshore regions of Alaska; for permitting needs and to be conservative, the data shown in Table 3.1-5 are assumed to represent worst-case pollutant levels for these regions. Data from an old NPS Interagency Monitoring of Protected Visual Environments (IMPROVE) station on Simeonof Island in the upper Aleutian chain provide a comparison to these conservative values (Environ 2010). The maximum 24-hour PM_{10} concentration at this site during the 2001-2004 time period was 26.50 micrograms of pollutant per cubic meter of air (µg/m$^{3)}$, which is less than half the value shown in Table 3.1-5. Although this monitoring site is remote, the area is subject to dust events and may show particulate levels that are higher than those that would be seen in true offshore locations. It should be noted that this Aleutian island monitoring was performed over 1,287 km (800 mi) from the project area described in this EIS.

In another effort to determine offshore background levels, particulate data have more recently been collected as part of the Wainwright Monitoring Program, and the data have been processed to account for the effects of community fugitive dust and combustion sources and sea salt particulates to determine regional background particulate levels for offshore sources (AECOM 2010). The maximum representative 24-hour PM_{10} concentration at this site was 49 µg/m^3, which is just slightly lower than the value presented in Table 3.1-5. By the same processing method, the Wainwright data shows maximum regional $PM_{2.5}$ levels of 3 and 10 µg/m^3, for the annual and 24-hour periods, respectively (AECOM 2010). This corresponds well with the 98th percentile 24-hour $PM_{2.5}$ concentration (NAAQS reporting standard) at the Simeonof IMPROVE site, which was 9.3 µg/m^3 (Environ 2010).

As shown in Table 3.1-5, the maximum measured concentrations are all well below the NAAQS and Alaska State Standards. These values are indicative of the relatively good air quality in the area, and show that there is still room for future offshore activities that would not necessarily jeopardize the regions ability to meet the federal and State of Alaska air quality standards.

3.1.6 Acoustics

3.1.6.1 Introduction to Acoustics

Sound Characteristics

Sound is a physical phenomenon consisting of minute vibrations that travel through a medium, such as air or water. When a source vibrates, its forward movement compresses the molecules in the adjacent medium (water or air) and creates a region of higher pressure relative to the ambient pressure in the medium. As the surface of the vibrating object moves back toward its original position, the molecules of the surrounding medium are pulled back and a region of lower pressure results. These are called *compressions* and *rarefactions*, respectively. The speed at which these compressions and rarefactions travel away from the source depends on the compressibility and density of the media and is called the *speed of sound*. The layers of compressions and rarefactions result in a *sound wave*. Sound waves travel much faster in water than in air.

Sound is generally described in terms of frequency (or pitch), intensity, and temporal properties (short or long in duration). The following text provides a general description of these terms. For more details, there are several publications and books that provide detailed overviews of acoustics, such as Richardson et al. (1995) and Au and Hastings (2008) for underwater sound, and Harris (1998) for airborne sound.

Frequency, measured in *Hertz* (Hz), is a measure of how many times each crest of a sound pressure wave passes a fixed point within a second. For example, when a drummer beats a drum, the skin of the drum vibrates a number of times per second. A particular tone that makes the drum skin vibrate 100 times per second generates a sound pressure wave at 100 Hz, and this vibration is perceived as a tonal pitch of 100 Hz. Sound frequencies between 20 Hz and 20,000 Hz are within the range of sensitivity of the best human ear. Some mysticetes (baleen whales) produce and likely hear sounds below 20 Hz, while odontocetes (toothed whales) produce and hear sounds at frequencies much higher than 20,000 Hz (also reported as 20 kiloHertz [kHz]).

Acoustic *intensity* is defined as the acoustical power per unit area. The intensity, power, and energy of a sound wave are proportional to the average of the squared pressure. Measurement instruments and most receivers (humans, animals) sense changes in pressure which is measured in Pascals (Pa). Pressure changes due to sound waves can be measured in Pa but they are more commonly expressed in *decibels* (dB). The decibel is a logarithmic scale that is based on the ratio of the sound pressure relative to a standard reference pressure p_{ref}. Different standard reference pressures are used for airborne sounds and underwater sounds. The airborne standard pressure reference is p_{ref}(air) = 20 microPascals (µPa), where 1 µPa = 0.000001 Pa. The underwater standard reference pressure is p_{ref}(water) = 1 µPa. The formula used to convert a pressure p measured in µPa to sound pressure level P measured in dB is $P = 20 \log_{10}[p/p_{\mathrm{ref}}]$. Because of the logarithmic nature of the decibel, sound levels cannot be added or subtracted directly. If a sound's pressure is doubled, its sound level increases by approximately 6 dB, regardless of the initial sound level. This can be illustrated by considering a sound having pressure p_1; it has decibel level $P_1 = 20 \log[p_1/p_{\mathrm{ref}}]$. Now consider a sound with twice the pressure: $p_2 = 2p_1$. It has decibel level $P_2 = 20 \log[p_2/p_{\mathrm{ref}}] = 20 \log[2p_1/p_{\mathrm{ref}}] \approx P_1 + 6$ dB.

Sound Metrics

The metrics most commonly used for evaluations of underwater sound effects on marine mammals are peak pressure (0-peak or peak-to-peak), root-mean-square (RMS) sound pressure level (SPL), and sound exposure level (SEL). Figure 3.1-5 shows a representation of a sinusoidal (single-frequency) pressure wave to help illustrate the various metrics. The amplitude of the pressure is shown on the vertical axis, and time is shown on the horizontal axis. The pressure of the wave is shown to fluctuate around the neutral point. The *peak sound pressure* is the absolute value of the maximum variation from the neutral position; therefore, it can result from either compression or a rarefaction. The *peak-to-peak sound pressure* is the difference between the maximum and minimum pressures. The average amplitude is the average of absolute value of pressure over the period of interest. The *RMS amplitude* is a type of average that is determined by squaring all of the amplitudes over the period of interest, determining the mean of the squared values, and then taking the square root of this mean. The RMS amplitude of an impulsive signal could vary significantly depending on the length of the period of interest (DOSITS 2011). SEL is a metric that is related to the sound energy per area received over time, though it does not have energy units. It is proportional to the square of the sound pressure and the time over which a sound is received.

An *audiogram* shows the lowest level of sounds that an animal or human can hear (hearing threshold) at different frequencies (pitch). The y-axis of the audiogram is sound levels expressed in dB (either in-air or in-water) and the x-axis is the frequency of the sound expressed in Hz. A typical audiogram for human hearing is shown on Figure 3.1-6a. In evaluating airborne noise impacts, the method commonly used to quantify environmental sound consists of evaluating all frequencies of a sound according to a weighting system that reflects that human hearing sensitivity varies with sound frequency. The most common frequency weighting to assess human hearing sensitivity and noise impacts is referred to as A-weighting and the decibel level measured is called the A-weighted sound level (dBA). Figure 3.1-6b shows the A-weighting function, with sound levels expressed in dB on the y-axis and frequency on the x-axis. Another human hearing weighting function commonly used includes C-weighting, which is used to address human hearing sensitivity when exposed to loud sound. Common metrics used to for airborne noise include the L_{eq} (equivalent sound level) – the energy-mean A-weighted sound level during a measured time interval and the L_{min} and L_{max} – the RMS minimum and maximum noise levels during the monitoring period.

When evaluating potential noise impacts on wildlife, the A-weighting curve is usually not applied, as it is based on human hearing. Figure 3.1-7 shows hearing thresholds for some terrestrial and marine mammals as compared to the hearing threshold for humans. Figure 3.1-8 illustrates the proposed M-weighting functions for marine mammals by Southall et al. (2007).

Comparisons of underwater and airborne sound levels are difficult for several reasons, primarily due to the differences in the media (especially the characteristic impedance of the media), and it is important to take into account the reference pressure level noted previously (1 µPa for underwater, 20 µPa for airborne). Sound pressure level is derived from the equation SPL = 20 log (p/p_{ref}), where p is the acoustic pressure being measured and p_{ref} is the reference pressure. Thus, 26 dB must be added to the dB level measured in air in order to have the same reference level in water (20 log 20) = 26. Table 3.1-6 shows underwater and airborne sound pressure levels and the relationship with the pressure. While it may be useful to compare the difference in a source sound level or hearing sensitivity of a marine mammal to a terrestrial mammal, this is for comparison purposes only.

O’Neill et al. (2010a and 2010b) provide formulas for calculating underwater levels of impulsive noise used for the purpose of estimating biological impacts, and in particular the peak SPL, the root-mean-square (rms) SPL, and the SEL. The peak SPL is the maximum instantaneous sound pressure level attained from one or more pressure pulses (O’Neill et al. 2010). The rms SPL is the square root of mean square pressure level over a specified time window containing the pressure pulse; a common time window for airgun seismic pulses is the interval containing 90 percent of the pulse energy, and the resulting metric is referred to as the 90 percent rms SPL (O’Neill et al. 2010). The SEL is a measure related to the sound energy or exposure rather than sound pressure, and may be expressed as a per-pulse metric or a cumulative metric over multiple pulses for airgun signals (O’Neill et al. 2010).

Table 3.1-6 Sound Levels of Typical Sources

Pascals	Underwater sound level (dB re 1 µPa)	Airborne sound level (dB re 20 µPa)	Typical underwater sounds	Typical airborne sounds
1,000,000	240	214	1 m from hypothetical airgun array	
100,000	220	194	2 kg high explosive at 100 m	
10,000	200	174		Some military guns at 1 m
1,000	180	154		Sonic booms
100	160	134	Large ship, 100 m	
10	140	114	Fin whale call, 100 m	Discomfort threshold for humans, 500 m from jet takeoff
1	120	94		
0.1	100	74		15 m from auto at 55 km/hr
0.01	80	54	Ambient sound, Sea state 4	Speech in noise at 1 m
0.001	60	34	Ambient sound, Sea state 0	Speech in quiet at 1 m
0.001	40	14		
20 µ	26	0		Human threshold

Notes: dB re 1 Pa = decibels referenced to 1 microPascal; m = meters; km = kilometers; hr = hour
Source: Richardson et al. (1995)

The evaluation of noise effects on marine wildlife is difficult for several reasons. Sound level thresholds corresponding to injurious effects are difficult to determine without actually causing injuries to animals. The lowest level of injurious effect from noise exposure is damage to hearing organs. Permanent threshold shift (PTS), as opposed to temporary hearing shift (TTS), is considered an auditory injury. Studies to measure the threshold of sound exposure leading to onset of PTS in marine mammals do not involve the actual inducement of PTS. Rather, PTS thresholds have been estimated by measuring thresholds for onset of TTS and extrapolating those thresholds according to the amount of additional exposure required to increase the TTS to a non-recoverable state (Southall et al. 2007). Additionally, knowledge of the frequency sensitivities of different species groups to loud sounds can be incorporated into PTS thresholds using M-Weighted cumulative SELs, as demonstrated in Southall et al. (2007). Southall et al. (2007) also propose peak pressure thresholds for PTS.

Behavioral effects thresholds are likewise difficult to determine due to the highly variable reactions of animals to sound (NRC 2003a). Variability in reactions may occur as a result of individual's hearing ability, sex, age, and the context of the sound exposure. Context can include habitat, current activity of the animal and past exposure experiences. Additionally, the sensation level of a sound, which is the relative received level of a particular sound as compared to the animal's basic hearing threshold at the frequency of that sound, can factor into how an animal may respond to a sound. Sensation levels can be taken into consideration where audiograms are available for a species; however, there are no available measurements of audiograms for mysticetes.

When evaluating acoustic impacts, it is also important to take into account the temporal characteristics of the sound. A sound may be *transient* in nature (a relatively short duration with an obvious start and stop) or *continuous* (no obvious start or stop). NMFS considers transient sound as *pulsed* and continuous sound as *non-pulsed*. Examples of transient sounds include explosions, airguns, impact pile drivers, and sonar. Examples of continuous sounds include an operating drillship or ship underway. However, it is important to note that that source-path-receiver model discussed below will influence how a sound is perceived by the receiver. For example, sound from a ship underway is continuous at the source, but will not be a continuous to a stationary receiver once it has passed by. Another example is that transient sound such as airguns are impulsive at the source, but due to the many factors that influence propagation, may be perceived as non-pulse at a farther distance by a receiver. As described in detail in Southall et al. (2007), pulses are transient sounds with rapid rise-time and high peak pressures and are possibly injurious to mammalian hearing. Non-pulsed sounds may not result in as much damage, but may still cause behavioral changes.

Ambient Noise

Ambient noise is the background noise, encompassing a myriad of sources, some of which are known and others unknown. The noise sources may include natural and anthropogenic sources near and far away. Ambient noise varies with season, location, time of day, and frequency.

The ambient noise in an environment will influence how well an animal may detect sounds of interest, such as calls by other members of their species, or sounds from prey and predators. Animals will only react to sounds that they can detect. To be detected, sounds must exceed the hearing threshold of the animal, and they have to approach or exceed the ambient sound levels in the same frequency band. When the hearing threshold is below the current ambient noise level, as quite often occurs, then ambient noise limits the maximum distance at which a sound source can be detected. Because both hearing thresholds and ambient noise levels vary with frequency, it is important to examine the spectral (variation with frequency) properties of the ambient noise.

Two recent studies of arctic ambient noise have been performed in the Beaufort and Chukchi seas. Roth et al. (2012) performed three years of ambient noise measurements from 2006-2009 with autonomous acoustic recorders deployed on the continental slope in 265m (869 ft) water depth, approximately 130 km (81 mi) north of Barrow, Alaska. Delarue et al. (2012) performed five years of measurements from 2007 to 2011 using multiple autonomous recorders deployed over a wide area of the eastern Chukchi Sea shelf in water depths of 18 m to 80 m (59 to 262 ft). Roth et al. (2011) report mean spectrum levels in September and October of 80-83 dB re 1 $\mu Pa^2/Hz$ at 20-50 Hz, decreasing at ~5 dB/octave above 50 Hz. All other months had lower levels due to lower average wind speeds and to presence of ice. May had the lowest spectrum level (65 dB re 1 $\mu Pa^2/Hz$ at 50 Hz); that was attributed to lowest mean wind speeds and high ice cover. Delarue et al. (2012) report similar ambient spectral levels in winter months, with a median level of 71 dB re 1 $\mu Pa^2/Hz$ from 10 Hz to 40 Hz but decreasing slightly less rapidly at ~4 dB per octave above 40 Hz. The summer spectral levels of Delarue et al. (2012) differ from those of Roth et al. (2011); Delarue et al. (2012) show increasing spectral levels with frequency from ~67 dB re 1 $\mu Pa^2/Hz$ at 20 Hz to 76 dB re 1 $\mu Pa^2/Hz$ at 100 Hz, then decreasing with frequency above 300 Hz at ~5 dB/octave. Interestingly, the low-frequency roll-off below 100 Hz observed by Delarue et al. (2012) is not observed in Roth et al.'s (2011) measurements. That roll-off is likely due in part to reduced support of low frequency sound propagation in the shallow waters of the shelf. It is not observed in the winter data and that is likely due to reduced wind and wave noise in the mid-frequency band when ice cover is present. Delarue et al. (2012) suggest their relatively higher levels between 100 and 300 Hz in summer are also influenced by noise from seismic surveys that have occurred on the shelf during their measurements. Delarue et al. (2012) also show that marine mammal vocalizations can locally or regionally influence ambient noise levels over substantial time periods. They specifically indicate that male bearded seal calls dominate the ambient noise field during their mating period from mid-April to early June over much of the Chukchi shelf, including most of the lease area, and their calls can raise the ambient spectrum from 100 Hz to 1 kHz by as much as 20 dB.

Propagation of Sound

Richardson et al. (1995) describe a useful method for considering the process of sound generation, propagation and perception. This method is referred to as the "source-path-receiver" model. Each of the three components is introduced below and then discussed in more detail in the following text.

- ***Source:*** the source of the emitted sound (such as an airgun or drillship). It has particular acoustic characteristics including its amplitude and its pitch.
- ***Path:*** the route from source to the receiver of the sound wave. The path may alter the nature of the source sound as it travels from the source to the receiver (terms often used are transmission or propagation). The path can include segments through air or water, or both.
- ***Receiver:*** the human or animal that perceives the sound after it has left the source and propagated over the path. Receivers have specific detection abilities, so not all receivers will detect or perceive a sound the same way.

Sources of underwater sound may be physically small, such as the transducers of small positioning sonars, or very large, such as ice-breaking vessels. In both cases acousticians generally characterize their sound emissions using a metric known as *source level*. The source level does not necessarily indicate the sound level that could be measured at any location near the source. Rather, it represents the equivalent pressure that would occur at a reference distance, typically 1 m (3.3 ft), from a point source under the assumption that, when observed by receivers at large distances, the point source and the actual source produce the same received sound pressure level. This definition of source level can lead to confusion about actual sound levels experienced near large or spatially-distributed sources. For example, large vessels emit sound energy into the water from several parts of their hull and from their propellers. The total sound energy produced by all parts of the vessel will be quite large so received sound levels at distance from large vessels are often high. The source level is computed by scaling that received level back to 1 m (3.3 ft) from a single point location, assuming that the entire sound energy of the vessel was produced at that point location. The source level is therefore larger than the actual pressure level at 1 m (3.3 ft) from any single part of the vessel. Distributed sources with multiple elements, such as airgun arrays, also have source levels that are higher than the actual sound levels experienced close to any part of the source. The reason again is that the source level allocates all of the energy from multiple airguns to a single point location. The source level represents the pressure that would be measured at 1 m (3.3 ft) from that location. While point source levels are not useful for accurately predicting pressure very close to larger or distributed sources, they are very useful for predicting sound levels at larger distances. Generally the distance at which the approximation becomes valid is several times the dimension of the source itself. For synchronized sources, such as airgun arrays, the actual distance at which the point source approximation becomes accurate is also dependent on the spatial extent of the source relative to the sound wavelength, and it therefore depends on the frequency of the sound.

Path refers to the media through which sounds propagate on their way from the source to the receiver. The path affects the *Transmission loss,* which represents the total amplitude change from the source position (actually at 1 m [3.3 ft] from the source) to the receiver. Transmission loss is generally represented in decibels, and it is a measure of the overall decrease in acoustic intensity. It is comprised of several other loss mechanisms, including *spreading loss*, *reflection* and *refraction loss*, and *absorption*. Simply, spreading loss refers to the decrease in pressure that results from the increasing surface area a sound wavefront covers as it moves further from the source. The sound energy becomes spread over larger areas, so the energy per unit area, and consequently pressure, decreases. In a uniform and boundless medium, sound spreads out from the source in a spherical dimension – sound levels in this situation typically diminish by approximately 6 dB due to spreading loss when the distance is doubled. In shallow water environments where acoustic paths are bounded by the surface and seabottom, the rate of spreading loss decreases due to trapping of sound energy by the boundaries. If the surface and bottom were perfectly-reflecting then the spreading loss at longer distances would be referred to as cylindrical – sound levels in this situation would diminish by 3 dB per doubling distance. Reflection (sound waves "bouncing" off surfaces) and refraction (bending of the propagation path) affect sound propagation and can lead to areas of higher or lower sound level than if they were not present. Absorption is the loss of acoustic energy by internal scattering and conversion of pressure energy into heat within the propagation medium. Transmission loss underwater varies with temperature, sea conditions, source and receiver depth, water chemistry, bottom composition, and topography. Transmission loss parameters in air vary with air temperature and humidity, wind, turbulence, cloud cover, type of ground cover between source and receiver, and source and receiver height. In nearly all cases, transmission loss varies with frequency, which is an important consideration in the application of the source-path-receiver model; it is common to apply the model separately to smaller frequency bands, and those individual band results are combined later.

Receiver refers to the listening device or animal that experiences the sound at the far end (opposite the source) of the acoustic path. The receiver can refer specifically to the hearing organs of animals but high-amplitude sounds can affect other organs. In any case, the receiver will have varying sensitivity to different frequencies. Hearing-related effects such as masking and auditory injury depend on the sound amplitude and the frequency distribution of the sound. Some sound metrics used for effects evaluation take into account the frequency-dependent hearing sensitivity of different species as was discussed in the Sound Metrics section above.

As noted previously, this section provides a very basic introduction to acoustic terminology that will be used in this EIS. For more details, there are many textbooks available that provide more details (e.g., Richardson et al. 1995, Au and Hastings 2008, Harris 1998). Furthermore, a website with some basic introductions to sound in the sea is located at: http://www.dosits.org/.

Due to the differences in the acoustic environment of the U.S. Beaufort and Chukchi seas (both underwater and airborne), they are discussed separately in the following text. For the purposes of the acoustics section of this EIS only, the region around Barrow will be included in the Chukchi Sea discussion.

3.1.6.2 Beaufort Sea

Airborne Acoustics

The existing airborne noise environment in the coastal areas of the Beaufort Sea is influenced by sounds from natural and anthropogenic sources. Similar to the Chukchi Sea (discussed below in Section 3.1.6.3), the primary natural source of airborne noise on the offshore, nearshore, and onshore regions is wind, although wildlife can produce considerable sound during specific seasons in certain nearshore and onshore regions. Anthropogenic noise levels in the Beaufort Sea region are higher than the Chukchi Sea due to the oil and gas developments of the nearshore and onshore regions of the North Slope, particularly in the vicinity of Prudhoe Bay. Noise sources consist of regular air and vehicular traffic on the roads within the few development areas (such as around Deadhorse). Noise is also produced by the operations of heavy construction and industrial equipment that service the wells, processing facilities, pipelines, camps, etc. Industrial activities occur throughout the region on a year-round basis. There have been numerous airborne noise studies along the North Slope throughout development of the area. Sound levels near oil and gas development sites with equipment are similar to other industrial sites with levels 70 to 90 dBA (e.g., Shepard et al. 2001, EPA 1974). Sound levels farther from equipment are closer to the natural background levels of 45 to 60 dBA (BLM 2004). Noise sources and associated sound levels near the communities of Nuiqsut and Kaktovik will be similar to those described for the Chukchi Sea.

Underwater Acoustics

Underwater noise is comprised of natural and anthropogenic sources. It varies temporally (daily, seasonally, annually) depending on weather conditions and the presence of anthropogenic and biological sources. Natural sound sources in the Arctic Ocean include earthquakes, wind, ice, and sounds from several animal species. Figure 3.1-9 shows the Wenz curves (Wenz 1962), which summarized the range of ocean background noise at different frequencies (as reported in NRC (2003a). Earthquakes and other geologic processes (subduction, spreading, faulting, volcanic, hydrothermal vent activity) typically generate loud, low frequency (<100 Hz) sounds that propagate for long distances. Atmospheric effects, such as wind, lightning, thunder, and rain at the surface have a significant effect on ambient sound levels. Sources of underwater noise in the Beaufort Sea are the same as those described below for the Chukchi Sea (Section 3.1.6.3); however, due to different bathymetry, current, and level of anthropogenic activities, the ambient noise environment is more variable. The Beaufort Sea offshore environment can be divided into three primary acoustic environments: a) shallow bays bounded by barrier islands; b) shelf region with water depths from 10 m to 250 m depth [33 to 820 ft]; and c) basin slope with depths 1,000 to 3,000 m (3,280 to 9,843 ft). The basin floor is 3,000 to 3,500 m (9,843 to 11,483 ft) further offshore but fewer marine mammals are present there, and anthropogenic activities are limited in the very deep ocean region. The shallow bays are less conducive to low frequency sound propagation, and this generally reduces both anthropogenic and natural sound levels relative to the deeper Beaufort Sea environment. However, past oil and gas activities have largely been concentrated in these regions, so anthropogenic noise is more prevalent here. The shelf region has similar depth and acoustic properties to the Chukchi shelf environment. Recent seismic surveys have been performed on the Beaufort Sea shelf in Camden and Harrison Bays that have generated exploration noise footprints similar to those produced by exploration over the Chukchi Sea lease areas. Underwater sound channels form when there is a change in the velocity of the water column. The deeper basin slope and basin include a near-surface sound channel that can support long-range propagation of distant sounds, but at relatively low levels – distant seismic survey sounds are commonly detected here and over deeper parts of the shelf. Those sounds are believed to have propagated from long distances through the sound channel and then with increasing attenuation as they encounter shallower water when propagating over the shelf.

Biological sounds from marine mammals in the Beaufort Sea region are generally lower than those in the Chukchi Sea. This is primarily a result of reduced numbers of the two most vocal species, walrus and bearded seals, in the Beaufort Sea. Bowhead vocalizations will contribute during the spring and fall migrations, but the migration corridor in the Beaufort, and consequently the region exposed to vocalizations, is predominantly along a narrower path that follows approximately 16 to 48 km (10 to 30 mi) from shore. Bowhead vocalizations in September and October are limited to low frequency moans below approximately 1000 Hz. Bowhead calling structure evolves from simple calls to complex calls and songs from October to December, but most bowheads have already migrated into the Chukchi Sea by this time (Delarue et. al. 2009). The complex calls and songs extend in frequency from less than 100 Hz to several kilohertz. Wind and sea ice contribute greatly to the noise environment (e.g., Blackwell and Greene et al. 2004, Blackwell and Greene 2006, Blackwell et al. 2009) in the Beaufort Sea.

Anthropogenic sounds are primarily in the nearshore and shelf region, and include noise from vessel traffic, primarily in the Prudhoe Bay region, as there are three docks with deep draft capability. During the open water season, there are barges and tugs present with supplies ranging from fuel and food to large modules for oil and gas processing onshore, research vessels, and crew supply vessels from Northstar to West Dock (Blackwell and Greene 2006).

Existing North Slope production operations extend from Alpine in the west to Point Thomson and Badami in the east. Most of the production operations on the North Slope are onshore, but there are a few offshore units that contribute to the underwater noise environment. The Northstar oilfield was discovered in 1983 and developed by BP in 1995. The offshore oilfield is 10 km (6 mi) from Prudhoe Bay in about 10 m (39 ft) of water. Sounds in the near and far shore have been measured from Northstar throughout construction and operation and these measurements continue today (BP 2009) with analysis of potential effects of the island on bowhead migration. Broadband noise from Northstar reaches background noise levels during drilling by 9.4 km (5.8 mi) from the island (Blackwell et al. 2004). The Oooguruk Unit is located adjacent to Kuparuk River Unit in shallow waters of Harrison Bay. Pioneer and its partner, Eni, constructed an offshore drill site and onshore production facilities pad in 2006 on State of Alaska leases, and this unit has been operating since 2008. Studies during construction of Oooguruk showed noise from drilling were not detected outside the barrier islands, and vessels were the primary noise source (Pioneer

2009). The Nikaitchuq Unit is located at Spy Island, north of Oliktok Point and the Kuparuk River unit and northwest of the Milne Point Unit and has been operating since 2010.

3.1.6.3 Chukchi Sea

Airborne Acoustics

The existing airborne environment in the coastal areas of the Chukchi Sea is comprised of natural and anthropogenic sources. The primary natural source of airborne noise on both the offshore, nearshore, and onshore regions is wind, although wildlife will contribute some during specific seasons in the nearshore and onshore regions. For example, shorebirds are often quite loud in the summer season in breeding areas. Walrus produce several types of grunts, snorts, and whistle sounds while on-land haulout sites; these haulout sites are often many thousands of animals. Anthropogenic activity is relatively limited in the Arctic offshore relative to other seas, but occasional vessel traffic from tourism, research, or oil and gas activities and local activity generates some airborne noise. Anthropogenic noise levels in the nearshore and onshore region will be higher in populated areas – the coastal communities of Wainwright, Point Lay, Point Hope, Kivalina, and Barrow – with increasing noise levels associated with the larger communities. Community noise consists of aircraft, vehicular traffic (including all-terrain vehicles and snow machines), construction equipment, people talking/yelling, dogs barking, power plants, skiffs used for hunting, generators, etc. There have been no detailed existing noise surveys in these communities, but overall sound levels associated with smaller communities with smaller roads and relatively few aircraft range from very quiet during periods of low wind (<20 dBA) to 65 to 70 dBA during periods of higher human activity and wind (EPA 1974). Typical community noise levels during the daytime are likely 50-65 dBA, and levels during the nighttime are likely 35 to 45 dBA (EPA 1974).

Noise from offshore vessels will contribute very little to the ambient airborne noise environment as there are no existing ports or docks in any of these communities deep enough for the larger vessels to come within a few miles.

Underwater Acoustics

Sources of underwater noise in the Chukchi Sea are the same as those described above for the Beaufort Sea (Section 3.1.6.2). In the Chukchi Sea, surface wind affects ambient noise levels, causing variations in up to 20 dB in the ambient noise environment (Hannay et al. 2011). The presence of sea ice can dramatically change the ambient noise environment, either by affecting propagation or as a source of noise. Areas with 100 percent sea ice coverage may reduce or eliminate noise from waves or surf (Richardson et al. 1995). As ice forms in shallower waters, sound propagation efficacy of low frequency sounds may be reduced (NRC 2003a). The movement of the ice can also be a significant source of noise in the Arctic Ocean. In areas of continuous fast-ice cover, the ice cracking due to thermal stresses can be a dominant source of noise, usually between 100 to 1,000 Hz (Milne and Ganton 1964). Hannay et al. (2001) also report ice as being a major source of noise throughout the Chukchi Sea.

Biological acoustic sources include marine mammals and fish. During specific seasons, marine mammal calls contribute substantially to the ambient noise levels in the Chukchi Sea. As described in Section 3.2.4, there are a variety of marine mammals that occur in the Chukchi Sea, all of which produce sounds throughout the open water season. Since the late 1970s and early 1980s, seafloor mounted passive acoustic monitoring devices have been deployed near Barrow as part of the bowhead whale acoustic census (e.g., Clark and Johnson 1984). Since 2006, there have been detailed passive acoustic monitoring recorders deployed throughout the Chukchi Sea as part of oil and gas-sponsored environmental studies. The recent recorder locations range from Cape Lisburne to Barrow and from 5 nautical miles (NM) nearshore to more than 100 NM offshore (e.g., Cornell 2010, Hannay et al. 2011). Bowhead whales pass through the region during their spring and fall migrations. They produce a variety of sounds in the 20 to 3,500 Hz frequency range (George et al. 2004, Cornell 2010, Hannay et al. 2011). Walrus are in the Chukchi Sea from late spring through the fall. They produce a variety of sounds ranging from grunts to knocks that are fairly broadband (100 Hz – 10 kHz). In 2008, walrus were detected most frequently in late September (Cornell 2010). In 2009, walrus were detected most frequently in late August to mid-September, particularly between Hanna Shoal and Wainwright (Hannay et al. 2011). Bearded seals are detected throughout the year on recorders throughout the Chukchi Sea, but during the breeding season (May), sounds from the male bearded seals increase the ambient background levels by as much as 20 dB in the 400 Hz range (Hannay et al. 2011). While sound production by fish in the arctic is not well understood, acoustic recorders in the Chukchi Sea have captured some low frequency grunt-like sounds, mainly less than 100 Hz, which may be produced by arctic cod (Cornell 2010).

Anthropogenic noise sources include vessel traffic, oil and gas exploration, and other miscellaneous sources. Vessel traffic includes a wide range of vessel sizes with varying noise levels. Vessel types include small skiffs used for whaling, scientific research vessels, re-supply barges for the communities, large barges carrying oil and gas processing modules to the North Slope (see Transportation Section 3.3.7 for more details on traffic), some tourism and recreation vessels, icebreakers, and vessels associated with oil and gas exploration activities. As summarized in several acoustic texts (e.g., Richardson et al. 1995, NRC 2003a, Au and Hastings 2008), sounds associated with vessel traffic are primarily generated by cavitation of the propeller, but some sound from on-board machinery is also transmitted through the hull into the water. Source levels for smaller vessels are typically between 120 and 150 dB re 1 µPa at 1 m with most of the energy below 5,000 Hz (Richardson et al. 1995), while source levels for tugs pulling large barges are typically lower frequency (below 1,000 Hz) with greater source levels (~170 dB re 1 µPa at 1 m). In the Chukchi Sea, tugs and barges typically travel approximately 50 NM from shore from the Bering Strait through to Prudhoe Bay or into Canada. Research and oil and gas vessels transit throughout the lease sale area that is more than 50 NM from shore. However, these vessels make occasional transits to within a few miles from shore to change out the research and crew personnel as required.

Sources of anthropogenic sound in the Chukchi Sea associated with oil and gas exploration include all of the activities identified in Chapter 2: deep penetration seismic surveys; high resolution geophysical surveys; and exploratory drilling. The sound levels and associated frequencies were described in Chapter 2. There are no production islands in the Chukchi Sea at this time. There are no ports or docks in the Chukchi Sea, so there has been little introduction of construction noise (such as pile driving or dredging) in this region to date.

Because the Chukchi Sea continental shelf has a highly uniform depth of 30 to 50 m, it strongly supports sound propagation in the 50 Hz to 500 Hz frequency band (Funk et al. 2008). This is of particular interest because most of the industrial sounds from large vessels, seismic sources, and drilling are in this band, and this is likely within the greatest hearing sensitivity of bowhead whales.

3.1.7 Water Quality

Water quality is a term used to describe the physical, chemical, and biological characteristics of water, usually with regard to its ability to perform or support a particular function. Water quality criteria or standards can be generally defined using an established set of parameters that are related to the utility of the water for a particular set of purposes (e.g. protection of marine biota, maintenance of subsistence food resources).

Since drilling of the first OCS exploration well in 1981, a variety of onshore and offshore oil exploration and development projects have been conducted in and adjacent to both the Alaskan Beaufort and Chukchi seas (NRC 2003b). Over 20 discoveries have been made in areas such as Endicott (an offshore field in state waters), Sagavanirktok Delta North (onshore near Prudhoe Bay), and Badami (Beaufort Sea) (Brown et al. 2010). The effects of past oil and gas exploration and development must be considered in order to accurately and completely characterize current water quality in the Alaska Arctic Region OCS (Brown et al. 2010). In addition to inputs resulting from oil and gas exploration and development, anthropogenic materials may be introduced to the Beaufort and Chukchi seas through influx from the Bering Sea, river runoff, coastal erosion, and atmospheric deposition (Woodgate and Aagaard 2005).

However, the majority of the water flowing into the Beaufort and Chukchi seas is relatively free from the influence of human activity, and there are currently no impaired waters (as defined by the Clean Water Act Section 303(d)) identified within the Arctic Region by the State of Alaska (ADEC 2010).

3.1.7.1 Applicable Regulations

State of Alaska water quality standards for designated uses of marine and fresh water are available in the most recent version of 18 AAC 70, or from the ADEC web site (www.dec.state.ak.us/water/wqsar/).

Pursuant to the Clean Water Act, certain discharges from oil and gas exploration facilities in the Beaufort and Chukchi seas require authorization by the EPA in the form of an NPDES general permit or if in State waters, by the ADEC. To be eligible for permitting, discharges into the ocean may not cause an unreasonable degradation of the marine environment as determined under 40 CFR Part 125 Subpart M.

The Arctic NPDES General Permit AKG-28-0000 for wastewater discharges from Arctic oil and gas facilities expired on June 26, 2011. On October 29, 2012, EPA issued two general permits for exploration discharges into the Beaufort and Chukchi seas, permit numbers AKG-28-2100 and AKG-28-8100, respectively. The general permits authorize discharges from 13 categories of waste streams, subject to effluent limitations, restrictions, and requirements. The general permits became effective on November 28, 2012 and are effective for five years. The permits require operators to submit Notices of Intent to EPA requesting authorization to discharge at least 120 days prior to commencing discharges. Changes to the permits include elimination of the authorization to discharge non-aqueous drilling fluids and associated drill cuttings (i.e., only water-based drilling fluids and cuttings are authorized); elimination of the authorization to discharge test fluids; expansion of the scope and requirements of the environmental monitoring program (EMP); increases in the chemical additive inventory and reporting requirements for all discharges, including limitations on chemical additive concentrations; prohibition of the discharge of water-based drilling fluids and drill cuttings during active bowhead whaling activities in the Beaufort Sea, unless the EPA authorizes the discharge after review of the operator's evaluation of the feasibility of drilling facility storage capacity and land-based disposal alternatives; and other changes. A detailed summary of the changes is included in the EPA fact sheet (see pages 11-12 of the fact sheet) for NPDES General Permits for Oil and Gas Exploration Facilities on the Outer Continental Shelf and Contiguous State Waters, available online at http://www.epa.gov/region10/pdf/permits/npdes/ak/arcticgp/Beaufort_and_Chukchi_General_Permits_Fact_Sheet.pdf.

Draft Ocean Discharge Criteria Evaluations (ODCEs) for the Beaufort and Chukchi Permits have also been performed by the EPA (EPA 2012c and EPA 2012d). The final ODCEs are available at http://www.epa.gov/region10/pdf/permits/npdes/ak/arcticgp/beaufort/Beaufort_Final_ODCE_1029012.pdf and http://www.epa.gov/region10/pdf/permits/npdes/ak/arcticgp/chukchi/Chukchi_Final_ODCE_102912.pdf. The 60-day public comment period closed on March 30, 2012. EPA responded to public comments in a "response to comments" document included with the final permits and reissued the permits on October 29, 2012.

The latest information on water-quality standards from the EPA is available in the current edition of 40 CFR Part 131. The EPA National Recommended Water Quality Criteria are available at http://water.epa.gov/scitech/swguidance/standards/current/index.cfm.

The US Coast Guard has regulations related to pollution prevention and discharges for vessels carrying oil, noxious liquid substances, garbage, municipal or commercial waste, and ballast water (33 CFR Part 151). The State of Alaska regulates water quality standards within three miles of the shore.

3.1.7.2 Water Quality Parameters

The following water quality variables are discussed because of their importance to the functioning of the potentially affected ecosystem.

Temperature and Salinity

Temperature often dictates the ability of water to support a particular biological community and also influences a wide range of other chemical and physical parameters. It is therefore an important variable for establishing baseline water quality of the affected environment. Higher water temperatures decrease the ability of water to hold oxygen, reduce the density of the water, and may also increase the likelihood of an algal bloom. Rapid temperature shifts impact the health of marine species, while long-term temperature changes may have a considerable impact on ecosystems. Increases in water temperature encourage the growth of heat-tolerant organisms, which may include introduced species. Decreases in water temperatures generally slow down biological productivity and may decrease food availability to fish and other grazing animals. Factors that influence water temperature include time of day, season, depth of water, flow rate, tidal influence, nearby cooling water outfalls, and the location of the sampling point.

Salinity influences the density of water and can fluctuate due to ice formation and melting, freshwater influx from rivers, rainfall, evaporation, and tidal cycles. Due to the need to maintain a balance of water and salts within cells (osmoregulation), many organisms have narrow salinity tolerance ranges. The salinity of typical open ocean seawater is usually about 35 ppt (35,000 milligrams per kilogram [mg/kg]), or 35 grams of salt dissolved in 1,000 grams of water. Salinity may also be quantified using psu, which correspond closely to ppt. The salinity measurement represents the total of all the salts dissolved in the water. Although the salt is comprised of many different ions, those ions are present in relatively constant proportions to each other in open ocean seawater. The principal ions in standard open ocean seawater are chloride, sodium, and magnesium. Together, they constitute over 89 percent of the ions dissolved in standard seawater (Millero 1996).

Strong seasonal variation is apparent in temperature and salinity profiles from the Beaufort and Chukchi seas.

Throughout the spring and early summer, surface warming and associated ice melting increase the sea surface temperature (a maximum value near 8° C), decrease the sea surface salinity (a minimum value near 20 psu), and cause both the thermocline and halocline to occur at relatively shallow depths (20 to 50 m) (Chu et al. 1999). During summer, profiles of temperature and salinity in the Beaufort and Chukchi seas show a multilayer structure, with a shallow mixed layer of warm low-salinity water overlying cooler saltier deep layers.

During winter, low solar energy input resulting from long periods of darkness leads to radiative heat loss from the surface. Cooling at the sea surface destabilizes the shallow mixed layer through strong upward heat flux and salt rejection by ice freezing and results in an isothermal/isohaline structure characterized by relatively uniform temperatures and salinities over the entire depth of the water column (Chu et al. 1999).

Turbidity and Total Suspended Solids

Turbidity is an expression of the optical property that causes light to be scattered and absorbed by a water sample. Turbidity measurements are expressed in Nephelometric Turbidity Units (NTU). Turbidity is caused by suspended matter or other impurities that interfere with the clarity of the water. These impurities may include silt, eroded soils, suspended organic solids, and plankton and other microorganisms (EPA 1999b). Turbidity is an optical property that is closely related to the concentration of total suspended solids in the water. Measurements of total suspended solids are expressed in milligrams per liter (mg/L).

In the Beaufort and Chukchi seas, natural turbidity is caused by particles from riverine discharge, coastal erosion, and resuspension of seafloor sediment, particularly during summer storms. Because the particles that interfere with the clarity of the water are predominantly from terrestrial sources, naturally-occurring turbidity levels in the Beaufort Sea are greatest in near shore waters and generally decrease with distance from shore as particles settle out of the water column (Trefry et al. 2009). Similar spatial trends in turbidity can be expected to occur in the Chukchi Sea; however due to the current regime in the Chukchi Sea and the relatively wide shallow Chukchi shelf, resuspended seafloor sediments may contribute substantially to offshore turbidity levels in the Chukchi Sea (Pickart et al. 2005).

Turbidity can affect phytoplankton growth by limiting the depth to which light penetrates the water column. High turbidity levels may also affect filter-feeding organisms and influence the ability of fish gills to absorb dissolved oxygen. Pollutants and pathogens may be associated with suspended solids, such that changes in turbidity may indicate changes in the ability of the water to support marine biota.

Turbidity in the Beaufort and Chukchi seas varies depending on the season of the year, weather conditions, and the location. Turbidity levels are generally higher during the summer open-water period relative to the winter ice-covered period.

Measurements of turbidity in nearshore Beaufort Sea waters during summer show large variations due to changes in wind conditions. Under relatively calm conditions (winds less than 5 knots) during late summer, turbidity levels are likely to be less than 3 Nephelometric Turbidity Units and under high winds (greater than 25 knots), turbidity may be in excess of 80 Nephelometric Turbidity Units (Figure 3.1-10) (Boehm 2001).

Nearshore waters generally have high concentrations of suspended material during spring and early summer because runoff from the rivers produces very high turbidity adjacent to the river mouths. Maximum values correspond to midseason river-discharge peaks following large rainfall events in the Brooks Range. The highest levels of suspended particles in the discharge are found during breakup; maximum concentrations of total suspended solids ranged from 60 mg/L to 106 mg/L in the Kuparuk River during 2006 and 285 mg/L (2004) to 353 mg/L (2006) in the Sagavanirktok River (Trefry et al. 2009). Turbidity is also affected by natural erosion of organic material along the shorelines. Erosion and flooding associated with autumn and spring storms may increase inputs of organic material from the shorelines and locally increase turbidity (MMS 2008). The resulting turbidity limits light availability and measurably reduces primary productivity of shallow coastal waters (Dunton et al. 2004).

In winter, the turbidity in water under the sea ice is generally lower compared to the summer open water season. As sea ice forms during fall, particulates are removed from the water column by ice crystals and are locked into the ice cover. Formation of surface ice also causes a decrease in waves and currents in response to wind. As a result of decreased wind energy input, the capability of the water to retain particles in suspension diminishes. Settling of particles decreases the turbidity in the water column.

In April 2000, as part of the Arctic Nearshore Impact Monitoring in Development Area (ANIMIDA) project, the turbidity levels at various depths in the water column under about 2 m (6.6 ft) of ice were determined from water samples collected from stations in the vicinity of the Endicott development island, the Northstar Island, and in Foggy Island Bay (Boehm 2001). Turbidity measurements ranged from 0.15 to 1.35 Nephelometric Turbidity Units (Boehm 2001). These levels are 10 to >100 times lower than values obtained during the open-water period of August 1999 (Figure 3.1-10) and provide a good indication of turbidity under the 1.6 to 2.4-m (5.3 to 7.9-ft) thick layers of sea ice (Boehm 2001). The lowest levels of turbidity were observed at the more-offshore stations.

Metals

Concentrations of solid-phase metals in sediment, and dissolved-phase metals in marine waters, help identify spatial and temporal trends in the distribution of potential anthropogenic chemicals (Brown et al. 2010).

In the marine environment, metals are found in the dissolved, solid, and colloidal phases. The distribution of metals among the three phases depends upon the chemical properties of the metal, the properties of other constituents of the seawater, and physical parameters. Current EPA water quality criteria for metals in marine waters are based on dissolved-phase metal concentrations because they most accurately reflect the bioavailable fraction, and hence the potential toxicity of a metal (EPA 2009b). The State of Alaska has adopted these criteria for protection of state waters in 18 AAC 70. EPA also uses these criteria to ensure protection of federal waters (EPA 2006b).

The main inputs of naturally-occurring metals to the Arctic Ocean are derived from terrestrial runoff, riverine inputs, and advection of water into the Arctic Ocean via the Bering Strait inflow and the Atlantic water inflow. Atmospheric inputs of metals to the environment should be relatively small compared to inputs from marine and terrestrial sources (Moore 1981, Yeats and Westerlund 1991). Naturally occurring concentrations of metals are generally higher in the Chukchi Sea relative to those in the Beaufort Sea. The higher concentrations are thought to come from Bering Sea water that passes first through the Chukchi Sea and then through to the Beaufort Sea (Moore 1981, Yeats 1988). Metals from the Bering Sea may be deposited in Chukchi Sea sediments as Bering Sea water flows over the relatively shallow Chukchi Sea Shelf.

Concentrations of dissolved metals were measured in seawater samples from the coastal Beaufort Sea during both the ANIMIDA and Continuation of Arctic Nearshore Impact Monitoring in Development Area (cANIMIDA) projects (Table 3.1-7) (from Neff 2010). Concentrations of dissolved arsenic, chromium, and lead were lower than reported values for surface seawater worldwide. Arsenic concentrations in the low-salinity nearshore samples were below the world average for open ocean waters because dissolved arsenic concentrations in seawater vary concomitant with salinity. In contrast, concentrations of dissolved cadmium, copper, and zinc were higher than in typical surface seawater. Concentrations of dissolved barium were similar to those in typical surface seawater, except during 2000 and 2001, when more nearshore samples were collected (Neff 2010).

Another part of the cANIMIDA program involved measurement of existing concentrations of fourteen metals (Ag, As, Be, Cd, Co, Cr, Cu, Hg, Ni, Pb, Sb, Tl, V, and Zn) in sediment from the nearshore Alaskan Beaufort Sea (Brown et al. 2010). Four other metals (Al, Fe, Ba, and Mn) were included in the study as indicator metals because they provide insight into sediment composition (Al in clays and Fe in iron oxide coatings), the presence of drilling discharges (barium in barite, a common additive in drilling fluids), and sediment redox conditions (manganese, a redox-sensitive metal) (Brown et al. 2010).

Aluminum rarely is introduced into the environment by anthropogenic activities. Normalizing concentrations of other metals to those of aluminum provides a valuable tool for identification of potential sources of contamination. This technique was used by Brown et al. (2010) to identify a total of about 17 minor anomalies in the concentrations of measured metals relative to aluminum (0.9 percent of data points) in the cANIMIDA area. However, the authors concluded that concentrations of potential contaminants in suspended sediments, as well as dissolved and particulate metals and hydrocarbons in the development area, are primarily from terrestrial sources and are nearly always at background levels (Neff 2010).

Hydrocarbons and Organic Contaminants

Hydrocarbons are organic compounds comprised entirely of hydrogen and carbon. Hydrocarbons can be divided into three general categories based on their molecular structures: 1) saturated hydrocarbons (alkanes) contain only single bonds; 2) unsaturated hydrocarbons (alkenes and alkynes) contain one or more double or triple bonds; 3) aromatic hydrocarbons (including polycyclic aromatic hydrocarbons [or PAH]) contain one or more aromatic ring. Because of their nonpolar molecular structures, most hydrocarbon compounds have very low solubility in water, and tend to associate with organic material or solid phase particles (such as sediments) in the environment.

Petroleum is a complex mixture of saturated, unsaturated, and aromatic hydrocarbons, and other related compounds.

Background hydrocarbon concentrations in Beaufort Sea water are present at concentrations of one part per billion or less (Trefry et al. 2004). Whole water samples from three areas of the Beaufort Sea sampled as part of the cANIMIDA study contained 37 to 69 ng/L (parts per trillion) total petroleum hydrocarbons (Neff 2010). Most of the PAH compounds in the whole water samples were associated with the particulate fraction (Neff 2010). Concentrations of dissolved PAH ranged from 13 to 19 ng/L. The low molecular weight 2- and 3-ring PAH were much more abundant than the higher molecular weight 4- through 6-ring PAH in both the particulate and dissolved fractions, indicating that much of the PAH content in surface waters was from a petroleum source (Neff 2010).

Hydrocarbons analyzed in Beaufort Sea sediments include total saturated hydrocarbons (SHC) C9 through C40, PAH, and triterpanes (Brown et al. 2010). An established technique of evaluating the significance of the measured sediment hydrocarbons to overall ecological risk of the region involves comparisons to sediment quality guidelines or benchmarks. Sediment quality guidelines have been developed to assess possible adverse biological effects from metals, polychlorinated biphenyls (PCBs), pesticides, and PAH. The commonly utilized criteria are the Effects Range Low (ERL) and Effects Range Median (ERM) presented by Long et al. (1995). (It should be noted that more recent consensus-based sediment quality guidelines are available (*e.g.*, MacDonald et al. 2000, Buchman 2008)). The general applications of the guidelines have been to state that adverse biological effects are “rarely” observed when PAH levels are less than the ERL, “occasionally” observed when contaminants are present at levels between the ERL and ERM, and “frequently” observed when concentrations exceed the ERM. ERL and ERM values have been developed for 13 individual PAH compounds and three classes of PAH (low- and high-molecular-weight PAH, and Total PAH).

Saturated Hydrocarbons

For most Beaufort Sea stations, the total saturated hydrocarbon concentrations in surficial sediments are low relative to the guideline concentrations, ranging from 0.21 to 16 milligrams per kilogram (mg/kg) (Boehm 2001). These hydrocarbons are a mixture of terrestrial plant waxes with lower levels of petroleum hydrocarbons.

Samples of river sediments and peat have total saturated hydrocarbon values of 5.8 to 36 mg/kg and 21 to 32 mg/kg, respectively (Boehm 2001). Sediments were sampled in the Colville, Kuparuk, and Sagavanirktok rivers. Peat samples came from areas along the Colville and Kuparuk rivers. The compositions of saturated hydrocarbons in the river and peat samples were similar to the composition in Beaufort Sea surficial sediments. This similarity indicates a common source of saturated hydrocarbons for river sediments and nearshore surficial sediments.

The highest total saturated hydrocarbon value, 50 mg/kg, for this suite of samples was found at the station west of West Dock in Prudhoe Bay (Boehm 2001). The sample from this station also contained high concentrations of metals and indicated contamination from an anthropogenic source.

Table 3.1-7 Mean concentrations of dissolved metals and salinity in seawater water collected from the coastal Beaufort Sea and near Northstar Island during the open-water season in 2000 through 2006. All dissolved metal concentrations are µg/L (parts per billion).

Polycyclic Aromatic Hydrocarbons

PAH concentrations measured during the ANIMIDA project were within the range of values reported from previous studies in the Beaufort Sea and other areas (Boehm 2001). The PAH distributions for most of the surficial sediments sampled during the cANIMIDA project show that the PAHs are primarily of a combined fossil fuel origin (i.e., petroleum and coal) with a biogenic component (perylene), and a smaller fraction of pyrogenic or combustion-related constituents (e.g., 4-, 5-, and 6-ring PAHs) (Brown et al. 2010).

ERL and ERM values have been developed for 13 individual PAH compounds and three classes of PAH (low- and high-molecular-weight PAH, and Total PAH). A comparison of the Total PAH from all ANIMIDA and cANIMIDA sediments from the study region in 1999 through 2006 to the ERL and ERM criteria shows that none of the measured Total PAH concentrations exceed the ERL (Brown et al. 2010). The mean Total PAH values from each study region were generally an order of magnitude lower than the respective ERLs (Brown et al. 2010). Similarly, the individual PAH concentrations did not exceed the ERLs for the individual 13 PAHs (Brown et al. 2010).

Based on sediment quality criteria, the concentrations of PAH found in the cANIMIDA study area sediments are not likely to pose ecological risk to marine organisms (Brown et al. 2010).

Triterpanes

Triterpanes are biogenic organic molecules found in both petroleum and non-petroleum sediment extracts and applied as biomarkers to identify the origins of hydrocarbon mixtures (Waples and Machihara 1990). The structures of triterpane molecules generally include from 19 to 30 carbon atoms, with some exceptions up to 45. Because triterpane molecules are relatively stable in the environment and easily analyzed using widely available instrumentation, the size distribution of triterpane molecules in a sample can be often provide useful information about the source of the sample (Simoneit et al. 1990).

Several surficial sediment samples analyzed from the cANIMIDA study area have triterpane distributions indicative of a petroleum source (Neff 2010). At the site west of West Dock, the triterpane distributions corroborate other organic data indicative of diesel fuel contamination in this area. However, the triterpanedistribution data also indicate the presence of petroleum products “heavier” than diesel, as the distillation process typically removes triterpanes from diesel-range fuels. The cANIMIDA Task 2 final report, “Hydrocarbon and Metal Characterization of Sediments in the cANIMIDA Study Area,” suggests that petroleum contamination at the site west of West dock is comprised of a complex hydrocarbon mixture including diesel and heavier hydrocarbons such as heavy fuel oil or crude oil (Brown et al. 2010). Drilling mud/cutting residues from historical exploratory drilling in the area (i.e., Tern Island) could be the source of this contamination , as the historical standard practices involved disposal of used drill muds on the ice during winter drilling (Brown et al. 2010). At other sampled sites, triterpane distributions are indicative of naturally occurring hydrocarbon inputs to the sediments (e.g. erosional inputs of regional shales, coal, peat, etc.) (Brown et al. 2010).

Other Organic Contaminants

Surface samples were also analyzed for pesticides, polychlorinated biphenyls, semivolatile organic compounds, and selected volatile organic compounds. Concentrations of these substances were within a low range, and were usually below the limits of detection for the analysis (MMS 2008).

3.1.8 Environmental Contaminants and Ecological Processes

This section includes descriptions of ecological processes and ecosystem functions in the affected environment and the environmental contaminants that potentially affect those processes and functions.

Brief descriptions of the ‘ecosystem goods and services’ provided by the U.S. Beaufort and Chukchi seas ecosystem will provide context for subsequent evaluation of potential cumulative impacts on the ecosystem and impacts on the local communities that depend on healthy ecosystems for their social, cultural and subsistence way of life.

3.1.8.1 U.S. Beaufort and Chukchi Seas Marine Ecosystem Goods and Services

"Ecosystem functions" refer to properties of the Alaska Arctic region habitat, biological and geochemical systems and the processes facilitated by those systems. Ecosystem goods (such as subsistence foods) and services (such as waste assimilation) represent the benefits that human populations derive, directly or indirectly, from those ecosystem functions (Costanza et al. 1997). Ecosystem services consist of the flows of materials, energy, and information from natural capital stocks (*i.e.* habitats, biological and geochemical systems) that combine with human actions to produce value or welfare for humans (Costanza et al. 1997). A large number of Beaufort and Chukchi seas ecosystem functions can be identified, and many of the goods and services that depend on those ecosystem functions are discussed in other sections of this document. Some examples of relevant ecosystem functions, goods, and services from the region are summarized in Table 3.1-8.

Table 3.1-8 Examples of Arctic Ecosystem Functions, Goods, and Services.

Ecosystem goods and services	Ecosystem Functions	Examples
Subsistence food	Primary production, nutrient cycling, and trophic processes	Edible animals and plants; fish (subsistence food resources)
Waste treatment; water purification	Recovery of mobile nutrients and or breakdown of contaminants	Pollution control; detoxification
Climate regulation	Regulation of temperature, precipitation, albedo	Climate change mitigation; biogeochemical stability
Raw materials	Provision of raw materials, fuel	Oil and gas
Recreation resources	Provision of opportunities for recreation	Wildlife viewing; recreational boating; tourism
Cultural Resources	Provision of opportunities for non-commercial uses	Aesthetic, spiritual, educational, and scientific values

The values of ecosystem goods and services in the Beaufort and Chukchi seas are usually derived from interplay among various ecosystem components— the physical environment, chemical environment, and biological communities. Ecosystem goods and services are only rarely the product of a single species or component. Therefore, the interactions of various ecosystem components must be considered as important aspects of the affected environment.

3.1.8.2 Identification of Stressors of Potential Concern

A stressor can generally be defined as anything that negatively affects human health and/or ecological processes. Stressors can be physical (e.g. temperature), chemical (i.e. contaminants), or biological (e.g. bacterial contamination). In order to assess potential ecological effects, and related impacts to ecosystem goods and services, stressors potentially resulting from oil and gas exploration activities in the Beaufort and Chukchi seas must be identified. All three types of stressors may be directly or indirectly associated with oil and gas exploration. However, this section will focus on chemical Stressors of Potential Concern (SOPCs) (i.e., contaminants) resulting from oil and gas exploration activities in the Beaufort and Chukchi seas. Particular consideration will be given to levels of anthropogenic chemicals in the environment that may be accessible to organisms for assimilation and possible toxicity (i.e., bioavailable).

Existing development in the project area provides multiple sources of contaminants that may be bioavailable. Chronic discharges of contaminants occur during every breakup from fluids entrained in the ice roads. Entrained contaminants from vehicle exhaust, grease, antifreeze, oil, and other related fluids pass into the Beaufort Sea system. These discharges may involve organic contaminants with high potential for bioaccumulation (Brown et al. 2010). Although drilling fluids and cuttings are usually disposed of through onsite injection into a permitted disposal well, or transported offsite to a permitted disposal location, some drilling fluids are discharged at the sea floor before well casings are in place. Drill cuttings and fluids contain relatively high concentrations of contaminants that have high potential for bioaccumulation, such as dibenzofuran and PAHs (see Table 3.1-9). Historically, drill cuttings and fluids have been discharged from oil and gas drilling in the project area, and residues from historical discharges may be present in the affected environment (Brown et al. 2010).

Table 3.1-9 Water Quality Data for Drill Cuttings

Pollutant	Range of Concentrations Before Washing	After Washing
Conventional Parameters		
pH	5.70 – 8.42	7.00 – 9.20
Specific gravity (kg/L)	1.26 – 2.07	0.98 – 1.59
BOD-5 (mg/kg) (Biological Oxygen Demand)	325 – 4,130	3,890 – 8,950
UOD-20 (mg/kg) (Universal Oxygen Demand)	2,640 – 10,500	12,800 – 26,600
TOC (mg/kg) (Total Organic Carbon)	58,300 – 64,100	23,000 – 27,200
COD (mg/kg) (Chemical Oxygen Demand)	190,000 – 291,000	90,600 – 272,000
Oil & Grease (mg/kg)	54,200 – 130,000	8,290 – 108,000
Metals (mg/kg) (average of duplicate samples on a dry weight basis)		
Zinc	107 – 2,710	114 – 3,200
Beryllium	<1.0	<1.0
Aluminum	6,020 – 10,900	5,160 – 10,500
Barium	34 – 84.8	27.2 - 235
Iron	16,600 – 30,800	17,400 – 20,600
Cadmium	0.402 – 16.4	0.408 – 15.8
Chromium	9.48 – 11.7	10.7 - 12
Copper	20.6 – 55.3	20.4 – 42.6
Nickel	<6 – 12.1	6.2 – 15.9
Lead	21.4 - 298	47.6 - 264
Mercury	0.09333 – 0.4893	0.0920 – 0.944
Silver	0.447 – 0.574	0.222 – 0.568
Arsenic	7.07 – 10.3	7.0 – 10.6

Pollutant	Range of Concentrations Before Washing	After Washing
Selenium	<3.0	<3.0
Antimony	<0.06 - <0.35	<0.06 - <0.35
Thallium	0.235 – 0.57	0.134 – 0.866
Organics (µg/kg) (wet weight basis)		
Acenaphthene	677 – 38,800	
Naphthalene	3582 – 149,000	63,500
4-Nitrophenol	30,400	
N-Nitrosodiphenylamine	2,870 – 56,500	3,150 – 24,300
Bis (2-ethylhexyl) Phthalate	17,300	
Phenanthrene	59,900 – 145,000	25,800 – 65,700
Pyrene	18,900	7,860
Dibenzothiophene	37,300	15,000
Dibenzofuran	2,150 – 33,700	21,700
N-Dodecane	23,000 – 403,000	6,300 – 185-000
Diphenylamine	56,500	5,900 – 23,400
Alphaterpineol	6,310	
Biphenyl	4,230 – 69,400	1,170 – 33,000

While chemical concentration data are useful for determining the relative degrees of contamination among sampling sites, they provide neither a measure of adverse biological effects nor an estimate of the potential for ecological effects (Calow and Forbes 2003). One way to relate chemical concentrations to the potential for adverse effects involves comparisons of measured values to established threshold values. Previous studies in the U.S. Beaufort and Chukchi seas have employed the system described by Long and Morgan (1990), and Long et al. (1995) for comparison of measured values to ERL and ERM concentrations for contaminants in marine and estuarine sediments. Brown et al. (2010) used ERL concentration values as the thresholds above which adverse effects are predicted to occur to sensitive life stages and/or species. The ERM values for the chemicals were the concentrations equivalent to the 50 percentile point in the screened available data. They were used as the concentration above which effects were frequently or always observed or predicted among most species. Because the ERL and ERM concentrations account for the effects of individual chemical stressors on multiple species from different trophic levels, this approach may provide a basis for predicting the likelihood of ecosystem-level impacts that could result from inputs of chemical contaminants.

Many of the organic contaminants associated with past development in the project area (*e.g.*, PAH) have low solubility in water due to their nonpolar molecular structures. As a result of low aqueous solubility, these compounds tend to associate with organic material or solid-phase particles (such as sediments) in the environment. Similarly, the elemental forms of some potentially toxic metals, such as lead and mercury, have low aqueous solubility. However, these metals may react with other naturally occurring chemical species to form soluble compounds. For example, elemental mercury (Hg) is relatively insoluble in water, while mercuric chloride ($HgCl_2$) and dimethyl mercury (C_2H_6Hg) are considerably more soluble.

The aqueous solubility of a contaminant is an important parameter for determining its behavior in the environment, and the potential pathways through which organisms could be exposed to the contaminant.

The differential solubility of a contaminant between organic and aqueous phases can be expressed as the octanol-water partition ratio. Contaminants with high octanol-water partition ratios are relatively hydrophobic and tend to associate with organic molecules in the environment (*e.g.*, sediments and lipids). Contaminants with lower octanol-water partition ratios are relatively hydrophilic, and elevated concentrations of these soluble contaminants may be found in the water. The behavior of a contaminant in the environment, and the potential pathways for exposure of organisms, depend upon the aqueous solubility of the contaminant as well as the physical, chemical, and biological characteristics of the environment. For these reasons, chemical concentration data from different matrices (*e.g.*, water, sediments, and biota) must be considered in combination with an understanding of the processes that connect ecosystem components in order to meaningfully predict the impacts of chemical contaminants on ecosystem processes.

The relationships between chemical contaminants and ecosystem processes must be considered when assessing the potential for ecological and societal consequences of pollution (Calow and Forbes 2003).

3.1.8.3 Exposure of Biological Communities

The fundamental theoretical basis for assessing the environmental impacts of contaminants is provided by the dose–response model, in which the number of individual organisms in a test population responding to different doses of a chemical is used as a measure of the chemical toxicity (Calow and Forbes 2003). Results of dose-response experiments are often expressed in terms of a fixed percentile (*e.g.*, the LD_{50}, or the dose at which 50 percent of the test population suffers a lethal response). However, it is generally recognized that the dose-response model is an oversimplification of real ecological conditions and fails to take into account the ecosystem-level effects of contaminants (Calow and Forbes 2003). The dose-response model traditionally used in environmental impact assessment only considers the effects of stressors on individuals or populations and does not account for impacts that may occur at the ecosystem level (Figure 3.1-11).

Ecology is rarely concerned only with individuals or populations. Communities (mixed species groups) and ecosystems (communities in interaction with their abiotic surroundings) can persist, within limits, despite losses of individuals or populations. What matters is persistence of ecosystem functions and prevention of irreversible reductions that could lead to extinction (Calow and Forbes 2003). The ecosystem of the U.S. Beaufort and Chukchi seas is dynamic, and there are complex relationships between biological community structure, environmental chemistry, and the ecosystem functions responsible for the provision of ecosystem goods and services. Extrapolating the results of toxicity tests to likely ecosystem-level effects involves a number of uncertainties (Calow and Forbes 2003). However, there are some general trends, which should increase confidence in relating the results from toxicity tests to more complex ecological systems.

When ecosystems are not affected by strong external perturbations, certain well-defined developmental trends can be observed. For example, in the absence of external disturbance, the biomass in a system tends to increase, and net community production tends to decrease (Odum 1985). An increase in respiration at the community-level should be the first early warning sign of stress because repairing damage caused by stress requires diverting energy from growth and production to maintenance. Thus, the respiration to biomass ratio (R/B) increases as damage induced by a stressor is repaired (Odum 1985). Accordingly, stressed ecosystems tend to exhibit a decreased ratio of biomass to energy flow, or a low efficiency of converting energy to biological structure. In practice, it is difficult to detect small increases in respiration in large open systems. However, changes in the rates of physiochemical processes (*e.g.* respiration and photosynthesis) can be measured at the community level, and this is the level at which we should search for early warning signs of stress (Odum 1985). Changes in rates of production and respiration relative to biomass are more useful than lethal responses as indicators of early system-level stress.

Stressed systems also exhibit changes in nutrient cycling, which are analogous to the changes in energetics described in the previous paragraph. Rates of nutrient turnover increase in perturbed systems, and the recycling of nutrients within systems becomes less efficient. In an unperturbed system, the transfer of nutrients between trophic levels is relatively complete, and net nutrient loss from the system is accordingly low (Odum 1985). However, in response to system-level stress the couplings between trophic levels become less organized and nutrients are lost from the system as a result. Exported or unused primary production tends to increase in response to system-level stress (Odum 1985). As a result, food chains become shorter because of reduced energy and nutrients at higher trophic levels, and diversity of apex species tends to decline.

Measurement of ecosystem-level responses to stress involves a number of uncertainties. However, energy flows and nutrient cycles provide robust information about ecosystem functions, and must be considered in order to assess the cumulative effects of environmental contaminants in the U.S. Beaufort and Chukchi seas.

3.1.8.4 Oil Spill History

Several studies have reviewed the history of oil industry spills in the U.S. OCS and Canadian Beaufort Sea (Hart Crowser 2000, Anderson and LaBelle 2000, State of Alaska 2007a, b, Nuka Research and Planning Group 2010). The state of knowledge related to Beaufort Sea oil spills, including an extensive literature review, is presented by SL Ross Environmental Research Ltd. et al. (2010). The responses to five spills on the North Slope of Alaska, in particular the March 2006 pipeline release from an infield pipeline onto snow-covered tundra, are described by Majors and McAdams (2008).

Because sufficient historical data on large (greater than or equal to 1,000 barrels) offshore oil spills do not exist for the Alaska Arctic OCS regions, agencies rely upon estimates to represent expected frequency and severity of oil spills in these regions (Holland-Bartels et al. 2011, Bercha International Inc. 2006, 2008 [in OCS Study MMS 2006-033 and OCS Study MMS 2008-O35] and MMS 2007a). Oil spill occurrence estimates have been generated for several expected future oil and gas development scenarios (including exploration, production, and abandonment) in the Beaufort and Chukchi seas (Bercha International Inc. 2006 and 2008 [in OCS Study MMS 2006-033 and OCS Study MMS 2008-035] and MMS 2007a). The above referenced reports describe oil spill occurrence models based on fault-tree analysis. Fault-tree analysis is a method for estimating spill rates resulting from the interactions of other events. Fault trees are logical structures that describe the causal relationship between the basic system components and events resulting in system failure. Fault-tree models are graphical techniques that provide a systematic estimate of the combinations of possible occurrences in a system, which can result in an undesirable outcome. Using fault trees, base data from the Gulf of Mexico were modified and augmented to represent expected Arctic offshore oil spillage frequencies.

3.1.8.5 Existing Regulatory Control of Discharges

Regulatory control of ocean discharges associated with oil and gas exploration activities in the Alaska Arctic Region OCS is largely under the purview of the EPA. A more detailed discussion of the existing regulatory controls of ocean discharges, including national and regional contingency plans for response to oil and hazardous substance discharges and releases, can be found in Section 2.3.3.

3.2 Biological Environment

3.2.1 Lower Trophic Level Ecology

The following section describes the lower trophic level environments in the Beaufort and Chukchi seas, trophic level interactions, and the influence of climate change on lower trophic level ecology. Descriptions of the physical environment such as physical oceanography and water quality have been discussed in Sections 3.1.1 and 3.1.7 respectively, so therefore are not repeated here. Lower trophic levels have been described in several EISs for oil and gas lease sales in both the Beaufort and Chukchi seas (MMS 1990, 1991, 2007c, 2008 and 2009a, Foster et al. 2010); these descriptions are incorporated in this document by reference and are summarized below.

3.2.1.1 Lower Trophic Level Environments

Lower trophic levels can be categorized as: epontic (living on the underside of or in sea ice); pelagic (living in the water column); and benthic (living on or in the sea bottom) (MMS 1991).

Epontic

Microalgae are found in sea ice as it forms in the fall, but the origin of the cells is not known (Horner and Schrader 1982). One theory suggests the species may be present in low numbers in the water column and may be incorporated into the ice as it forms (Horner and Schrader 1982, MMS 1991). The primary producers in the epontic community are ice algae, which live within or attached to the undersurface of sea ice. The ice algae form a concentrated food source for a variety of animals, including amphipods, copepods, ciliates, worms, and fishes, especially in the early spring (Gradinger et al. 2009).

The primary production of epontic communities is largely tied to under-ice light levels, which decrease with increasing ice thickness, snow cover, and sedimentation. Gradinger and Bloom (2005) found that algal blooms were up to two orders of magnitude lower in ice that had high sedimentation loads. Light appears to be the major factor controlling the distribution, development, and production of the ice algal assemblage. These epontic algal communities provide the sole source of fixed carbon for higher trophic levels in ice covered waters, when other sources are absent (NRC 2004). For example, Lee et al. (2010) documented increases in primary productivity in benthic communities resulting from additions by epontic organisms during winter months and as ice recedes.

Pelagic

Planktonic organisms occur in the water column and are subject to the movement of the water, as they are unable to effectively swim against currents. Plankton is comprised of two basic groups, phytoplankton, the primary producers or plant component of the plankton, and zooplankton, the animal component of the plankton (MMS 1991).

The timing of sea ice breakup is critical for phytoplankton production as it provides a stable surface layer with an abundance of light needed for photosynthesis. Spring algal blooms often occur near the sea-ice edge due to wind-driven upwelling of nutrients. Phytoplankton abundance and distribution can be determined with the use of satellite technology by measuring chlorophyll concentrations or ocean color, i.e. “greenness” of the surface water (Wang et al. 2005). High chlorophyll concentrations have been recorded in the southwestern Chukchi Sea and along the coast of the Beaufort Sea (Wang et al. 2005). In fact, primary production rates in the southwest Chukchi Sea are among the highest ever recorded. Generally, these values are much lower near the coast, yet there are areas of high productivity on the continental slope of the Beaufort Sea, in the northern part of the Chukchi shelf between the 50- and 100 m- isobaths, in the southern part of the Chukchi southwest of Point Hope, and on the shelf northwest of Point Barrow (Sukhanova et al. 2009). Favorable conditions on the western Beaufort Sea shelf off Point Barrow in the late summer and fall concentrate euphausiids and copepods (Ashjian et al.,2010, Moore et al., 2010; Okkonen et al., 2011). These concentrations attract large numbers of bowhead whales and other marine mammals (Okkonen et al. 2011, Clarke et al. 2011b, 2011c). Because of this unique biological community, the area has been designated as a special habitat area (see Section 4.5.2.6).

Zooplankton life histories and community structures are intricately coupled to phytoplankton production as prey resources. Therefore, areas with high primary phytoplankton productivity also possess high zooplankton abundance and diversity (Hopcroft et al. 2010). In addition, the spatial distribution of zooplankton communities is strongly tied to physical and chemical differences in water masses (Iken et al. 2010). The zooplankton communities in the Beaufort and Chukchi seas are largely dominated by copepods, mostly *Calanus* and *Pseudocalanus*, followed by larvaceans, and euphausids (Ashijan et al. 2003, Hopcroft et al. 2010). Zooplankton samples in the Beaufort Sea also have included coelenterates, nematodes, annelids, mollusks, tunicates, decapod crustaceans, and barnacles (MMS 1991). Pteropods, cnidarians, and ctenophores are also important constituents of these pelagic communities. This community structure is similar to that in the Pacific and Bering Seas compared to the Arctic due to the high transport rate of water masses northward along the Anadyr current.

Benthic

The shallow continental shelves of the Beaufort and Chukchi seas are among the largest in the world (Grebmeier et al. 2006). Each possess varying substrates such as fine sands, muds, and silts (BOEMRE 2010a) and are closely tied to the distribution of benthic fauna. For example, in benthic communities, mollusks, polychaete worms, and amphipods are patchily distributed in sandy, silty, or muddy sediments (Conlan et al. 2008, Feder et al. 2007). Among the benthic biota, there are localized areas of abundant and diverse marine life where boulders provide a hard substrate for algae and epibenthic macrofauna, such as kelp, to attach (Dunton et al. 2006). The benthic communities in the Beaufort and Chukchi seas can be categorized as: benthic microalgae (microscopic plants); macroscopic algae (large seaweeds); and benthic invertebrates (organisms that live on the bottom of a water body).

Benthic Microalgae

Benthic-microalgal assemblages, consisting primarily of diatoms, have been studied in the nearshore area off Barrow (Matheke and Horner 1974), off Narwhal Island (Horner and Schrader 1982), and in Stefansson Sound (Horner and Schrader 1982, Dunton 1984). The relationship of the species found in sediments with those found in the ice-algal assemblage is unclear, although some species occur in both assemblages. Primary productivity of the benthic microflora in the Chuckchi Sea in the nearshore area off Barrow, as reported by Matheke and Horner (1974), ranged from less than 0.5 mg C/m^2/hr in winter (when the sampling area was covered with ice), to almost 57.0 mg C/m^2/hr in August. This peak-productivity value was about eight times the peak value for ice-algal production and approximately twice that of the phytoplankton. The productivity of these various assemblages peaked at different times: ice-algal productivity peaked in May; phytoplankton productivity peaked in the first half of June; and productivity of the benthic microalgae peaked during late July and August. Although Matheke and Horner (1974) reported high productivities for benthic microalgae over the summer, Horner and Schrader (1982) and Dunton (1984) estimate that benthic microalgae contribute approximately two percent of the annual carbon produced in the Stefansson Sound Boulder Patch, with production in the absence of turbid ice figured at about 0.4 g C/m^2/yr. Until recently, primary production was considered extremely low, based on a sparse data set, but recent work by Cota et al. (1996), Wheeler et al. (1996), Gosselin et al (1997), and Pomeroy (1997) (as cited in Aagaard et al 1999), indicate that annual primary production in the mostly ice covered waters of the Arctic Ocean is about 15 to 30 gC/m2. Primary producers in the Arctic include phytoplankton, ice algae, and benthic microalgae and macrophytes, which are generally assumed to respectively contribute about 95 percent, 5 percent, and <1 percent to panarctic marine productivity (Aagaard et al 1999). Although ice algae have historically been considered of minor importance, studies indicate they may be more important tototal primary production in the Arctic Ocean than previously estimated (Gosselin et al. 1997).

Recent changes in benthic biomass in some Arctic seas, or parts thereof, probably reflect shifts in energy flux patterns, regionally related to sea ice loss. Biomass changes over the past one to three decades include an increase in epifaunal biomass in parts of the Bering and Chukchi seas (Bluhm and Grebmeier 2011).

Macroscopic Algae

Although most substrates in the Beaufort and Chukchi seas are unsuitable for settlement and growth of large algae, some still persist. Hard substrates (such as cobbles and boulders) occur sporadically, allowing for larger kelp communities. The occurrence of such substrates does not always coincide with large algae since ice gouging can prevent its establishment or growth.

Kelp beds are known to fulfill many diverse habitat functions in other regions of the world's coastal oceans, such as providing three-dimensional space, protection, food, and nursery areas for juvenile life stages (Iken 1999, Iken et al. 1997, Dean et al. 2000, Beck et al. 2003) and as such, often increase the number of associated fauna (Taylor 1998). In the Boulder Patch, located in the central Alaskan Beaufort Sea, for example, an important portion of carbon channeling through the food web is derived from macroalgae and approximately 60 percent of the particulate organic matter found in the environment (Dunton and Schell 1987, Dunton 1984).

Kelp beds have been found in the Beaufort Sea in Stefansson Sound, the Boulder Patch, and Camden Bay. The Boulder Patch is an isolated macroalgal-dominated rocky bottom habitat within the usually soft-sediment environment of the Beaufort Sea. A map of the Boulder Patch shows the location of this habitat in Steffanson Sound between Point Brower and Cross and Narwhal islands (Coastal Marine Institute 2011). The Boulder Patch has been studied extensively, and more than 140 species of invertebrates have been identified including sponges, byrozoans, and hydrozoans with the dominant taxa being red and brown algae (Dunton et al. 2007, MMS 2007c, 2003). The biodiversity and community structure patterns vary among different locations within the Boulder Patch, mainly due to differences in light levels and substrate type. Light limits the growth of kelp in the winter when nutrient levels are high, and, in the summer, nutrients limit the growth when light levels are high (Dunton and Schell 1986). Kelp also has been observed shoreward in an area behind a shoal near Konganevik Point in Camden Bay.

Although systematic surveys for macroscopic algae, especially kelp beds, have not been undertaken in the northeastern Chukchi Sea, records from a variety of sources indicate the presence of at least two kelp beds along the nearshore coast. One first described by Mohr et al. (1957) and confirmed by Phillips et al. (1982) is located about 20 km (12.4 mi) northeast of Peard Bay, near Skull Cliff. Another was reported by Phillips and Reiss (1985a) approximately 25 km (15.5 mi) southwest of Wainwright in water depths of 11 to 13 m (36 to 43 ft). Even without detailed surveys, it appears that kelp beds are not frequently encountered in the Chukchi Sea. Mohr et al. (1957) remarked that kelp were found at only one of 18 stations sampled by the Arctic Research Lab's LCM William E. Ripley as it traveled from Point Barrow to Wainwright; the one station where it found algae was near Skull Cliff. The predominant alga at this station was the kelp, *Phvllaria dermatodea*. Two other known algae, *Laminaria saccharina* and *Desmarestia viridis*, also were abundant; and seven species of red algae were sampled. Johnson et al. (1993) reported observing very large quantities of green algae (probably *Ulva* and *Enterornorpha*) which were being utilized as a feeding area by brant. Other macroscopic algae have been noted in Peard Bay, as drift algae and when fouling anchors (Truett 1984). The areal extent and the inherent possibility of variability in areal extent have not been determined.

Benthic Invertebrates

Benthic invertebrates in the Beaufort and Chukchi seas can generally be divided into two main categories: epifauna and infauna, based on their relationship with the substrate. Infaunal organisms live within the substrate and, as a result, are often sedentary. Epifaunal organisms, on the other hand, generally live on or near the surface of the substrate (MMS 1990). Benthic communities offshore can be quite diverse.

Organisms commonly found in surveys include echinoderms, sipunculids, mollusks, polychaetes, copepods, and amphipods (Dunton, Schonberg, and McTigue, 2009; Rand and Logerwell, 2011).

Blanchard et al. (2010) reported that infauna in Burger and Klondike survey areas, associated with the Chukchi Sea Lease Sale 193, are abundant, contain many animals with high biomass, and comprise diverse communities. They found that average abundance, biomass, and number of infauna taxa were significantly higher in Burger than in Klondike, but macrofaunal communities in both survey areas were similarly diverse. Macrofaunal community structure was discovered to be correlated with environmental characteristics such as percent sand, salinity, and phaeopigment concentrations, associated with topography, water currents and other related factors within their survey areas. The Lease Sale 126 EIS (MMS 1991) explains that the area around the Burger Prospect is inhabited by polychaete *Maldane*, brittle star *Ophiura*, sipunclid (peanut worm) *Golfingia*, and bivalve *Astarte*. Ambrose et al. (2001) found that brittle stars were overwhelmingly dominant in some parts of the northeastern Chukchi Sea.

Blanchard et al. (2010) also sampled a gray whale feeding area northwest of Wainwright and found the site to be dominated by amphipods, whereas the faunal communities found in Burger and Klondike were dominated by bivalves and polychaete worms.

As with the infauna, Blanchard et al. (2010) reported that the epifaunal communities of Burger and Klondike comprise taxon groups with high abundance and biomass reflecting diverse communities. Immobile fauna such as sponges, encrusting bryozoans, hydroids, soft corals, and tube worms thrive on the rocky and macroalgal substrates (Dunton et al. 2007, Konar and Iken 2005).

In the Beaufort Sea, Dunton et al. (1982) describes the discovery of the “Boulder Patch,” an arctic kelp community in an area of cobbles and boulders with attached kelp and invertebrate life. He reported that sponges and cnidarians were the most conspicuous invertebrates there because of the large size of some species, their abundance, and their striking shapes and colors. Two sponges *Choanites lutkenii* and *Phakettia cribrosa* and pink coral (*Gersemia rubiformis*) are widespread. At least four sea anenomes (order *Actinaria*) are present. Other conspicuous invertebrates include several species of *Tubularia*, a stalked hydrozoan. Smaller less-conspicuous epilithic animals (such as hydroids and encrusting sponges) form a turf-like covering on rocks. Molluscs, bryozoans, and members of the urochordate group are common on rocks and attached to other biota. The chiton Amicula vestita constitutes the greatest percentage of molluscan biomass, and juvenile mussels of the genus Musculus have the greatest density. Erect and encrusting colonies of bryozoans are common on rocks and red algae. The inconspicuous sea spider, *Nymphon grossipes*, is usually found among these dense mats of algae and attached invertebrates.

Aquatic Invasive Species

An “invasive species” is defined as “a species whose introduction does or is likely to cause economic or environmental harm or harm to human health where it is introduced” (Executive Order 13112 of February 3, 1999: Invasive Species). Potential vectors for introducing aquatic invasive species are ballast-water discharge, fouled ship hulls, and equipment placed overboard (e.g., anchors, seismic airguns, hydrophone arrays).

The USCG developed regulations (33 CFR 151) that implement provisions of the National Invasive Species Act of 1996. Vessels brought into the State of Alaska or Federal waters are subject to these USCG regulations, which are intended to reduce the transfer of invasive species. The regulations require operators to remove "fouling organisms from hull, piping, and tanks on a regular basis and dispose of any removed substances in accordance with local, State, and Federal regulations” (33 CFR 151.2035(a)(6)). The regulations, however, do not specifically call for the same removal procedures for ocean-bottom cables or seismic equipment. There is a low potential for pelagic organisms and seaweed to become entrained in equipment towed during a seismic survey (Kinloch et al. 2003). Typical organisms that are returned with the seismic streamers are jellyfish tentacles and shark teeth. These items are removed from the streamer by hand before it is rewound on the drum. A systematic cleaning and scraping of equipment at the completion of a survey, as the equipment is brought onboard the vessel, is another way to minimize transfer of marine species and ensure that the equipment is stored properly prior to transit to a new location.

Large and widespread communities of invertebrates were found during surveys carried out between the Chukotka Peninsula and Point Lay in the Chukchi Sea (Sirenko and Gagaev 2007). These were warm-water invaders of temperate Pacific origin, probably arriving by way of advection from southern waters. These communities included large invertebrate species such as bivalve molluscs (*Pododesmus machrochisma*) and crabs (*Telmessus cheiragonus* and *Oregonia gracilis*), species that were not previously recorded at this latitude. This published account confirms the potential of temperate species to become established in U.S. Arctic waters.

The potential for impacts by invasive species is considered within analyses of lower trophic levels for each alternative and under cumulative effects analysis for water quality, environmental contaminants and ecosystem functions, lower trophic levels, fish and essential fish habitat, and terrestrial mammals.

3.2.1.2 Trophic Level Interactions

In the Beaufort and Chukchi seas, the trophic levels not only interact, but are interdependent (Figure 3.2-1). For example, it is postulated that incomplete grazing of ice algae may allow a significant portion of the algal-cell population to remain intact, serving as a direct food source for the pelagic level, and if not fully consumed, may enhance the benthic level by sinking as either detritus (dead) or living, photosynthetically active, cells (Alexander and Chapman 1981, Niebauer et al. 1981, Stoker 1981).

Dynamics within the pelagic community are primarily influenced by transport of nutrients, phytoplankton, and consumers from the Bering Sea, plus the seasonal retreat of ice and subsequent bloom of open-water phytoplankton. Other primary producers such as kelp, benthic microalgae, or ice-algae may be locally or temporally important sources of carbon (the ice algae providing a burst of production before the open-water phytoplankton bloom). Zooplankton in the Chukchi Sea are thought to be similar to those of the middle Bering Sea shelf in species composition and as small, inefficient grazers of phytoplankton.

Thus, much of the local production, as well as plankton and detritus transported into the Chukchi Sea, may sink to the ocean floor and support benthic organisms. It has been suggested that the epibenthic (living on the surface of bottom sediments) community is dependent on detritus (Stoker 1981). Both the epifauna and infauna are important components in the diets of higher-order consumers.

In the spring, the melting and retreating ice edge of the Chukchi Sea leads to a highly productive and estuary-like near shore corridor that serves as the base of the food chain for coastal and marine Arctic species. The Chukchi Sea's shallow and highly productive sea floor also allows benthic species such as crustaceans and mollusks to flourish and create an important food source for wildlife specialized to feed at the ocean floor, such as walrus, seals, gray whales, and deep-diving sea birds (Audubon 2011).

The benthic faunal biomass is relatively high in the northeastern Chukchi, compared to the central and western Chukchi and compared to the rest of the Arctic seas (Grebmeier and Dunton 2000). Grebmeier and Dunton (2000) explain that the richness probably is due partly to the inability of Chukchi pelagic fauna to consume all of the primary production, thereby allowing a lot of organic matter to sink to the seafloor. They refer to the situation as weak or loose trophic “coupling,” and the Arctic Climate Impact Assessment (ACIA) refers to such loose coupling as “mismatch” between trophic levels (ACIA 2005).

3.2.1.3 Influence of Climate Change on Lower Trophic Level Ecology

Global climate change is altering the physical environment in the Arctic as described in Section 3.1.4.4. Such changes include warming air (Chapman and Walsh 2003) and sea temperatures, declining sea ice extent and thickness (Levi 2000, Parkinson 2000, Rothrock et al. 1999), salinity changes (Arrigo 2009), rising sea level, increasing precipitation and decreasing snow extent, loss of permafrost, and changes in terrestrial vegetation composition (IPCC 2007a). These changes in the physical environment will precipitate changes on lower trophic level ecology as described here. Although Arctic sea ice itself can be biologically productive, occasionally supporting large populations of diatoms and other primary producers (Gosselin et al. 1997), areal rates of CO2-fixation in sea ice habitats tend to be much lower than rates found in the adjacent ice-free ocean. Therefore, a loss of Arctic sea ice might be expected to increase the area favorable for phytoplankton growth and enhance the productivity of the Arctic Ocean (Arrigo 2009). In fact phytoplankton primary production in the Arctic Ocean has increased approximately 20 percent from 1998-2009, mainly as a result of increasing open water extent and duration of the open water season (Frey et al. 2011).

The Beaufort and Chukchi seas are characterized by short, open-water summer periods and long, ice-covered winters. However, the extent of the Arctic sea ice has decreased by approximately three percent over the last decade while the extent of the summer ice has decreased up to nine percent during this time period (IPCC 2007a). The 2007 summer ice extent was 39 percent below long term averages from 1979 to 2000 and changes such as these will likely impact the epontic community, and subsequently, the pelagic and benthic communities (MMS 2007c).

Information on generation times, life spans and doubling times are important in any assessment of effects on primary producers or other planktonic organisms. The doubling time for phytoplankton is short, even in the Arctic. Recent studies have shown that plankton growth rates in the Chukchi Sea range from $0.4d^{-1}$ (equivalent to a doubling in 2.5 days) to $0.16d^{-1}$ (equivalent to a doubling in 6.25 days) which results in doubling times of a few days (Grebmeier et al. 2009). In contrast, many Arctic zooplankton reproduce only once per year resulting in generation times of one year (Hopcroft et al. 2010). However, there are studies showing faster growth rates in warmer water (Feder et al. 2005). Therefore, warming ocean temperatures associated with climate change may increase zooplankton growth rates and generation times in the Beaufort and Chukchi seas.

Atmospheric climate variation and its impact on circulation, heat, salt and nutrient content of shelf waters and sea/shore fast ice formation are central issues in the Arctic seas. It is unlikely that ecosystem change will be understood until more studies examine the Arctic Oscillation-ecosystem interactions (NRC 2004a). Understanding the proximate and ultimate controlling factors of various trophic level standing stocks and production rates is essential for interpreting ecosystem change occurring presently in the Arctic (Aagaard et al. 1999). The impacts of climate change to the ecosystem are commonly thought to be from the bottom up through the nutrient-phytoplankton-zooplankton sequence, while human impacts are top down (Carmack and Macdonald 2002). However, the presence of sea ice as habitat for top-level predators such as polar bears means that climate change will directly affect higher trophic levels. An added element of the ecosystem in Arctic seas is shore-fast ice and its attendant phenomena (turbulence under ice, formation of freshwater pools due to blockage of river inflow).

3.2.2 Fish and Essential Fish Habitat

The following description of fish resources of the Beaufort and Chukchi seas largely adopts the “Fish Resources” section from the Beaufort and Chukchi Sea Planning Area Lease Sale 209, 212, 217, and 221 DEIS (MMS 2008). This section is almost fully incorporated into this document with some modifications, primarily to include the most recent information available since publication.

Over 400 fish species are known to inhabit Arctic seas and adjacent waters, which include marine, migratory (mostly anadromous), and freshwater fish species that enter brackish water (diadromous species). The Alaskan Chukchi and western Beaufort seas support at least 107 fish species, representing 25 families (Mecklenburg et al. 2002, Logerwell and Rand 2010, Love 2005, Harris 1993, Johnson et al. 2010) (see Table 3.2-1). Families and sub-families include lampreys, sleeper sharks, dogfish sharks, herrings, smelts, whitefish, trout and salmon, lanternfish, cods, sticklebacks, greenlings, sculpins, sailfin sculpins, fathead sculpins, poachers, lumpsuckers, snailfish, eelpouts, pricklebacks, gunnels, wolffish, sand lances, and righteye flounders. Forty-nine known species are common to the Beaufort and Chukchi seas. A recent study by Logerwell and Rand (2010) identified five fish species formerly not known to occur in Arctic waters. A similar situation has been reported for Canadian Arctic waters where the most recent compilation of marine and anadromous fish resulted in updating the species known to occur in this area (Coad and Reist 2004).

Freshwater species inhabiting the Arctic coastal plain have been better described than marine species (Table 3.2-1). While freshwater habitats could be affected by naturally or chemically dispersed oil from a spill moving up the freshwater channel, this section focuses more extensively on coastal and marine fish/fishery resources and habitats because there is greater potential for Arctic exploration activities to impact these resources

Few species currently covered by fishery-management plans occur in these waters; however, an Arctic Fishery Management Plan was approved in August of 2009 by the North Pacific Fisheries Management Council (NPFMC) to address Arctic fisheries issues. The NPFMC's policy as articulated in that plan is to *"prohibit commercial harvest of all fish resources of the Arctic Management Area until sufficient information is available to support the sustainable management of a commercial fishery"* (NPFMC 2009). No timeline has been set for such a decision to be made.

The following information summarized from the Arctic Fishery Management Plant (NPFMC 2009) describes the current commercial, subsistence, and recreational fisheries in the Arctic.

Commercial fisheres in the Arctic are limited to several small fisheries solely in state waters that are managed by the State of Alaska. These include a small commercial fishery for chum salmon, although other fish species are incidentally harvested, in the Kotzebue Sound region. Fished from coastal set nets, salmon are sold locally; some are shipped to other markets outside the region. A commercial fishery for whitefish occurs in the delta waters of the Colville River that flows into the central Beaufort Sea. This fishery is for Arctic and least cisco, and a few other species are harvested incidentally. The market for these fish is local, although some whitefish have been marketed in the Barrow and Fairbanks areas. While no large-scale fisheries currently exist in the Beaufort Sea, both the U.S. and Canada anticipate that sustained warming will enable and encourage the development of Beaufort Sea fisheries (Lewis-Koskinen 2010).

Subsistence fishing occurs throughout the coastal region by residents of villages in this region. Harvest areas are described on Figures 3.3-26 and 3.3-27. Table 3.3-7 in Section 3.3.2.3 Subsistence Resources provides an overview of Community Subsistence Harvest by Species Group (percent total harvest by species, total harvest and pounds per capita).

Fishing activities occur near human settlements of Wainwright, Barrow, Nuiqsut, and Kaktovik, and in all nearshore areas during open water seasons and to a limited extent during winter. Near Wainwright, residents use gill nets to fish near river mouths (except Kokolik), at ocean passes, in Kasegaluk Lagoon, and at Sitkik Point. The season lasts from early July to late September. The nets are moved about 24 km (15 mi) up the Kukpowruk River in September for grayling fishing. A variety of salmon, whitefish, flounder, smelt, herring, and an occasional char are taken. Subsistence fisheries for pink and chum salmon occur in the Colville and Itillik rivers and at Elson Lagoon near Barrow (Carothers 2010). In general, fish species include Pacific salmon (chum and pink), whitefish, Arctic char, Arctic grayling, burbot, lake trout, northern pike, capelin, rainbow smelt, Arctic cod, tomcod, and flounder.

There are few recreational fisheries in the area, including no catch and release fishery management programs. Personal use fisheries may occur on a variety of species, occasionally in EEZ waters, but little data are available and these probably occur on a very small scale. Personal use fisheries may more accurately be described as subsistence fisheries, although there may be some level of "sport" fishing activity near Kotzebue or Barrow. Most recreational catch in the Arctic likely would occur in state waters and thus fall under the classification of sport, subsistence, or personal use fisheries, these fisheries are regulated by Alaska state law. No data are available to determine the trends in landings, including species targeted, in recreational fisheries in the Arctic Management Area.

Table 3.2-1 Freshwater, Migratory, and Marine Fish Species of the Alaskan Arctic

Order/Family	*Species Name*	Common name	Primary Assemblage[1]	Source[2]
Petromyzontiformes				
Petromyzontidae	*Lampetra tridentata*	Pacific lamprey	MI	MMT
	Lampetra camtschatica	Arctic lamprey	MI	MMT
Squaliformes				
Dalatiidae	*Somniosus pacificus*	Pacific sleeper shark	MA	MMT
Squalidae	*Squalus acanthias*	spiny dogfish	MA	MMT
Clupeoiformes				
Clupeidae	*Clupea pallasii*	Pacific herring	MA	MMT
Cypriniformes				
Catostomidae	*Catostomus catostomus*	longnose sucker	FW	MMT
Esociformes				
Esocidae	*Esox lucius*	northern pike	FW	MMT
Umbridae	*Dallia pectoralis*	Alaska blackfish	FW	MMT
Osmeriformes				
Osmeridae	*Mallotus villosus*	capelin	MA	MMT
	Osmerus mordax	rainbow smelt	MA	MMT
Salmoniformes				
Salmonidae / Coregoninae	*Stenodus leucichthys*	inconnu	MI	MMT
	Coregonus sardinella	least cisco	MI	MMT
	Coregonus autumnalis	Arctic cisco	MI	MMT
	Coregonus laurettae	Bering cisco	MI	MMT
	Coregonus nasus	broad whitefish	MI	MMT
	Coregonus pidschian	humpback whitefish	MI	MMT
	Thymallus arcticus	Arctic grayling	FW	MMT
Salmonidae / Salmoninae	*Salvelinus alpinus*	Arctic char	MI	MMT
	Salvelinus malma	Dolly Varden	MI	MMT
	Oncorhynchus gorbuscha	pink salmon	MI	MMT
	Oncorhynchus kisutch	coho salmon	MI	MMT
	Oncorhynchus tshawytscha	Chinook salmon	MI	MMT
	Oncorhynchus keta	chum salmon	MI	MMT
	Oncorhynchus nerka	sockeye salmon	MI	MMT
Myctophiformes				
Myctophidae	*Benthosema glaciale*	glacier lanternfish	MA	MMT
Gadiformes				
Gadidae	*Boreogadus saida*	Arctic cod	MA	MMT
	Arctogadus glacialis	polar cod	MA	MMT

Order/Family	*Species Name*	Common name	Primary Assemblage[1]	Source[2]
	Arctogadus borisovi	toothed cod	MA	MMT
	Eleginus gracilis	saffron cod	MA	MMT
	Theragra chalcogramma	walleye pollock	MA	MMT
	Gadus macrocephalus	Pacific cod	MA	LR
	Gadus ogac	ogac	MA	MMT
Lotidae	*Lota lota*	burbot	FW	MMT
Gasterosteiformes				
Gasterosteidae	*Gasterosteus aculeatus*	threespine stickleback	FW	MMT
	Pungitius pungitius	ninespine stickleback	FW	MMT
Scorpaeniformes				
Hexagrammidae	*Hexagrammos stelleri*	whitespotted greenling	MA	MMT
Cottidae	*Triglops pingelii*	ribbed sculpin	MA	MMT
	Hemilepidotus papilio	butterfly sculpin	MA	MMT
	Hemilepidotus jordani	yellow Irish lord	MA	MMT
	Icelus spatula	spatulate sculpin	MA	MMT
	Icelus bicornis	twohorn sculpin	MA	MMT
	Gymnocanthus tricuspis	Arctic staghorn sculpin	MA	MMT
	Cottus aleuticus	coastrange sculpin	MA	MMT
	Enophrys diceraus	antlered sculpin	MA	MMT
	Megalocottus platycephalus	belligerent sculpin	MA	MMT
	Myoxocephalus quadricornis	fourhorn sculpin	MA	MMT
	Myoxocephalus scorpius	shorthorn sculpin	MA	MMT
	Myoxocephalus scorpioides	Arctic sculpin	MA	MMT
	Myoxocephalus jaok	plain sculpin	MA	MMT
	Myoxocephalus verrucosus	warty sculpin	MA	LR
	Triglops nybelini	bigeye sculpin	MA	LR
	Microcottus sellaris	brightbelly sculpin	MA	MMT
	Artediellus gomojunovi	spinyhook sculpin	MA	MMT
	Artediellus scaber	hamecon	MA	MMT
	Artediellus pacificus	hookhorn sculpin	MA	MMT
	Artediellus ochotensis	Okhotsk hookear sculpin	MA	MMT
	Cottus cognatus	slimy sculpin	FW	MMT
Hemitripteridae	*Blepsias bilobus*	crested sculpin	MA	MMT
	Nautichthys pribilovius	eyeshade sculpin	MA	MMT
Psychrolutidae	*Eurymen gyrinus*	smoothcheek sculpin	MA	MMT
	Cottunculus sadko	Sadko sculpin	MA	MMT
Agonidae	*Hypsagonus quadricornis*	fourhorn poacher	MA	MMT
	Pallasina barbata	tubenose poacher	MA	MMT
	Occella dodecaedron	Bering poacher	MA	MMT
	Leptagonus decagonus	Atlantic poacher	MA	MMT

Order/Family	*Species Name*	Common name	Primary Assemblage[1]	Source[2]
	Podothecus veternus	veteran poacher	MA	MMT
	Ulcina olrikii	Arctic alligatorfish	MA	MMT
	Aspidophoroides monopterygius	alligatorfish	MA	MMT
Cyclopteridae	*Eumicrotremus derjugini*	leatherfin lumpsucker	MA	MMT
	Eumicrotremus andriashevi	pimpled lumpsucker	MA	MMT
Liparidae	*Liparis gibbus*	variegated snailfish	MA	MMT
	Liparis tunicatus	kelp snailfish	MA	MMT
	Liparis bristolensis	Bristol snailfish	MA	MMT
	Liparis fabricii	gelatinous seasnail	MA	MMT
	Liparis callyodon	spotted snailfish	MA	MMT
	Careproctus sp. cf. rastrinus	salmon snailfish	MA	LR
	Liparis marmoratus	festive snailfish	MA	LR
Perciformes				
Zoarcidae	*Gymnelus hemifasciatus*	halfbarred pout	MA	MMT
	Gymnelus viridis	fish doctor	MA	MMT
	Lycodes seminudus	longear eelpout	MA	MMT
	Lycodes mucosus	saddled eelpout	MA	MMT
	Lycodes turneri	estuarine eelpout	MA	MMT
	Lycodes polaris	polar eelpout	MA	MMT
	Lycodes raridens	marbled eelpout	MA	MMT
	Lycodes rossi	threespot eelpout	MA	MMT
	Lycodes sagittarius	archer eelpout	MA	MMT
	Lycodes palearis	wattled eelpout	MA	MMT
	Lycodes pallidus	pale eelpout	MA	MMT
	Lycodes squamiventer	scalebelly eelpout	MA	MMT

3.2.2.1 Major Surveys of Coastal and Marine Fish Resources and Habitats

MMS (2008) identified the following as some important surveys conducted in the Beaufort and Chukchi seas in the last century.

In 1932 and 1933 Russians A.P. Andriyashev, K.I. Panin, and P.V. Ushakov conducted the first major scientific collections of fish in the Chukchi Sea (Raymond 1987). Andriyashev (1955; a translation of a report published in 1937) described basic information concerning fish collected by Russian expeditions of the Bering and Chukchi seas.

Frost and Lowry (1983) reported on thirty-five successful otter-trawl tows that were conducted in the northeastern Chukchi and western Beaufort seas in August-September of 1976 and 1977. In 1976, two tows were made in the western Beaufort Sea in water 40 m (131 ft) and 123 m (404 ft) deep. In 1977 (August 2 to September 3), 33 tows were made in the northeastern Chukchi and western Beaufort seas in waters 40 to 400 m (131 to 1,312 ft) deep. Numerous tows were conducted near the southern edge of pack ice. Frost and Lowry (1983) caught 133 fish belonging to 14 species in trawls made in 1976. In the more extensive trawls conducted in 1977, 512 fish belonging to 17 species were captured, of which 65 percent were represented by just three species (*Boreogadus saida*, *Lycodes Polaris* and *Icelus bicornis*).

Fechhelm et al. (1984) reported results of an ichthyological survey conducted in 1983 that focused primarily on Arctic fish usage of, and ecological dependence on, marine estuarine environments along the northeastern Chukchi Sea coast from Peard Bay to Point Hope. Data were collected primarily during the open-water summer season and, to a lesser extent, in winter. The most prominent species encountered during the survey were Arctic cod, Arctic staghorn sculpin, fourhorn sculpin, capelin, shorthorn sculpin, hamecon, Arctic flounder, and saffron cod. Fourhorn sculpin and Arctic flounder occurred in nearshore waters (<1 km [<0.6 mi]), while the remaining sculpins were found exclusively in deeper, offshore (>1 km [<0.6 mi]) waters. Arctic and saffron cod were found to occupy both nearshore and offshore waters.

Barber et al. (1994) reported data obtained in the northeastern Chukchi Sea between Cape Lisburne in the south to the ice edge in the north between 1989 and 1992. Collectively, these surveys and associated studies reflected a sparse sampling of fish resources across the northeastern Chukchi Sea. Sampling effort has been spatially and temporally irregular and disjunct. More recent survey efforts, such as those by Logerwell and Rand (2010), Norcross et al. (2009) and by Shell Oil and ConocoPhillips (yet to be released) have added, and will add, to this body of knowledge.

A 3-year study (1988, 1990, and 1991) of epipelagic fish inhabiting Beaufort Sea coastal waters in Alaska documented spatial and temporal patterns in fish distribution and abundance and examined their relationships to thermohaline features during summer (Jarvela and Thorsteinson 1999). Significant interannual, seasonal, and geographical differences in surface water temperatures and salinities were observed. In 1990, sea ice was absent and marine conditions prevailed, whereas, in 1988 and 1991, heavy pack ice was present and the dissolution of brackish water along the coast proceeded more slowly. . Arctic cod, capelin, and snailfish were the most abundant marine fish captured, while Arctic cisco was the only abundant diadromous species.

In summer 2004, a Russian-American Long-term Census of the Arctic expedition was conducted in the Bering and Chukchi seas (Stein et al. 2005). The primary study area lay between Wrangel Island and Herald Canyon in Russia Federation territorial waters to Cape Lisburne, Alaska, to Point Barrow, Alaska, and south to the Bering Strait. Fish biologists on the expedition noted the following qualitative conclusions: (1) the Chukchi benthic community is highly diverse and patchy; and (2) both fish abundance and diversity seem lower in the Chukchi Sea than in the Bering Sea. The largest catches occurred to the south and were usually at least one order of magnitude higher than those in the north. Also, biologists noted several range extensions or rare species.

Logerwell and Rand (2010) conducted a recent study in Alaskan Arctic waters as part of a.joint effort with NMFS, the University of Washington, and the University of Alaska Fairbanks. Researchers surveyed offshore marine fish and invertebrates and the physical and biological oceanography of the western Beaufort Sea in the vicinity of Cape Simpson to Cape Halkett. The study assessed benthic and demersal communities separately and reported arctic cod was by far the most common species encountered. Both demersal and pelagic fish were most common along the outer edge of the continental shelf, particularly in the northwest portion of the Beaufort Sea. Five species not previously documented in Arctic waters were identified in this study. Several recent BOEM sponsored studies of fish and lower trophic organisms in the Beaufort and Chukchi seas have been completed with final reports expected in 2014 (BOEM 2011f, 2011g, 2011h).

Fish assemblages and populations in other marine ecosystems of Alaska (e.g. Gulf of Alaska, Bering Sea) have undergone observable shifts in diversity, distribution, and abundance during the last 20 to 30 years, and the recent findings of Logerwell and Rand (2010) suggest that a similar trend is occurring in the Arctic. Five species previously not documented in the region were encountered in the Logerwell and Rand (2010) study, so it is possible other existing research no longer accurately and precisely reflects the current distribution, abundance, and habitat-use patterns of fish resources in the northeastern Chukchi and western Beaufort seas. It is also reasonable to suggest that because of the sparseness of data from limited surveys in the past, that previously undocumented species being observed in recent studies may simply be the result of sample locations.

Logerwell and Rand (2010) made a concerted effort to address this by recording Catch Per Unit Effort (CPUE) in order to provide a baseline for future comparisons.

Recent efforts have also been made to document traditional ecological knowledge of the region’s fishery resources by Iñupiat residents. Brewster (2011) noted that the Iñupiat have identified many of the large fish congregation areas and migratory routes and placed their fishing camps accordingly. Therefore, cabin locations could be used as an indicator of critical fish habitat in coastal areas.

3.2.2.2 The Ecology of Alaskan Arctic Fish

Three large marine ecosystems (LMEs) encompass coastal and offshore waters of Arctic Alaska. They include the Bering Sea, Chukchi Sea, and Beaufort Sea. Each LME is characterized by distinct hydrographic regimes, submarine topographies, productivity, and trophically-dependent populations. The Chukchi Sea LME represents a transition zone between the fish assemblages of the Beaufort and Bering LMEs. Aspects of these three LMEs are discussed below because they interact and influence the others.

Aquatic systems of the Arctic undergo extended seasonal periods of ice cover and other harsh environmental conditions. Fish inhabiting such systems must be biologically and ecologically adapted to surviving such conditions so as to produce offspring that eventually do the same. Behavioral strategies of each life stage are evolutionarily timed to coincide with environmental conditions favoring survival to the next lifestage (MMS 2008). The process of natural selection favors individuals that are adapted to survive such conditions. Important environmental factors that Arctic fish must contend with include reduced light, seasonal darkness, ice cover, low biodiversity, and low seasonal productivity (see McAllister 1975 for a description of environmental factors relevant to Arctic fish).

The lack of sunlight and extensive ice cover in the Arctic during winter months influence primary and secondary productivity, making food resources very scarce during this time; most of a fish's yearly food supply must be acquired during the brief Arctic summer (Craig 1989). The Chukchi Sea is warmer, more productive, and supports a more diverse fish assemblage than the western Beaufort Sea (Craig 1984 citing Morris 1981, Craig and Skvorc 1982). Norcross et al. (2009) identified 30 demersal fish species within 10 families in a 2004 bottom trawl survey of the Chukchi Sea. Conversly, Johnson et al. (2010) identified 16 fish species in a 2004 to 2009 bottom trawl and seine study of nearshore waters in the western Beaufort Sea. Although the Chukchi Sea supports a more diverse fish assemblage than the western Beaufort Sea, Arctic waters support considerably fewer fish species than warmer waters to the south such as the Bering Sea or Gulf of Alaska.

Marine waters of the Beaufort and Chukchi seas offer 2- and 3-dimensional area for Arctic fish to exploit; these include nearshore waters and substrates (occurring landward of the continental shelf break, as delimited by the 200-m (656-ft) isobath) and oceanic waters and substrates (occurring seaward of the continental shelf break [>200-m isobath]) (Figure 3.1-12). The fish of the eastern Chukchi and western Beaufort seas use a range of waters and substrates for spawning, breeding, feeding, or growing to maturity (MMS 2006c).

3.2.2.3 Primary Fish Assemblages

Arctic fish of Alaska have been categorized into assemblages that take into account habitat use and life-history strategies (Craig 1984, Craig 1989, Moulton and George 2000, Gallaway and Fechhelm 2000). A life-history strategy is a set of co-adapted traits designed by natural selection to solve particular ecological problems (Craig 1989 citing Stearns 1976).

The primary assemblages of Arctic fish are:

- Freshwater fish that spend their entire life in freshwater systems (although some also might spend brief periods in nearshore brackish waters);
- Marine fish that spend their entire life in marine waters (some also spend brief periods in nearshore brackish waters along the coast); and
- Migratory fish that move between and are able to use fresh, brackish, and/or marine waters due to various biological stimuli or ecological factors.

While some Arctic fish species are described in the scientific literature and in surveys as being abundant in the region, it is important to note that when compared to lower latitude marine environments overall abundance would be considered low for Arctic fish species The recent report by Logerwell and Rand (2010), which documents the presence of commercially valuable walleye pollock and Pacific cod and confirms the extension of their ranges, leaves open the question of relative abundance of these species.

The following discussion of fish assemblages is limited to marine and migratory fish species since none of the proposed project activities occur near freshwater fish habitat and therefore no impacts are anticipated.

3.2.2.3.1 Marine Fish

Most of the surveys/studies of marine fish in the EIS project area have been performed in coastal waters landward of the 200-m (656-ft) isobath (e.g. Logerwell and Rand 2010, Frost and Lowry 1983, Jarvela and Thorsteinson 1999). In areas where coastal surveys have been conducted, seasonal trends in relative abundance of dominant (abundant) fish species are evident (Logerwell and Rand 2010, Jarvela and Thorsteinson 1999). Robust population estimates or trends for marine fish of the region are unavailable. Distribution and abundance data for marine fish species are generally known at the coarsest grain of resolution (e.g. common, uncommon, rare), although a few studies include abundance estimates (qualitative or quantitative) for localized areas (Logerwell and Rand 2010, Frost and Lowry 1983, Griffiths et al. 1998, Jarvela and Thorsteinson 1999). Detailed information generally is lacking concerning the spread, density, or patchiness of their distribution in either the Beaufort or Chukchi seas, although Logerwell and Rand (2010) made a concerted effort to address this issue by providing a baseline CPUE for future comparison. Data concerning habitat-related densities; growth, reproduction, or survival rates within regional or local habitats; or productivity rates by habitat, essentially are unknown for fish inhabiting waters seaward of the nearshore, brackish-water ecotone. There will be some level of incomplete information on distribution and habitat-related data for marine fish; however, sufficient information is available to support sound scientific judgements and reasoned managerial decisions. Logerwell and Rand (2010) recently reported on the results of a western Beaufort Sea study that used bottom trawls to sample for demersal fish and hydroaccoustics and mid-water trawls to sample for pelagic fish. They found that invertebrates dominated the demersal catch, with arctic cod being the most common fish species caught. Arctic cod were the most prevalent species caught in pelagic habitats. Thirty-two species of fish were identified, and comparison of results with historical data suggests the northward expansion of some species ranges, such as pollock and Pacific cod.

Frost and Lowry (1983) reported anatomical, reproductive, and prey statistics for selected species sampled (arctic cod, polar eelpout, twohorn sculpin, hamecon, arctic alligatorfish, leatherfin lumpsucker, fish doctor, and spatulate sculpin) from 35 otter-trawl tows performed in the northeastern Chukchi and western Beaufort seas in August-September 1976 and 1977. Prey of the summarized species as a group consists of copepods, amphipods, isopods, mysids, euphasiids, polychaete worms, cumaceans, caprellids, shrimp, brittle stars, and arctic cod. Nineteen species of fish were identified; three species (arctic cod, polar eelpout, and twohorn sculpin) accounted for 65 percent of all fish caught.

Marine fish prefer the colder, more saline coastal water seaward of the nearshore brackish-water zone. As summer progresses, the nearshore zone becomes more saline due to decreased freshwater input from rivers and streams. During this time, marine fish often share nearshore brackish waters with diadromous fish (e.g. char), primarily to feed on the abundant epibenthic fauna or to spawn (Craig 1984). In fall, when diadromous fish have moved out of the coastal area and into freshwater systems to spawn and overwinter, marine fish remain in the nearshore area to feed.

Marine fish in the region primarily feed on marine invertebrates and/or fish. They rely heavily on epibenthic and planktonic crustacea such as amphipods, mysids, isopods, and copepods. Because the feeding habits of marine fish in nearshore waters are similar to those of diadromous fish, some marine fish are believed to compete with diadromous fish for the same prey resources (Craig 1984, Fechhelm, Buck, and Link 2006). Competition is most likely to occur in the nearshore brackish water ecotone, particularly in or near river deltas. As nearshore ice thickens in winter, marine fish probably continue to feed under the ice but eventually depart the area as ice freezes to the bottom some 2 m (6 ft) thick. Seaward of the bottomfast ice, marine fish continue to feed and reproduce in coastal waters all winter (Craig 1984). Many evidently spawn during winter, some in shallow coastal waters, and others in deeper waters. Arctic cod spawn under the ice between November and February (Craig and Halderson 1981). Snailfish spawn farther offshore by attaching their adhesive eggs to rock or kelp substrate (MMS 2008).

Ecological Groups (secondary Assemblages) of Marine Fish

To better understand fish resources and the potential impacts of disturbances to their populations and habitats, the scale of the primary marine fish assemblage has been further refined into ecological groups (secondary assemblages) based on fish behavior and ecology, and general oceanographic/landscape features, such as the continental shelf break or polar ice. The purpose of characterizing finer scale hierarchical organization of Arctic fish is to enhancethe analysis of potential impacts in a data-deficient setting, particularly concerning marine fish. Many species overlap to some degree in these ecological groups, due in part to the different habitat areas used by different lifestages (e.g. arctic cod occur in both nearshore-demersal [as adults] and cryopelagic [as juveniles] groups) (MMS 2008).

Based on the general ecology and three-dimensional occurrence of marine fish in the sea, the following secondary marine fish assemblages have been identified: nearshore-demersal, nearshore-pelagic, oceanic-demersal, and oceanic-pelagic. An additional and important assemblage that is unique to polar regions is the cryopelagic fish assemblage. Following are characterizations of each secondary fish assemblage, and Table 3.2-2 identifies species associations for secondary fish assemblages.

Table 3.2-2 Species Associations in Secondary Marine Fish Assemblages[1]

Species Name	Common name	Secondary Assemblage[2]				
		ND	NP	OD	OP	CP
Somniosus pacificus	Pacific sleeper shark	X		X		
Squalus acanthias	spiny dogfish	X		X		
Clupea pallasii	Pacific herring		X		X	
Mallotus villosus	capelin		X			
Osmerus mordax	rainbow smelt		X			
Benthosema glaciale	glacier lanternfish		X

[1]Table based on Table III.F-2 in MMS 2007c and Table C-1 (Appendix C) in BOEMRE 2011b.
[2]ND = Nearshore Demersal, NP = Nearshore Pelagic, OD = Offshore Demersal, OP = Offshore Pelagic, CP = Cryopelagic

The Nearshore-Demersal Assemblage

This assemblage is comprised of marine fish living at or near the seafloor of the continental shelf (landward of the 200-m [656 ft] isobath) and capable of active swimming. Species of this assemblage attributed to being widespread and/or abundant include the fourhorn sculpin, twohorn sculpin, polar eelpout, and Arctic flounder (BOEMRE 2011b).

The Nearshore-Pelagic Assemblage

Fish inhabiting the water column over the continental shelf (landward of the 200-m isobath) comprise the nearshore-pelagic assemblage. Some fish of this assemblage utulize the upper water column (pelagic species), while others exhibit greater use of the lower depths or the entire water column and seafloor (benthopelagic species). Species of this assemblage considered widespread or abundant include the Pacific herring, arctic cod, capelin, and Pacific sand lance. Two benthopelagic species are uncommon (fourline snakeblenny and slender eelblenny); the polar cod is considered rare.

The Oceanic-Demersal Assemblage

Fish living on or close to substrates below oceanic waters are encompassed in the oceanic-demersal assemblage. The ogac, ribbed sculpin, spatulate sculpin, shorthorn sculpin, spinyhook sculpin, archer eelpout, pale eelpout, and daubed shanny are among the fish included in this assemblage (MMS 2008).

The Oceanic-Pelagic Assemblage

Fish inhabiting the water column of oceanic waters seaward of the 200-m isobath comprise this assemblage; most species exhibit some preference of bathymetric stratification. Those species chiefly occurring within the upper 200 m (656 ft) of the water column are called epipelagic fish. Fish inhabiting oceanic waters between 200 m and 1,000 m (656 to 3,281 ft) in depth are termed mesopelagic fish. Bathypelagic fish are those species inhabiting depths >1,000 m (3,281 ft) in depth; as yet, there are no known bathypelagic fish in the Alaskan Beaufort Sea. Several of the epipelagic species include the walleye pollock, Pacific herring, arctic cod, polar cod, and Pacific sand lance (note that several of these species also use nearshore and ice-covered waters).

The Cryopelagic Assemblage

The term "cryopelagic" is used to describe fish that actively swim in nearshore or oceanic waters but, during their lifecycle, are associated in some way or other with drifting or fast ice (Andriyashev 1964). The cryopelagic fish assemblage is further described by Andriyashev (1970) as such:

> *Both young and adult fish can be associated with ice or water immediately below the ice. These relationships are usually trophic in nature, but in some cases ice provides fish with a shelter from predators or even a substratum for sucking. The association of fish with ice can be observed easily and often. The more intimate aspects of their behavior are, however, still little known*….

Andriyashev (1970) described what may be the first known cryopelagic fish species, the arctic cod (*Boreogadus saida*; previously known as polar cod). Arctic cod often occur in ice holes, cracks, hollows, and cavities in the lower surface of the ice and are most common near the ice edge or among broken ice. As the ice thaws at these margins, plankton grow and provide a food source. It is possible that they also feed on the amphipod-diatom ice community inhabiting the lower ice layer. Arctic cod are a common food of ringed seal (*Phoca hispida*), bearded seal (*Erignathus barbatus*), white whale (*Delphinapterus leucas*), narwhal (*Monodon monoceros*) and other marine mammals, many marine birds (including gulls, guillemots, etc.) and fish (citing Klumov 1937, and Andriyashev 1954). The arctic cod is abundant in the region, and their enormous autumn-winter pre-spawning swarms are well known. The species also is very widely distributed and makes distant migrations, not only along the shelf areas in the Arctic Basin, but also in higher latitudes. In addition to the arctic cod, other cryopelagic fish of the Alaskan Arctic Region include polar cod, toothed cod, and Pacific sand lance.

3.2.2.3.2 Migratory Fish

Migratory (or diadromous) fish can move between and are able to live in fresh, brackish, and/or marine waters due to various biological stimuli such as feeding or reproduction; or ecological factors such as temperature, oxygen level, or specific spawning-habitat needs. Numerous strategies exist for the use of these different habitats, and as such, different terms are used to define those life histories. The term diadromous is considered the most inclusive category because its definition incorporates all migration types (anadromous, catadromous and amphidromous) between marine and freshwaters, including single lifetime events, repetitive multiyear events, spawning migrations, feeding migrations, and seasonal movements between environments (Craig 1989).

Anadromous Fish

Anadromous fish employ a life history pattern involving single or repeated migrations between overwintering sites and coastal waters, followed by a spawning migration into freshwater at maturity.

This cycle consists of three broad phases: spawning; freshwater residency (of juveniles); and anadromy (Craig 1989). The most commonly studied anadromous fish are salmon, of which all five Pacific species are found within the project area.

Pacific Salmon

All five species of Pacific salmon occur in the Alaskan Beaufort and Chukchi seas (Craig and Halderson 1986, NMFS 2005): the pink, chum, sockeye, chinook, and coho salmon. A large body of information exists on the life histories and general distribution of salmon in Alaska (NMFS 2005). Pacific salmon life history, general distribution, fisheries background, relevant trophic information, habitat, and biological associations are described by NMFS (2005:Appendix 5) and incorporated herein by reference. More information regarding the biology, ecology, and behavior of Pacific salmon is described in Augerot (2005), Quinn (2005), and Johnson and Daigneault (2008).

Salmon numbers decrease north of the Bering Strait, and they are realtively rare in the Beaufort Sea (Craig and Halderson 1986). Spawning runs in Arctic streams are minor compared to those of commercially important populations farther south (Craig and Halderson 1986). There is little evidence for viable self-sustaining salmon populations occurring in the Beaufort Sea. Salmon are currently not successful at establishing and persisting in this area, probably because only marginal freshwater habitats for overwintering exist (Craig 1989, Fechhelm and Griffiths 2001).

Rivers south of Point Hope support comparatively large runs of chum and pink salmon (Craig and Halderson 1986). Craig and Halderson (1986) noted that only a few pink salmon and, to a lesser degree, chum salmon, occur with any regularity in Arctic waters north of Point Hope and presumably maintain small populations in several of the northern drainages; most occurring in streams along the Chukchi Sea coast west of Barrow.

Chinook, Sockeye, and Coho Salmon

Kotzebue Sound is the northernmostdocumented spawning population of chinook salmonin Alaska (Healey 1991); however, there are indications of a small run of chinook salmon in the Kugrua River southwest of Point Barrow at Peard Bay (Fechhelm and Griffiths 2001, citing George, pers. commun.). Small numbers of chinook salmon reportedly are taken each year in the Barrow domestic fishery, which operates in Elson Lagoon (Fechhelm and Griffiths 2001, citing George, pers. commun.). Strays have been captured in the Kuk River, near Wainwright (Craig and Halderson 1986) and in Fish Creek, which drains to Harrington Bay in the Beaufort Sea.

The northernmost known population of spawning coho salmon is in the Kuchiak River (Johnson and Daigneault 2008), and coho salmon have occasionally been captured in marine waters farther east, near Prudhoe Bay (Craig and Halderson 1986). This is particularly important because juvenile fish must overwinter at least one winter in freshwater before entering the marine environment. Overwintering stream habitat may be reduced by as much as 97 to 98 percent by late winter (Craig 1989).

There are no known stocks of sockeye salmon in Arctic waters north of Point Hope (Craig and Halderson 1986). Sockeye salmon northernmost documented spawning population is Kotzebue Sound (Stephenson 2006, citing Burgner 1991).

Pink Salmon

Pink salmon are widely distributed over the northern Pacific Ocean and Bering Sea; they also occur to a lesser degree in Arctic waters (Augerot 2005). Pink salmon are the most abundant salmon species in the Beaufort and Chukchi seas, although their abundance is greatly reduced compared to waters farther south (Craig and Halderson 1986, Fechhelm and Griffiths 2001). Their abundance generally increases from east to west along the Alaskan Beaufort Sea coast. Augerot (2005) depicts pink salmon of limited spawning distribution in the Alaskan Arctic.

Craig and Halderson (1986) proposed that pink salmon spawn successfully and maintain small but viable populations in some Arctic drainages. Small runs of pink salmon occur in nine drainages north of Point Hope (Craig and Halderson 1986, Fechhelm and Griffiths 2001), including the Kuk, Kokolik, Kugrua, and Kukpowruk rivers (Fechhelm et al. 1983 as cited in Kinney 1985). They are reported as present in the Pitmegea and Utukok rivers.

Unlike other nonsalmonid anadromous fish species in Arctic Alaska, the pink salmon is a short-lived species that places all its reproductive effort into a single spawning event and then dies. With its rigid 2-year lifecycle, there is virtually no reproductive overlap between generations; therefore, every spawning event must be successful for the continued survival of the stock (Craig and Halderson 1986).

Run timings are inexact. Along the northeastern Chukchi Sea coast, run times in spawning streams may occur in mid-July; while along the western Beaufort coast, run times appear to commence in late July until the end of August (Craig and Halderson 1986). Occurrence of adult salmon in spawning streams in mid- to late July indicates their presence in marine waters along the Arctic coast as much as several weeks in advance of the runs.

Pink salmon eggs hatch in early to mid-winter and fry emerge from the gravel in spring. At that time, the fry move downstream and remain in the estuary and nearshore areas for up to a month prior to moving offshore (Schmidt et al. 1983). Schmidt et al. (1983) state: "*It is likely the North Slope populations move westerly towards the Chukchi Sea and upon maturing at the age of 2 years, the salmon then return to their natal streams to spawn in the fall.*"

Generally, early marine schools of pink salmon fry, often in large, dense aggregations, tend to follow shorelines and, during the first weeks at sea, spend much of their time in shallow water only a few centimeters deep (NMFS 2005:Appendix F). It has been suggested that this nearshore period involves a distinct ecological life-history stage in both pink and chum salmon. In many areas throughout their ranges, pink salmon and chum salmon fry of similar age and size commingle in both large and small schools during early life in the marine environment.

Diet studies show that pink salmon are both opportunistic and generalized feeders, and, on occasion, they specialize in specific prey items (NMFS 2005:Appendix F). Young-of-the-year probably do not feed significantly during the short period spent in natal streams but feed on copepods and other zooplankton in estuaries and nearshore areas (Schmidt et al. 1983). As the fish grow, larger prey species become important, including amphipods, euphausiids, and fish (Schmidt et al. 1983 citing Morrow 1980 and Scott and Crossman 1973). Craig and Halderson (1986) state that most (adult) pink salmon caught in Simpson Lagoon had not fed recently (88 percent empty stomachs, n=17). The only available information on marine feeding is from Kasegaluk Lagoon, where stomachs of 17 captured adult salmon contained mostly fish (chiefly arctic cod), with some amphipods and mysids (Craig and Halderson 1986, citing Craig and Schmidt 1985). Studies indicate that juvenile pink salmon are primarily diurnal feeders (NMFS 2005: Appendix F).

Chum Salmon

Chum salmon are widely distributed in Arctic waters but are relatively less common than pink salmon (Craig and Halderson 1986, Babaluk et al. 2000, Fechhelm and Griffiths 2001). The Pitmegea, Kukpowruk, Kuk, Kukolik, Kuchiak, and Kugrua rivers along the northeastern Chukchi Sea coast are reported to support small populations of chum salmon. They are reported as present in the Utukok and Kuchiak rivers. Individual salmon and small schools have been collected in the Kukpuk River, Kasegaluk Lagoon, and along the Wainwright Coast (Craig and Halderson 1986, Fechhelm and Griffiths 2001).

Generally, chum salmon return to spawn as two to seven year olds (NMFS 2005). In general chum salmon get older from south to north. Seven-year-old chum are rare and occur mostly in the northern areas (e.g. the Arctic). Slow to rapid growth in the ocean can modify the age chum salmon reach maturity. For example, slower growth during the second year at sea causes some chum salmon to mature one to two years later.

Chum salmon fry, like pink salmon, do not overwinter in streams but out-migrate (mostly at night) from natal streams directly to estuaries/tidal wetlands shortly after emergence. In more southern waters, outmigration occurs between February and June (chiefly during April and May). Chum salmon have two habitat requirements that are essential in their life history that make them very vulnerable: (1) reliance on upwelling ground water for spawning and incubation and (2) reliance on estuaries/tidal wetlands for juvenile rearing after out-migrating from spawning streams. Chum salmon tend to linger near their natal stream and forage in estuaries and intertidal areas at the head of bays during summer. Estuaries are very important habitat for rearing chum salmon. Rearing juvenile chum salmon use a wide variety of prey species, including invertebrates (including insects) and gelatinous organisms (NMFS 2005).

In late summer, juvenile chum salmon migrate southward toward the Bering Sea, thereby avoiding the cold waters of the Arctic marine environment in winter. Chum salmon eat a variety of foods during their ocean life, e.g. amphipods, euphausiids, pteropods, copepods, fish, and squid larvae.

Amphidromous Fish

Amphidromous fish move between freshwater to marine waters (or vice-versa) at certain life phases for non-reproductive purposes (Craig 1989). In the Arctic, amphidromous species live longer, experience slower growth, and reach sexually maturity much later in life than Arctic anadromous fish. Amphidromous Arctic fish spend more time in brackish coastal waters than marine waters and overwinter in freshwater. Amphidromous fish typically have multiple migrations to freshwater before reaching spawning age. Even after reaching spawning age, spawning occurs only if their nutritional requirements were met during the brief Arctic summer. When spawning takes place, they do not necessarily die; some return years later to spawn again. Amphidromous fish inhabit many of the lakes, rivers, streams, interconnecting channels, and coastal waters of the North Slope. Common species include Arctic cisco, least cisco, Bering cisco, rainbow smelt, humpback whitefish, broad whitefish, Dolly Varden char, and inconnu. The highest concentration and diversity of amphidromous fish in the area occurs in river-delta areas, such as the Colville and the Sagavanirktok (Bendock 1997), while the most common species found in nearshore waters are Arctic and least cisco (Craig 1984). Lakes that are accessible to amphidromous fish typically are inhabited by them in addition to resident freshwater fish. The least cisco is the most abundant amphidromous fish found in these lakes.

With the first signs of spring breakup (typically June 5 to 20), adult amphidromous fish (and the juveniles of some species) move out of freshwater rivers and streams and into the brackish coastal waters nearshore (Craig 1989). They disperse in waves parallel to shore, each wave lasting a few weeks or so. Some disperse widely from their natal streams (e.g. Arctic cisco and some Dolly Varden char). Others, like broad and humpback whitefish and least cisco, do not; they are seldom found anywhere except for near the mainland shore (Craig 1984). Fechhelm (1999) suggested that humpback whitefish dispersing eastward along the coast from their overwintering grounds in the Colville River had been blocked by a solid-fill gravel causeways (West Dock) and that construction of a breach allowed these fish to extend their summer foraging range farther to the east. Similar results were reported by Fechhelm et al. (1999) for Arctic cisco and least cisco suggesting that small fish traveling eastward along the coast failed to bypass a causeway. Most amphidromous fish initiate relatively long and complex annual migrations to and from coastal waters (Bendock 1997). However, some populations of Dolly Varden char, least cisco, and broad and humpback whitefish never leave freshwater (Craig 1989). It is postulated that Arctic cisco in the Colville River area originated from spawning stocks of the Mackenzie River in Canada (Gallaway et al. 1983, Fechhelm and Fissel 1988, Fechhelm and Griffiths 1990), although there are reports from fishermen that Arctic cisco in spawning condition have been caught in the upper Colville and Chipp rivers (Moulton et al. 1985 citing Matumeak 1984, pers. commun.). However, the scientific evidence is overwhelming that the vast majority of the Arctic cisco inhabiting the Alaskan Beaufort Sea were carried there from Canada by westerly currents.

During the 3-to-4-month open-water season that follows spring breakup, amphidromous fish accumulate energy reserves for overwintering, and, if sexually mature, spawn. They prefer the nearshore brackish zone, rather than the colder, more saline waters farther offshore. While their prey is concentrated in the nearshore zone, their preference for this area is believed to be more correlated with its warmer temperature (Craig 1989, Fechhelm et al. 1993).

Amphidromous fish are more abundant along the mainland and island shorelines, but also inhabit the central waters of bays and lagoons. Larger fish of the same species are more tolerant of colder water (e.g. Dolly Varden char and Arctic and least cisco) and range farther offshore (Moulton et al. 1985, Thorsteinson et al. 1991). Smaller fish are more abundant in warmer, nearshore waters and the small, freshwater streams draining into the Beaufort Sea (Hemming 1993).

Infaunal prey density in the nearshore substrate is very low and provides little to no food for amphidromous fish. However, prey density in the nearshore water column is high, about five times that of freshwater habitats on the coastal plain, and the nearshore feeding area also is much larger (Craig 1989). For these reasons, both marine and migratory fish come to feed on the relatively abundant prey found in nearshore waters during summer. Amphidromous fish feed on epibenthic mysids and amphipods (often greater than 90 percent of their diet) and on copepods, fish, and insect larvae (Craig and Halderson 1981, Craig et al. 1984, Craig 1989). In early to midsummer when amphidromous fish are most abundant in nearshore waters, little dietary overlap is observed among them. However, in late summer when they are less abundant and their prey is more abundant, dietary overlap becomes common (Moulton et al. 1985). Marine birds also compete for the same food resources during this time. Migratory fish do little to no feeding during their migration back to freshwater and when spawning, but some resume feeding during winter. Most amphidromous fish return to freshwater habitats in the late summer or fall to overwinter and, if sexually mature, to spawn. Others, such as cisco and whitefish, return much earlier, arriving 6 to 10 weeks before spawning starts, thus forfeiting about half of the nearshore-feeding period (Craig 1989). Char, cisco, and whitefish spawn in streambed gravels in fall in the Sagavanirktok River. Spawning in the Arctic environment can take place only where there is an ample supply of oxygenated water during winter. Because of this and the fact that few potential spawning sites can meet this requirement, spawning often takes place in or near the same area where fish overwinter (Craig 1989). Variation in recruitment between years may be highly influence by variability in weather patterns, like the strength of easterly winds (ABR, Inc. et al. 2007).

3.2.2.4 The Influence of Climate Change

Changes in the climate of the Arctic are being documented. While climatic warming is not distributed evenly across the Arctic, the Bering, Chukchi, and Beaufort seas are clearly experiencing a warming trend (ACIA 2005). This warming is altering the distribution and abundance of marine life in the Arctic. The better known fish resources such as capelin, arctic cod, Pacific sand lance, and Bering flounder can exhibit very large interannual fluctuations in distribution, abundance, and biomass. Climate change experienced in the past and apparently accelerating in Arctic Alaska likely is altering the distribution and abundance of their respective populations from what was known from past surveys. For a more detailed discussion of climate change in the Arctic, see Section 3.1.4.4.

Climate change can affect fish production at both the individual and population level through a variety of means (Loeng 2005). Direct effects of temperature on the metabolism, growth, and distribution of fish occur. Food-web effects also occur through changes in lower trophic-level production or in the abundance of predators, but such effects are difficult to predict. Fish-recruitment patterns are strongly influenced by oceanographic processes such as local wind patterns and mixing and by prey availability during early life stages. Recruitment success sometimes is affected by changes in the time of spawning, fecundity rates, survival rate of larvae, and food availability (MMS 2008). An analysis of the Arctic cisco data in the Colville Delta suggests, for example, that survival of certain age classes is reduced during summers with above average temperature and below average ice concentrations (ABR, Inc. et al. 2007).

For example, a climate shift occurred in the Bering Sea in 1977, abruptly changing from a cool to a warm period (ACIA 2004 and 2005). The warming brought about ecosystem shifts that favored herring stocks and enhanced productivity for Pacific cod, skates, flatfish, and noncrustacean invertebrates. The species composition of seafloor organisms changed from being crab dominated to a more diverse assemblage of echinoderms, sponges, and other sea life. Historically high commercial catches of Pacific salmon occurred. The walleye pollock catch, which was at low levels in the 1960s and 1970s (2 to 6 million metric tons), has increased to levels >10 million metric tons for most years since 1980 (ACIA 2005). Additional recent climate-related impacts observed in the Bering Sea LME include significant reductions in seabird and marine mammal populations, unusual algal blooms, abnormally high water temperatures, and low harvests of salmon on their return to spawning areas. While the Bering Sea fishery has become one of the world's largest, numbers of salmon have been far below expected levels, fish have been smaller than average, and their traditional migratory patterns appear to have been altered.

Regarding the Beaufort and Chukchi seas, the Arctic Climate Impact Assessment, published in the mid-2000s (ACIA 2004 and 2005) concluded that the southern limits of distribution for colder water species such as arctic cod, and more southerly species from the Bering Sea, are both anticipated to move northward. Adjustments by one or more fish populations often require adjustments within or among LMEs, influencing the distribution and/or abundance of competitors, prey, and predators. Consequently, it appears reasonable to believe that the composition, distribution, and abundance of fish resources in the Beaufort and Chukchi seas are changing and are now different from that measured in the surveys conducted 16 to 18 years ago or earlier. Pacific cod, herring, walleye pollock, and some flatfish are likely to move northward and become more abundant, while capelin, arctic cod, and Greenland turbot are expected to have a restricted range and decline in abundance. Recent work supports this, with Logerwell and Rand (2010) concluding that climate change may have resulted in northward expansion of some species' ranges, including commercially valuable species such as pollock and Pacific cod (*Gadus macrocephalus*). This survey was also the first to document commercial-sized opilio crab (*Chionoecetes opilio*) in the North American Arctic.

The occurrence of pink and chum salmon in Arctic waters probably is due to their relative tolerance of cold water temperatures and their predominantly marine lifecycle (Craig and Halderson 1986 citing Salonius 1973). The expansion of chinook, sockeye, and coho salmon into the Arctic appears restricted by cold water temperatures, particularly in freshwater environments (Craig and Halderson 1986). Babaluk et al. (2000) noted that significant temperature increases in Arctic areas as a result of climate change may result in greater numbers of Pacific salmon in Arctic regions. The recent range extensions of pink, sockeye, and chum salmon in the Canadian Arctic, as described by Babaluk et al. (2000), indicate that some Pacific salmon may be expanding their distribution and abundance in the proposed project area.

A period of warming in the region between 1990 and 2007, documented and discussed by Moulton (2010) reviewed a number of biological response by freshwater fish in the Teshekpuk Lake region to warming temperatures, mostly relating to growth and condition. Least cisco showed faster growth rates during the warmer period and lake trout distribution may be influenced by the resulting additional prey distribution.

3.2.2.5 Essential Fish Habitat

The Magnuson Fishery Conservation and Management Act of 1976, which has been renamed the Magnuson-Stevens Fishery Conservation and Management Act (MSA), was enacted, along with other goals, to promote the protection of Essential Fish Habitat (EFH) in the review of projects conducted under federal permits, licenses, or other authorities that affect or have the potential to affect EFH. The Magnuson-Stevens Act defines EFH as "*those waters and substrate necessary to fish for spawning,* *breeding, feeding, or growth to maturity"* (NPFMC 2009). The NMFS and regional Fishery Management Councils (Councils) must describe and identify EFH in fishery management plans (FMPs), minimize to the extent practicable the adverse effects of fishing on EFH, and identify other actions to encourage the conservation and enhancement of EFH. Federal agencies that authorize, fund, or undertake actions that may adversely affect EFH must consult with NMFS, and NMFS must provide conservation recommendations to federal and state agencies regarding actions that would adversely affect EFH. Councils also have the authority to comment on federal or state agency actions that would adversely affect the habitat, including EFH, of managed species.

The 1996 amendments to the MSA set forth a mandate for NMFS, regional Fishery Management Councils, and other federal agencies to identify and protect EFH of economically important marine and estuarine fisheries. In Alaska, the NPFMC is the regional council responsible for fisheries management within the 3- to 200-nautical mile (nm) EEZ. This task is carried out through the development of FMPs, which guide the management of commercially harvested fish and shellfish. There are six FMPs that apply to Alaskan waters, and two of these apply to Arctic waters: the *Fishery Management Plan for the Salmon Fisheries in the EEZ off the Coast of Alaska* (Salmon FMP) (NPFMC 1990) and the *Fishery Management Plan for Fish Resources of the Arctic Management Area* (Arctic FMP) (NPFMC 2009). The Arctic FMP was completed in 2009 and governs commercial harvests of fish resources in U.S. waters of the Beaufort Sea and Chukchi seas (NPFMC 2009). The Salmon FMP governs management of all salmon fisheries that occur within the EEZ, including the Arctic.

FMPs must describe EFH in text, including reference to the geographic location or extent of EFH using boundaries such as longitude and latitude, isotherms, isobaths, political boundaries, and major landmarks. If differences exist among the descriptions of EFH in text, maps, and tables, the textual description is ultimately determinative of the limits of EFH (NPFMC 2009). FMPs must also include maps that display, within the constraints of available information, the geographic location of EFH or the geographic boundaries within which EFH for each species and life stage is found. EFH descriptive maps depict, and are complimentary to, each life history EFH text description, if known.

Presently, EFH has been described in the Alaskan Arctic for all five species of Pacific salmon, in addition to arctic cod, saffron cod, and opilio (snow) crab (NPFMC 2009). The vastness of Alaska and the large number of individual fish species managed by FMPs make it challenging to describe EFH by text using static boundaries, and descriptions are therefore often vague. Further, species are likely to have EFH described in the future, as conditions and resources require and allow.

EFH is designated based on the best available scientific information (NMFS 2005). The MSA defines categories to describe the level of understanding used to designate EFH that have previously been cited in environmental reports:

- Level 1: Presence/absence distribution data are available for some or all portions of the geographic range of the species;
- Level 2: Habitat-related densities of the species are available;
- Level 3: Growth, reproduction, or survival rates within habitats are available; and
- Level 4: Production rates by habitat are available

In addition, Level 0 was established to describe EFH for those life history stages where EFH could be inferred from another life history stage or a species with similar habitat characteristics. Arctic cod EFH is designated based on Level 1 information for adults and late juveniles. There are insufficient data available to designate EFH for eggs, larvae and early juveniles (NPFMC 2009). Pacific salmon EFH in Alaska is designated based primarily on Level 1 information for all species and life stages (NMFS 2005). Table 3.2-3 displays the level used to determine EFH status for Pacific salmon species in the Arctic.

Table 3.2-3 EFH Information Levels for Alaska Stocks of Pacific Salmon in the Arctic.

Species	Eggs & Larvae	Juveniles fresh water (fry smolt)	Juveniles estuarine	Juveniles marine	Adults, immature / maturing marine	Adults freshwater
Chinook	1	1	1	1	1	1
Coho	1	1	1	0[a]	1	1
Pink	1	0[a]	0[a]	0[a]	0[a]	1
Sockeye	1	1	0[a]	0[a]	0[a]	1
Chum	1	0[a]	0[a]	0[a]	0[a]	1-2

0[a] - Some information on a species' life stage from which to infer general distribution.
Data from NMFS 2005.

The EFH for Pacific salmon species has been described and mapped by NMFS (2005). Salmon EFH includes all those freshwater streams, lakes, ponds, wetlands, and other water bodies currently or historically accessible to salmon. Marine EFH for the salmon fisheries in Alaska includes all estuarine and marine areas used by Pacific salmon of Alaska origin, extending from the influence of tidewater and tidally submerged habitats to the limits of the EEZ. This habitat includes waters of the continental shelf (to the 200-m [656 ft] isobath). In the deeper waters of the continental slope and ocean basin, salmon occupy the upper water column, generally from the surface to a depth of about 50 m (164 ft). Chinook and chum salmon use deeper layers, generally to about 300 m (984 ft), but on occasion to 500 m (1,640 ft). A more detailed description of marine EFH for salmon found in Arctic Alaska is provided below, taken from the *Final EIS for Essential Fish Habitat Identification and Conservation in Alaska* (NMFS 2005):

Chinook Salmon

- *Estuarine EFH for juvenile Chinook salmon* is the general distribution area for this life stage, located in estuarine areas, as identified by the salinity transition zone (ecotone) and the mean higher tide line, within nearshore waters. Chinook salmon smolts and postsmolt juveniles may be present in these estuarine habitats from April through September.
- *Marine EFH for juvenile Chinook salmon* is the general distribution area for this life stage, located in all marine waters off the coast of Alaska from the mean higher tide line to the 200-nm limit of the EEZ, including the Gulf of Alaska, eastern Bering Sea, Chukchi Sea, and Arctic Ocean. Juvenile marine chinook salmon are at this life stage from April until annulus formation in January or February during their first winter at sea.
- *EFH for immature and maturing adult Chinook salmon* is the general distribution area for this life stage, located in marine waters off the coast of Alaska and ranging from the mean higher tide line to the 200-nm limit of the EEZ, including the Gulf of Alaska, eastern Bering Sea, Chukchi Sea, and Arctic Ocean.

Sockeye Salmon

- *Estuarine EFH for juvenile sockeye salmon* is the general distribution area for this life stage, located in estuarine areas, as identified by the salinity transition zone (ecotone) and the mean higher tide line, within nearshore waters. Under-yearling, yearling, and older smolts occupy estuaries from March through early August.
- *Marine EFH for juvenile sockeye salmon* is the general distribution area for this life stage, located in all marine waters off the coast of Alaska to depths of 50 m (164 ft) and range from the mean

higher tide line to the 200-nm limit of the EEZ, including the Gulf of Alaska, eastern Bering Sea, Chukchi Sea, and Arctic Ocean from midsummer until December of their first year at sea.

- *EFH for immature and maturing adult sockeye salmon* is the general distribution area for this life stage, located in marine waters off the coast of Alaska to depths of 200 m (656 ft) and range from the mean higher tide line to the 200-nm limit of the EEZ, including the Gulf of Alaska, eastern Bering Sea, Chukchi Sea, and Arctic Ocean.

<u>Coho Salmon</u>

- *Estuarine EFH for juvenile coho salmon* is the general distribution area for this life stage, located in estuarine areas, as identified by the salinity transition zone (ecotone) and the mean higher tide line, within nearshore waters. Juvenile coho salmon require year-round rearing habitat and also migration habitat from April to November to provide access to and from the estuary.
- *Marine EFH for juvenile coho salmon* is the general distribution area for this life stage, located in all marine waters off the coast of Alaska from the mean higher tide line to the 200-nm (230 mi) limit of the EEZ, including the Gulf of Alaska, eastern Bering Sea, Chukchi Sea, and Arctic Ocean.
- *EFH for immature and maturing adult coho salmon* is the general distribution area for this life stage, located in marine waters off the coast of Alaska to 200 m (656 ft) in depth and range from the mean higher tide line to the 200-nm (230 mi) (limit of the EEZ, including the Gulf of Alaska, eastern Bering Sea, Chukchi Sea, and Arctic Ocean.

<u>Pink Salmon</u>

- *Estuarine EFH for juvenile pink salmon* is the general distribution area for this life stage, located in estuarine areas, as identified by the salinity transition zone (ecotone) and the mean higher tide line, within nearshore waters and generally present from late April through June.
- *Marine EFH for juvenile pink salmon* is the general distribution area for this life stage, located in all marine waters off the coast of Alaska from the mean higher tide line to the 200-nm limit of the EEZ, including the Gulf of Alaska, eastern Bering Sea, Chukchi Sea, and Arctic Ocean.
- *EFH for immature and maturing adult pink salmon* is the general distribution area for this life stage, located in marine waters off the coast of Alaska to 200 m (656 ft) in depth and range from the mean higher tide line to the 200-nm limit of the EEZ, including the Gulf of Alaska, eastern Bering Sea, Chukchi Sea, and Arctic Ocean.

<u>Chum Salmon</u>

- *Estuarine EFH for juvenile chum salmon* is the general distribution area for this life stage, located in estuarine areas, as identified by the salinity transition zone (ecotone) and the mean higher tide line, within nearshore waters from late April through June.
- *Marine EFH for juvenile chum salmon* is the general distribution area for this life stage, located in all marine waters off the coast of Alaska to approximately 50 m (164 ft) in depth from the mean higher tide line to the 200-nm (230 mi) limit of the EEZ, including the Gulf of Alaska, eastern Bering Sea, Chukchi Sea, and Arctic Ocean.
- *EFH for immature and maturing adult chum salmon* is the general distribution area for this life stage, located in marine waters off the coast of Alaska to depths of 200 m (656 ft) and ranging from the mean higher tide line to the 200-nm (230 mi) limit of the EEZ, including the Gulf of Alaska, eastern Bering Sea, Chukchi Sea, and Arctic Ocean.

EFH for Arctic species has thus far been limited to 3 species identified in the Arctic FMP (NPFMC 2009). An attempt has been made to be as specific as possible regarding habitat use, but little reliable data exists on which to base these assessments. Therefore, the descriptions are omitted for some life stages and necessarily general for others. The full description of EFH for these species has been included below, taken from the *Essential Fish Habitat 5-Year Review for 2010 Summary Report* (NMFS 2010a):

Arctic Cod

- *Eggs, Larvae, and Early Juveniles* - Insufficient information is available to determine EFH for eggs, larvae, and early juveniles.
- *Late Juveniles* - EFH for late juvenile arctic cod is the general distribution areas for this life stage located in pelagic and epipelagic waters from the nearshore to offshore areas along the entire shelf (0 to 200 m [0 to 656 ft]) and upper slope (200 to 500 m [656 to 1,640 ft]) throughout Arctic waters and often associated with ice floes which may occur in deeper waters.
- *Adults* - EFH for adult arctic cod is the general distribution area for this life stage located in pelagic and epipelagic waters from the nearshore to offshore areas along the entire shelf (0 to 200 m [0 to 656 ft]) and upper slope (200 to 500 m [656 to 1,640 ft]) throughout Arctic waters and often associated with ice floes which may occur in deeper waters.

Saffron Cod

- *Eggs, Larvae, and Early Juveniles* - Insufficient information is available to determine EFH for eggs, larvae, and early juveniles.
- *Late Juveniles* - EFH for late juvenile saffron cod is the general distribution area for this life stage, located in pelagic and epipelagic waters along the coastline, within nearshore bays, and under ice along the inner (0 to 50 m [0 to 164 ft]) shelf throughout Arctic waters and wherever there are substrates consisting of sand and gravel.
- *Adults* - EFH for adult saffron cod is the general distribution area for this life stage, located in pelagic and epipelagic waters along the coastline, within nearshore bays, and under ice along the inner (0 to 50 m [0 to 164 ft]) shelf throughout Arctic waters and wherever there are substrates consisting of sand and gravel.

Snow Crab (*C. opilio*)

- *Eggs* - Essential fish habitat of snow crab eggs is inferred from the general distribution of egg-bearing female crab (see Adults).
- *Larvae and Early Juveniles* - Insufficient information is available to determine EFH for larvae and early juveniles.
- *Late Juveniles* - EFH for late juvenile snow crab is the general distribution area for this life stage, located in bottom habitats along the inner (0 to 50 m [0 to 164 ft]) and middle (50 to 100 m [164 to 328 ft]) shelf in Arctic waters south of Cape Lisburne, wherever there are substrates consisting mainly of mud.
- *Adults* - EFH for adult snow crab is the general distribution area for this life stage, located in bottom habitats along the inner (0 to 50 m [0 to 164 ft]) and middle (50 to 100 m [164 to 328 ft]) shelf in Arctic waters south of Cape Lisburne, wherever there are substrates consisting mainly of mud.

In 2008, Logerwell and Rand conducted an offshore marine fish survey in the Beaufort Sea. The survey was the first to document commercial-sized snow crab in the North American Arctic (Logerwell and

Rand 2010). This information may lead to an expansion of the EFH for snow crab in the future to include the western Beaufort Sea.

3.2.3 Marine and Coastal Birds

This section provides a baseline description of the marine and coastal birds that are likely to occur in the EIS project area and that may be affected by the actions described in the EIS. This section includes species of particular conservation concern, such as those listed under the ESA, and several groups of species that share certain characteristics important to the analysis of environmental consequences in Chapter 4.

Several million migratory marine and coastal birds occur in the Beaufort and Chukchi sea regions. Most occur on a seasonal basis related to the availability of open water. These birds occupy offshore and coastal marine, freshwater, and tundra habitats during the summer breeding and spring/fall migration seasons. Spring migrations into the Arctic typically occur from late March into June. Departure times during post-breeding or fall migration vary between species and also by sex within the same species. Most birds will be out of the Beaufort and Chukchi seas by late fall, typically in September or October, to avoid the formation of sea ice (Divoky 1987). The Beaufort and Chukchi seas' coastal lagoons are used by substantial numbers of breeding and post-breeding migratory birds during the short Arctic summer when waters are mostly ice free. Table 3.2-4 provides a list of marine and coastal birds in the EIS project area with common names, scientific names, and Iñupiaq names.

Table 3.2-4 Birds Occurring in Marine and Coastal Environments of the Alaska Beaufort and Chukchi Seas

Nomenclature for common and scientific names and taxonomic order has been taken from the Check-list of North American Birds (American Ornithologists' Union 2010). Iñupiaq names are provided for some species (Bacon and Akpik 2010).

Common Name	Scientific Name	Iñupiaq Name
Greater White-fronted Goose	*Anser albifrons*	Nibliq
Emperor Goose	*Chen canagica*	
Snow Goose (Lesser)	*Chen caerulescens*	Kaffuq
Brant	*Branta bernicla*	Niblinbaq
Canada Goose	*Branta canadensis*	Iqsrabutilik
Tundra Swan	*Cygnus columbianus*	Qubruk
American Wigeon	*Anas americana*	Ugiihiq
Mallard	*Anas platyrhynchos*	Kurugaqtaq
Northern Shoveler	*Anas clypeata*	Aluuttag, Qailuutag
Northern Pintail	*Anas acuta*	
Green-winged Teal	*Anas crecca*	Qaiffiq
Greater Scaup	*Aythya marila*	Qaqjuktuuq
Steller's Eider	*Polysticta stelleri*	Igniqauqtuq
Spectacled Eider	*Somateria fischeri*	Qavaasuk
King Eider	*Somateria spectabilis*	Qifalik
Common Eider	*Somateria mollissima*	Amauliqruaq
Surf Scoter	*Melanitta perspicillata*	
White-winged Scoter	*Melanitta fusca*	
Black Scoter	*Melanitta americana*	
Long-tailed Duck	*Clangula hyemalis*	Aaqhaaliq
Red-breasted Merganser	*Mergus serrator*	Aqpaqsruayuuq
Willow Ptarmigan	*Lagopus lagopus*	
Rock Ptarmigan	*Lagopus muta*	Niksaaktufiq
Red-throated Loon	*Gavia stellata*	Qaqsraupiabruk

Common Name	Scientific Name	Iñupiaq Name
Arctic Loon	*Gavia arctica*	
Pacific Loon	*Gavia pacifica*	Qaqsrauq
Common Loon	*Gavia immer*	
Yellow-billed Loon	*Gavia adamsii*	Tuullik
Red-necked Grebe	*Podiceps grisegena*	
Pelagic Cormorant	*Phalacrocorax pelagicus*	
Rough-legged Hawk	*Buteo lagopus*	
Golden Eagle	*Aquila chrysaetos*	
Gyrfalcon	*Falco rusticolus*	
Peregrine Falcon	*Falco peregrinus*	
Sandhill Crane	*Grus canadensis*	Tatirgak
Black-bellied Plover	*Pluvialis squatarola*	
American Golden-Plover	*Pluvialis dominica*	Tuulligouk
Pacific Golden-Plover	*Pluvialis fulva*	
Whimbrel	*Numenius phaeopus*	Siituvuk, Siituvak
Hudsonian Godwit	*Limosa haemastica*	
Bar-tailed Godwit	*Limosa lapponica*	
Ruddy Turnstone	*Arenaria interpres*	Taliqvak, Tuullignaq
Semi-palmated Sandpiper	*Calidris pusilla*	Liva Livaqpauraq, Nivilivilakpak
Western Sandpiper	*Calidris mauri*	
Pectoral Sandpiper	*Calidris melanotos*	Puvviaqtuuq
Sharp-tailed Sandpiper	*Calidris acuminata*	
Rock Sandpiper	*Calidris ptilocnemis*	
Dunlin	*Calidris alpina*	Iooauqtulik, Siggukpaligaraq
Long-billed Dowitcher	*Limnodromus scolopaceus*	
Red-necked Phalarope	*Phalaropus lobatus*	Qayyiubun
Red Phalarope	*Phalaropus fulicarius*	Auksruaq
Black-legged Kittiwake	*Rissa tridactyla*	
Ivory Gull	*Pagophila eburnea*	
Ross' Gull	*Rhodostethia rosea*	
Mew Gull	*Larus canus*	
Herring Gull	*Larus argentatus*	
Glaucous Gull	*Larus hyperboreus*	Nauyyaq, Nauyaq
Aleutian Tern	*Onychoprion aleuticus*	
Arctic Tern	*Sterna paradisaea*	
Pomarine Jaeger	*Stercorarius pomarinus*	
Parasitic Jaeger	*Stercorarius parasiticus*	
Long-tailed Jaeger	*Stercorarius longicaudus*	
Dovekie	*Alle alle*	
Common Murre	*Uria aalge*	Akpa
Thick-billed Murre	*Uria lomvia*	Akpa
Black Guillemot	*Cepphus grylle*	Ifabiq
Pigeon Guillemot	*Cepphus columba*	
Kittlitz's Murrelet	*Brachyramphus brevirostris*	
Parakeet Auklet	*Aethia psittacula*	
Least Auklet	*Aethia pusilla*	
Crested Auklet	*Aethia cristatella*	
Horned Puffin	*Fratercula corniculata*	
Tufted Puffin	*Fratercula cirrhata*	
Snowy Owl	*Bubo scandiacus*	Ukpik
Short-eared Owl	*Asio flammeus*	

Common Name	Scientific Name	Iñupiaq Name
Common Raven	*Corvus corax*	
American Robin	*Turdus migratorius*	
Eastern Yellow Wagtail	*Motacilla tschutschensis*	
Lapland Longspur	*Calcarius lapponicus*	
Snow Bunting	*Plectrophenax nivalis*	
American Tree Sparrow	*Spizella arborea*	
Savannah Sparrow	*Passerculus sandwichensis*	
Common Redpoll	*Acanthis flammea*	
Hoary Redpoll	*Acanthis hornemanni*	

3.2.3.1 Threatened and Endangered Birds

Spectacled Eider

Spectacled eiders are medium sized, diving sea ducks that spend most of the year in marine waters and nest along the Beaufort and Chukchi coastal areas, as well as the Yukon Kuskokwim Delta and in Siberia. They feed on benthic invertebrates in marine waters, primarily mollusks and crustaceans but also eat insects and insect larvae on the breeding grounds (Peterson et al. 2000). Biologists estimate that about 5,000 pairs currently nest on Alaska's Arctic coastal plain and at least 40,000 pairs nest in Arctic Russia. The current worldwide population estimate is between 200,000 and 300,000 birds, which is derived from winter surveys in the Bering Sea and includes non-breeding birds (USGS 2010).

Spectacled eiders are present in the Chukchi Sea during spring migration in May and June. After breeding, male eiders fly to nearshore marine waters in late June where they undergo a complete molt of their flight feathers. Nesting females remain on the coastal tundra until late August to early September and then congregate in molting areas. In Arctic Alaska, the primary molting area is Ledyard Bay, where males occur in the summer and breeding females occur in the fall (MMS 2008). Movement between nesting and molting areas takes several weeks because birds make many stops along the Beaufort and Chukchi coasts. Figure 3.2-7 shows the seasonal distribution of spectacled eiders in the EIS project area.

Spectacled eiders were listed as threatened under the ESA in 1993 as a result of severely declining populations in western Alaska, and possible declining populations in northern Alaska and eastern Russia (58 FR 27474, May 10, 1993). The USFWS published a Recovery Plan for the species in 1996 (USFWS 1996) and designated critical habitat in 2001 (66 FR 9146, February 6, 2001). Critical habitat includes several areas in the Bering Sea and also Ledyard Bay in the Chukchi (Figure 3.2-7).

Steller's Eider

Steller's eiders are the smallest species of eider. They spend most of the year in marine waters and nest in coastal tundra habitats. This species feeds on crustaceans, gastropods, mollusks, and marine worms. There are two geographical populations of Steller's eiders, one that winters in the North Atlantic Ocean and one in the Pacific Ocean. Most of the Pacific population nests in the coastal tundra of northeast Siberia, with less than five percent of the breeding population nesting in Alaska on the Yukon-Kuskokwim Delta and the Arctic coastal plain, especially around Barrow (USFWS 2002).

Steller's eiders return to the Arctic as spring thaw allows, migrating north in May and June. Along open coastline, Steller's eiders usually remain within about 400 m (1,312 ft) of shore in water less than 10 m (33 ft) deep but they can also be found in waters well offshore in shallow bays and lagoons or near reefs (USFWS 2000a). Molting patterns are similar to spectacled eiders, with males returning to molting areas in nearshore marine waters after breeding in late June or July and females molting after nesting season, including substantial use of Izembek Lagoon. Immature birds usually remain at sea until reaching breeding age at two to three years old (Fredrickson 2001). Figure 3.2-8 shows the seasonal distribution of Steller's eiders in the EIS project area.

The Alaska breeding population of Steller's eiders was listed as threatened under the ESA in 1997 due to a decline in breeding in Alaska (62 FR 31748, June 11, 1997). The USFWS designated critical habitat for Steller's eiders in 2001 (66 FR 8850, February 2, 2001), all of which is adjacent to the Bering Sea, and published a Recovery Plan for the species in 2002 (USFWS 2002).

Kittlitz Murrelet

Kittlitz's murrelets are small diving seabirds that eat fish and zooplankton. They occur discontinuously from Southeast Alaska to the eastern edge of the Alaskan Beaufort Sea and east to the Arctic National Wildlife Refuge (Day et al. 2011). They nest in rugged mountains near glaciers or in previously glaciated areas, sometimes up to 45 miles inland. In the EIS project area, the only known nesting habitat is on the Lisburne Peninsula (Figure 3.2-9). Population estimates for Kittlitz's murrelet are difficult to determine and range from 9,000 to 25,000 birds, the great majority of which are in Prince William Sound and Southeast Alaska (Denlinger 2006). There appears to be a great deal of annual variation in their occurrence in the Chukchi Sea (Day et al. 1999).

In response to a petition to list Kittlitz's murrelet under the ESA, the USFWS ruled in 2004 that conservation concerns warrant further investigation and that the species is considered a candidate for listing under the ESA, which was updated in 2011 (76 FR 66370, October 26, 2011). A candidate species is one for which there is enough information to support a proposal to list as endangered or threatened, but for which preparation and publication of a proposal is precluded by higher-priority listing actions. The USFWS has conducted numerous surveys and studies on this species since 2004.

Yellow-billed Loon

The yellow-billed loon is a large diving seabird which spends most of the year in marine waters feeding on fish and invertebrates and nests in Arctic tundra regions. This species migrates from wintering areas in more southern waters, arriving at breeding areas along the Arctic coast between mid-May and mid-June (North 1994). Yellow-billed loons are regular migrants along the coastlines of northern Canada, northern Alaska, and northwestern Alaska, and a rare migrant along the western Alaska coastline (Earnst 2004). Satellite telemetry data indicate that nesting yellow-billed loons have variable movement patterns on their nesting grounds (Rizzolo and Schmutz 2010). Yellow-billed loons that nested on inland lakes (>20 km from marine waters) between Barrow and Teshekpuk Lake did not travel to marine waters to forage but loons that nested nearer to the shore on the Seward Peninsula frequently foraged in marine waters (Rizzolo and Schmutz 2010).

Of the approximately 3,300 yellow-billed loons present on the breeding grounds on the Arctic coast, primarily between the Meade and Colville rivers in the National Petroleum Reserve-Alaska (NPR-A), it is likely that there are fewer than 1,000 nesting pairs, because some birds are non-breeders (Earnst et al. 2005). Additionally, there are approximately 1,500 yellow-billed loons, presumably immatures and non-breeding adults, which remain in near shore marine waters or in large rivers during the breeding season. In total, there are fewer than 5,000 yellow-billed loons on the Arctic coast breeding grounds and near shore marine habitat (Earnst et al. 2005). In addition, approximately 8,000 yellow-billed loons that nest in the Canadian Arctic (Fair 2002, as cited in Earnst et al. 2005) also must travel through the Beaufort and Chukchi seas during spring and fall migration between Canada and wintering grounds in eastern Asia (Schmutz et al. 2010). Figure 3.2-10 shows the seasonal distribution of yellow-billed loons in the EIS project area.

In response to a petition to list yellow-billed loons under the ESA, the USFWS determined in 2009 that listing the yellow-billed loon is warranted but precluded by other higher priority listing actions and that the species should be considered a candidate for listing (74 FR 12932, March 25, 2009). The USFWS has not made any additional determinations on the petition to list the species under the ESA.

3.2.3.2 Seabirds

There are many species of seabirds that occur in both the Beaufort and Chukchi seas, including representatives from several orders of birds, all of which are adapted for spending the majority of their time at sea. Most only come near land during the breeding season. Some species feed at or near the surface of the water while others dive deep to feed in the benthic environment.

Loons

There are five species of loons in the Arctic, including the yellow-billed loon described above, Arctic and common loons which are rare in the Beaufort and Chukchi seas, and the Pacific and red-throated loons which are common nesters. Loons are extremely good swimmers and divers but awkward on land, therefore they nest within one meter of water, near large, deep, tundra lakes and wetlands. Loons eat invertebrates, aquatic insects, and small fish (USFWS 2009a).

The majority of loons migrate along coastal routes, although some migrate using inland routes (Johnson and Herter 1989). Most of the loon's fall migration takes place in September, and they are commonly observed in flight as they migrate to southern locations for the winter (Divoky 1987). In a survey of bird density and distribution at the Burger and Klondike lease areas in the Chukchi Sea (Gall and Day 2009). Pacific loons were one of the eight most abundant species observed. Most of the observations occurred in mid-September to early October, and none were observed in late summer. Both red-throated and yellow-billed loons were rare during these surveys. USFWS surveys indicate the Pacific loon population on the North Slope has been growing substantially over the past ten years and has totaled about 27,000 birds the past few years (Larned et al. 2010).

The red-throated loon is the smallest of the loon species. USFWS surveys indicate the red-throated loon population on the North Slope has been relatively stable over the last 10 years and has totaled about 2,600 birds the past few years (Larned et al. 2010).

Short-tailed Shearwaters

Short-tailed shearwaters breed in the southern hemisphere and occur in the Bering Sea and Arctic waters during their non-breeding season, eating primarily crustaceans, fish and squid.

Short-tailed shearwaters are most common in the southern portion of the Chukchi Sea but are often found in the central and northern portions from late August to late September. They have been reported as far north as Barrow depending on the presence of sea ice. An estimated 100,000 passed Point Barrow in one day in mid-September 1984 (Divoky 1987). At the Burger and Klondike lease areas, Short-tailed shearwaters were observed in most seasons but were most abundant in early fall when they were by far the most common species seen (Gall and Day 2009).

Northern Fulmars

The northern fulmar is abundant in the offshore waters of the Chukchi Sea. There are approximately 1.4 million fulmars in Alaska, almost all of which breed in colonies in the Bering Sea (Denlinger 2006). Northern fulmars do not breed in the Chukchi Sea (Divoky 1987). Fulmars observed in the Chukchi, estimated at 45,000, from late August to mid-September are non-breeders or failed breeders (Divoky 1987). Reproduction rate is low, and breeding does not occur until they are 8 to 10 years old (Hatch and Nettleship 1998). Northern fulmars eat a wide variety of fish, squid, and zooplankton (especially copepods and amphipods) from near the sea surface and also commonly scavenge offal generated by commercial fishing and whaling operations (Hatch and Nettleship 1998). At the Burger and Klondike lease areas, northern fulmars were observed in all seasons but were most abundant in early fall at Klondike when they were the second most abundant species seen (Gall and Day 2009).

Ross' Gull

Ross' gull is a small Arctic species which is rare in the Beaufort Sea during the summer time because most breed in coastal areas in the Russian Arctic. If they are in the Beaufort during the summer, they are found in close association with the ice edge (Divoky et al. 1988). Ross' gulls were rarely observed at Burger in late fall (Gall and Day 2009). However, they are common migrants in the Beaufort and Chukchi seas around Point Barrow in the fall (Divoky et al. 1988). Up to 16,000 birds have been observed migrating east past Point Barrow in late September, presumably from their breeding grounds in the Russian Chukchi, and westward back into the Chukchi in mid-October. Ross' gulls are commonly seen during these fall migrations along the coast from Wainwright to Cape Halkett, approximately 100 miles (160 km) west of Point Barrow (Divoky et al. 1988).

Ivory Gull

The ivory gull breeds in areas of the high Arctic outside of Alaska and move to the Bering Sea in the winter (Mallory et al. 2008). They are present in the Beaufort and Chukchi seas in limited numbers during the spring and fall migrations and are uncommon to rare in the summer (Divoky 1987). These gulls eat invertebrates and ice-associated fish (walleye pollock and arctic cod). These birds tend to concentrate at the ice edge and at polynyas (recurring areas of open water), and may occasionally stop along the shores of Kasegaluk Lagoon, of Peard Bay, and near Barrow (Mallory et al. 2008). Ivory gulls were rarely observed at Burger in late fall (Gall and Day 2009).

Glaucous Gull

Glaucous gulls occur in low densities in the offshore areas of the Chukchi Sea but commonly congregate at food sources (Divoky 1987). These birds are found in higher densities along the coasts of both the Beaufort and Chukchi seas. They breed inland near freshwater but sometimes breed within coastal seabird colonies. Glaucous gulls nest in many habitats including: barrier islands; sea cliffs; open tundra; ice edges; freshwater lakes and ponds; and islets on river deltas (Denlinger 2006). An adjusted population for Alaska, including those that nest inland, is approximately 100,000 individuals (Denlinger 2006). Glaucous gulls are most common in the Chukchi Sea from late July to late September within 70 km (43.5 mi) of shore between Icy Cape and Barrow (Divoky 1987). They were observed in all seasons at Burger and Klondike but were most common in early fall (Gall and Day 2009).

Black-Legged Kittiwake

Black-legged kittiwakes nest on narrow cliff ledges in colonies that range from a few nests to several thousand (Denlinger 2006). They breed in colonies along the coast of the Chukchi Sea from Cape Thompson to Cape Lisburne, which are at the northern limit of the species range in Alaska (Denlinger 2006). Their diet consists of mostly fish including capelin, pollock, and herring. They are common in the Chukchi Sea north of Cape Thompson from mid-July until late September. From late August to late September, the population density for the central and southern portion of the Chukchi Sea is 2.3 birds/km^2 or an estimated population in excess of 400,000 birds in the pelagic Chukchi Sea (Divoky 1987). They were one of the most commonly observed species in all seasons at Burger and Klondike but were most common in early fall (Gall and Day 2009).

Jaegers

Pomarine jaegers, parasitic jaegers, and long-tailed jaegers are common in the Chukchi Sea in the summer until late September. Jaeger densities at sea tend to be higher in years when there is low breeding on the tundra (Divoky 1987). Breeding occurs along the Arctic coast and on the Yukon Delta. Jaegers are found sporadically at any one site, but sometimes are in large numbers near Barrow. They primarily feed by scavenging, predation on small birds, bird eggs, and young birds, and stealing food from other birds (Denlinger 2006). Pomarine and parasitic jaegers were observed in low numbers at Burger and Klondike and were most common at Burger in early fall (Gall and Day 2009).

Arctic Terns

Arctic terns nest near fresh or marine waters in open, treeless environments and are distributed widely along the Arctic coastal plain of the Beaufort and Chukchi seas. Population estimates in Alaska show that there may be several hundred thousand, most nesting inland (Denlinger 2006). They are rare in the pelagic waters of the Beaufort and Chukchi seas but congregate in nearshore areas to feed on zooplankton. Studies have found concentrations of arctic terns in Kasegaluk Lagoon and between Omalik Lagoon and Point Barrow (Dau and Larned 2005). Most leave the Arctic by mid-September, following a coastal route out of the Chukchi Sea in the fall (Divoky 1987). A few arctic terns were observed at Burger and Klondike, primarily in early fall (Gall and Day 2009).

Phalaropes

Red phalaropes and red-necked phalaropes are closely related to other shorebirds but are often considered to be seabirds because they spend most of the year at sea and nest in coastal tundra. Both species are common in the Chukchi Sea during open-water periods but few are found further north than Point Barrow (Divoky 1987). There is a minimum of one million phalaropes in the Chukchi Sea during the summer. These seabirds are found in pelagic waters and also within a few meters of shore due to zooplankton abundance; therefore, their distribution tends to be patchy (Divoky 1987). Red phalaropes are considered more common than red-necked phalaropes in Peard Bay (important for migrating juvenile red phalaropes) and Kasegaluk Lagoon (ASWG 2008). Small numbers of both species were observed in mixed-species flocks at Burger and Klondike, primarily in September (Gall and Day 2009).

Murres

Murres have a unique breeding strategy with high nesting density, colony departure in synchrony, and the majority of chick development taking place at sea with the male parent (Ainley et al. 2002). The flightless period for juvenile murres at sea lasts from early September to mid-November when they, along with attendant adult males (part of this period males will be flightless and molting), move quickly from the Chukchi Sea to winter locations in the Bering Sea (Hatch et al. 2000). Murres use their wings to propel themselves underwater and can dive as deep as 210 m (689 ft) to catch fish and invertebrate prey (Ainley et al. 2002).

There are two main breeding colonies of common murres and thick-billed murres along the Chukchi Sea coast (Hatch et al. 2000). Approximately 100,000 murres nest at Cape Lisburne, with about 70,000 being common murres. At Cape Thompson, there are about 390,000 nesting murres, of which 75 percent are thick-billed. The foraging ranges of these two breeding colonies are almost completely separate. The Cape Lisburne colony forages primarily northwest to northeast of Point Hope, while the Cape Thompson colony forages primarily southwest to southeast of Point Hope (Hatch et al. 2000). Thick-billed murres were one of the most common species observed at Klondike in the summer and early fall but were rare or absent at Burger and during other seasons (Gall and Day 2009). Common murres were also observed at Klondike in fair numbers, primarily in late summer and early fall.

Puffins

Tufted puffins nest in beach habitat by digging burrows or hiding under large pieces of driftwood or debris. They dive deep for fish and invertebrate prey. Around 18,000 horned puffins breed at colonies at Cape Lisburne and Cape Thompson. Only 100 breeding tufted puffins occur in these areas (USFWS 2006). Horned puffins are commonly observed in the Chukchi Sea by Cape Lisburne after the breeding season in September. They have also been seen near Barrow and are now breeding on Cooper Island in the western Beaufort Sea (USFWS 2006). Both species were observed at Klondike in low numbers, primarily in summer (Gall and Day 2009).

Black Guillemots

Black guillemots have a small breeding population in Alaska, with a combined total of fewer than 2,000 birds in both the Beaufort and Chukchi seas. Their breeding range is from Cape Thompson northward. Black guillemots nest in driftwood piles and manmade structures due to the low coastal tundra bluffs and gravel beaches lacking fissures or spaces that are suitable for breeding (Denlinger 2006). These birds tend to stay close to sea ice throughout their lifetime to feed on arctic cod. If the sea ice is beyond their foraging range, they will switch prey to other fish species as necessary (Divoky 1987). The black guillemots that breed on Cooper Island (between late June and early September), in the Beaufort Sea, also are found in the Chukchi Sea by Point Barrow during the early part of the breeding season (Divoky 1987). Black guillemots were also observed at Klondike in low numbers, primarily in summer (Gall and Day 2009).

Auklets

Parakeet auklets, least auklets, and crested auklets breed as far north as the Bering Strait, but move north into the Chukchi Sea from late August through early October where they feed on small zooplankton, often far from shore where strong vertical mixing carries the prey to the surface (Denlinger 2006). Based on limited data, crested auklets appear to be the most numerous auklet species in the Chukchi Sea during this time period (Divoky 1987). Perhaps a total of 100,000 auklets are present in the Chukchi Sea when combining all three species (Divoky 1987). Least and crested auklets were two of the most common species observed at Klondike, especially in fall, but were much less common at Burger (Gall and Day 2009).

3.2.3.3 Waterfowl

Many ducks, geese, and swans migrate to the Arctic for the summer to nest on the tundra. Some species, such as long-tailed ducks and eiders, spend most of their non-breeding seasons on marine waters and are often considered as seabirds. Other species are not often associated with marine waters but nest in coastal areas in the EIS project area and may be affected by associated onshore activities identified in this EIS.

Long-tailed Ducks

The long-tailed duck is a small sea duck that nests on marshy grass tundra, especially around polygon ponds, lakes, bogs, slow rivers, and barrier islands (Robertson and Savard 2002). They feed on crustaceans, shrimp, amphipods, clams and fish in marine waters and will eat freshwater insects, fish eggs, and plant material on their breeding grounds. Alaska is home to about 20 percent of the North American population of one million (Kirchhoff and Padula 2010). This species breeds in the Arctic and western Alaska and winters along the southern coast of Alaska south to Washington state. Long-tailed ducks migrate north along the Chukchi Sea coast and east along the Beaufort Sea coast from wintering areas to breeding areas in Arctic Alaska and Canada (Lysne et al. 2004). During the open-water period in the Beaufort Sea, long-tailed ducks are abundant in and near lagoons, but they also molt in Kasegaluk Lagoon on the Chukchi Sea coast (Flint et al. 2003). Kasegaluk Lagoon and Peard Bay are major long-tailed duck molting and pre-migratory areas (Lysne et al. 2004). In late June and early July, most male and nonbreeding females assemble in massive flocks in lagoons along the Beaufort Sea to molt, while a smaller number molt on large, freshwater lakes (Flint et al. 2003). Females and immature birds leave in August to October. Long-tailed ducks were the most common waterfowl observed at Burger and Klondike, but numbers were still relatively low. They were observed at both sites and in all seasons (Gall and Day 2009).

USFWS surveys indicate the long-tailed duck population on the North Slope has been above the 18 year mean but below the 20 year mean and has totaled about 34,000 birds the past few years (Larned et al. 2010).

Eiders

King and common eiders are two of the four world eider species (spectacled and Steller's eiders are discussed above). These large sea ducks breed in the Arctic and winter in marine waters along the southern coast of Alaska. They are always found near water and nest on Arctic tundra near lakes, bogs, and streams near the coast and up to 50 km (31.1 mi) inland. They eat mostly benthic organisms while at sea, and mollusks, aquatic insects, and plants on breeding grounds (Suydam 2000). Both eider species begin migration in April and arrive at their breeding grounds in May to early June; males leave breeding areas in late June and July to migrate to molting areas, while females and immature birds follow later.

The population status of king eiders is in question because of migration counts at Point Barrow, which declined 56 percent between 1976 and 1996, from 802,556 birds to about 350,835 birds, as well as a significant decrease in birds in the Northwest Territories (Suydam 2000). An estimated 499,423 king and 174,063 common eiders passed Point Barrow in the summer/fall migrations of 2002. In 2003, the summer/fall surveys estimated 365,680 king and 132,404 common eiders had passed Point Barrow. In the spring migrations, 304,966 king and 114,998 common eiders passed Point Barrow in 2003 while 591,961 king and 110,561 common eiders passed in 2004. This study indicated that, since 1996, the numbers of king eiders passing Point Barrow remained stable while common eiders have increased (Quakenbush et al. 2009c).

King eiders nest in highest densities on the Arctic coast between Wainwright and Prudhoe Bay, with concentration areas near Atqasuk and from Teshekpuk Lake to Deadhorse. Telemetry work by Oppel (2008) found that potentially all king eiders breeding in western North America use Ledyard Bay, Kasegaluk Lagoon, and Peard Bay as staging areas during migration.

An estimated 170,000 common eiders exist globally with about 54,000 nesting in Alaska, with populations remaining stable or slightly increasing (Kirchhoff and Padula 2010). Common eiders nest on barrier islands and spits along the coast from Kasegaluk Lagoon to Prudhoe Bay. Common molt areas in the Chukchi Sea are near Point Lay, Icy Cape, and Cape Lisburne, including Peard Bay (Johnson and Herter 1989). Small numbers of both king and common eiders were observed at Burger and Klondike (Gall and Day 2009).

Geese and Swans

Brant typically nest on barrier islands, offshore spits, or islands in large river deltas, no more than 40 km (24.8 mi) inland from the coast (Derksen et al. 1981). They migrate along the west coast of Alaska enroute to breeding areas on the Alaska coast or the Canadian High Arctic. The main nesting area for brant in Alaska is the Yukon-Kuskokwim delta but smaller colonies exist from the Seward Peninsula to Kasegaluk Lagoon (about 200 birds) and along the Beaufort coast east to the Canning River (about 3,000 birds) (Pacific Flyway Council 2002). The USFWS conducts waterfowl surveys along the Alaska Arctic coast every year and found a significant increase in the brant breeding population between 2001 and 2004 followed by stability at the higher level through 2009 (Larned et al. 2010). However, the USFWS survey design may not be the most appropriate to track population trends and more focused surveys have indicated a stable number of nests (346 to 386 nests total) at small colonies between Barrow and the Coleville Delta (Ritchie et al. 2002 and 2007, as cited in Larned et al. 2010). The largest concentrations of colonies and nests have been located in the Sagavinirktok River Delta, Prudhoe Bay, and Kuparuk areas (Stickney and Ritchie 1996). Kasegaluk Lagoon and Peard Bay are important stopover locations during the post breeding migration of this species.

Greater white-fronted geese breed along the coasts of the Bering, Chukchi, and Beaufort seas. The first week of June and the last week of August are peak migration times out of Kasegaluk lagoon. They typically breed on the tundra, within 30 km (18.6 mi) of the coast (Johnson and Herter 1989). USFWS surveys indicate the white-fronted goose population on the North Slope has been growing substantially over the past ten years and has totaled about 160,000 birds the past few years (Larned et al. 2010).

Lesser snow geese use Kasegaluk lagoon, an island in the Kukpowruk River delta (about 60 km [37.3 mi] south of Point Lay), and the Ikpikpuk River delta near Prudhoe Bay on the Arctic coast to nest (Ritchie and Rose 2009). Recent brood rearing monitoring surveys on sites east of Barrow found increases in populations on the Ikpikpuk River and growth in the colonies on both the Colville River delta and the Sagavanirktok River delta. Based on a combination of group sizes from points north and south of Point Lay at least 2,315 snow geese summered in Kasegaluk lagoon in 2008 (Ritchie and Rose 2009). USFWS surveys indicate the snow goose population on the North Slope has been growing substantially over the past ten years and has totaled about 28,000 birds the past few years (Larned et al. 2010).

Tundra swans nest in Arctic wetlands throughout Alaska. They form monogamous pairs, and the young remain with the parents until arrival on the breeding grounds the following year. Tundra swans eat submerged aquatic vegetation and benthic organisms (Limpert and Earnst 1994). USFWS surveys indicate the tundra swan population on the North Slope has been growing substantially over the past ten years and has totaled about 10,000 birds the past few years (Larned et al. 2010).

3.2.3.4 Shorebirds

Many species of shorebirds migrate long distances to nest in Arctic regions, often congregating in large numbers at favorable staging areas along the coast. Many shorebirds stop to replenish energy reserves and rest at high productivity sites like Kasegaluk Lagoon and Peard Bay. The Colville River Delta hosts 41,000 to 300,000 shorebirds between the end of July and early September each year (Andres 1994, USSCP 2004, Powell et al. 2010). Shorebird chicks leave their nests within 24 hours of hatching and never return but are protected by both parents until they are able to fly. Juvenile birds often group together in flocks, typically along the coast, to feed and prepare for their migration (Weiser 2008).

Dunlin are one of the main species of shorebirds that use Kasegaluk Lagoon for staging during migration. They are listed as a species of concern because of declining populations (USSCP 2004).

Semipalmated sandpipers nest on flat marshy tundra and raise their young in just a few weeks of Arctic summer. This species appears on the breeding territories in the first few weeks of June (Hicklin and Trevor 2010).

Pectoral sandpipers arrive on the breeding grounds in late May or early June. In Barrow, egg laying begins as early as the first week of June but most laying occurs from mid-June to the beginning of July. In the breeding areas, they feed on larvae and adult arthropods (Holmes and Pitelka 1998).

Bar-tailed godwits breed in sub-Arctic and Arctic tundra in western and northern Alaska. In September and early October, nearly 100,000 post breeding birds move along the Bering Sea Coast at staging grounds before flying nonstop to New Zealand. Both breeding and non-breeding sites show a rapid population decline (McCaffery and Gill 2001).

Buff-breasted sandpipers are rare breeders and visitors in northwestern Alaska and are considered highly imperiled due to threats in their winter habitat in South America (Brown et al. 2001).

American golden-plovers breed in dwarf shrub habitats and stage in dwarf-shrub and salt-grass meadows. The North American population is of conservation concern due to a decreasing population trend and threats during the non-breeding season in South America (USSCP 2004).

3.2.3.5 Traditional Knowledge about Birds

Most efforts to document traditional knowledge in the Arctic have focused mainly on harvested species of caribou, polar bears, and whales. This does not mean that traditional knowledge about birds does not exist or that it is not important. Braund and Associates (2010) note the importance of Thetis Island as a location that subsistence hunters are able to hunt eiders while also conducting seal hunts. A few studies have been conducted in Canada to document traditional knowledge on marine birds, including common eiders (Amauliqruaq), harlequin ducks, ivory gulls, and thick-billed murres (Akpa). In these Canadian studies, Inuit knowledge showed that eider populations in Hudson Bay declined due to changes in sea ice conditions which limited locations of open water for feeding eiders. Having this local knowledge helped scientists discover a problem that would have gone undetected (Gilchrist et al. 2005). In addition, local knowledge and western science was used in a study by Gearheard et al. (2006) comparing the sea ice in the Nunavut (Clyde River) region in Canada with the sea ice in the Barrow region in Alaska and how it affected hunting in those regions. For people in Barrow, changes in the seasonal sea ice patterns affected hunting activities for spring and fall whaling, which may affect seasonal harvest patterns for bird species.

3.2.4 Marine Mammals

3.2.4.1 Marine Mammals

Fifteen marine mammal species occur in the Beaufort and Chukchi seas (Table 3.2-5). All are federally protected under the MMPA. Six species – bowhead whale, humpback whale, fin whale, ringed seal, the Beringia Distinct Population Segment of bearded seal, and polar bear – are listed as either threatened or endangered under the ESA. The Pacific walrus is a candidate species for listing. The remaining species are neither listed nor currently proposed for listing under the ESA. The USFWS has jurisdiction over Pacific walrus and polar bears. The remainder is under the jurisdiction of NMFS.

This section includes information on population status and trends; distribution, migration and habitat use; reproduction and growth; survival; mortality; disease; hearing and other senses; and climate change. Information is derived from peer-reviewed papers, published and unpublished reports, and recent summary documents available for several species of concern, such as stock assessment reports (e.g. Allen and Angliss 2010, 2012a, 2012b) and status reviews (e.g. Boveng et al. 2008, Boveng et al. 2009, Cameron et al. 2010, Garlich-Miller et al. 2011, and Kelly et al. 2010a).

Table 3.2-5 Marine Mammal Species Found in the Beaufort and Chukchi Seas EIS Project Areas

Common Name	Scientific Name	Iñupiaq Name[a]	ESA Status
Cetaceans			
Bowhead whale	*Balaena mysticetus*	Agviq	Endangered
Humpback whale	*Megaptera novaeangliae*		Endangered
Fin whale	*Balaenoptera physalus*		Endangered
Minke whale	*Balaenoptera acutorostrata*		Not listed
Gray whale	*Eschrichtius robustus*	Agviqluaq	Not listed
Beluga whale	*Delphinapterus leucas*	Qixalugaq/Sisuaq	Not listed
Narwhal	*Monodon monoceros*		Not listed
Killer whale	*Orcinus orca*		Not listed
Harbor porpoise	*Phocoena phocoena*	Agviqsuaq	Not listed
Pinnipeds			
Ringed seal	*Phoca hispida*	Natchiq	Threatened
Spotted seal	*Phoca largha*	Qasigiaq	Not listed
Ribbon seal	*Histriophoca fasciata*	Qaigulik	Species of Concern
Bearded seal	*Erignathus barbatus*	Ugruk	Threatened
Pacific walrus	*Odobenus rosmarus divergens*	Aiviq	Candidate
Fissipeds			
Polar Bear	*Ursus maritimus*	Nanuq	Threatened

3.2.4.2 Cetaceans

Bowhead Whale: Western Arctic Stock

Species Description

Bowhead whales are baleen whales of the family Balaenidae. They are large, slow-swimming, rotund whales that lack a dorsal fin and are darkly colored with varying amounts of white on the chin, tail stock, and underside. The amount of white around the tail increases with age. In addition, whales often acquire distinctive scars, observed as white marks on the body, over time, which can be used to identify individuals (Rugh and Shelden 2009). The region by the blowholes (nostrils) is prominent and makes the head appear triangular in profile. Bowheads also have a distinctive neck area, or indentation between the head and back. The bowed shape of the mouth is what earned this whale its name (Rugh and Shelden 2009).

Bowheads can weigh up to 75 to 100 tons (150,000 to 200,000 lbs) and grow to 14 to 18 m (46 to 59 ft) in length, with the head comprising over a third of the body. Bowheads have the longest baleen plates of any whale, reaching lengths up to 4 m (13 ft) (Reeves and Leatherwood 1985). They may also have the largest mouth of any animal. They are well insulated from Arctic waters by blubber that is 5.5 to 28 cm (2.2 to 11 in) thick covered by 2.5 cm (1.0 in) of skin – the thickest blubber and skin combination of any whale (Rugh and Shelden 2009).

Population Status and Trends

The International Whaling Commission (IWC) historically recognized five bowhead whale stocks for management purposes: the Spitsbergen stock; Davis Strait stock; Hudson Bay stock; Okhotsk Sea stock; and the Western Arctic (Bering-Beaufort-Chukchi seas) stock. The current working hypothesis is that the Davis Strait and Hudson Bay bowhead whales comprise a single Eastern Arctic stock. Confirmation of stock structure awaits further scientific analyses (IWC 2011). The Western Arctic stock is the largest remnant population and the only stock within U.S. waters (Allen and Angliss 2011). It is also the only bowhead whale stock that occurs in the EIS project area.

Bowhead whales were severely depleted throughout their range during intense commercial whaling prior to the 20th century. They received international protection from commercial whaling beginning in 1931 (NMFS 2008b). The Western Arctic stock has since recovered substantially.

Systematic ice-based counts to assess abundance of bowhead whales migrating past Barrow during spring began in 1976. Initial estimates were based solely on visual observations. Traditional knowledge of Iñupiat Eskimo whalers pointed out shortcomings in these early counts, such as not accounting for and correcting for whales that continued to migrate under the ice of closed leads or that migrate farther offshore. As a result, an acoustic component was added to the census, allowing for the detection of whales not detectable by visual observers and for the development of correction factors (Huntington 2000). The whalers' traditional knowledge proved accurate and invaluable in advancing the accuracy of census estimates.

The most recent estimate of abundance derived from an ice-based census in 2001 was 10,470 bowhead whales in the Western Arctic stock (George et al. 2004). The estimated annual rate of increase from 1978 to 2001 was 3.4 percent. The 2001 estimate was subsequently revised to 10,545 bowhead whales (Zeh and Punt 2004 cited in Allen and Angliss 2011). Attempts to count bowheads migrating near Point Barrow in 2009 and 2010 were unsuccessful due to sea ice conditions (George et al. 2011). An ice-based count was successful in 2011; the data are currently being analyzed, with a new estimate antipacted by 2013 (Allen and Angliss 2012a, R. Suydam pers. comm 2012b). The population may be approaching carrying capacity despite showing no sign of a slowing in the population growth rate (Brandon and Wade 2006).

Capture-recapture analysis based on aerial photographs of individually identified bowhead whales provided alternative, and comparable, estimates of abundance. Schweder et al. (2009) calculated an estimate for 2001 of 8,250 whales and a yearly growth rate of 3.2 percent. Results based on images from 2003 through 2005 provided an estimated population abundance in 2004 of 12,631 whales, excluding calves (Koski et al. 2010). The abundance estimates calculated from photographic data were consistent with expected abundance and trend estimates from ice-based surveys (Koski et al. 2010).

The Western Arctic stock of bowhead whales remains listed as endangered under the ESA and is considered depleted under the MMPA.

Distribution, Migration and Habitat Use

Historically, Western Arctic bowhead whales are known to be distributed in seasonally ice-covered waters north of 60°N latitude and south of 75°N latitude in the western Arctic Basin (Braham 1984, Moore and Reeves 1993). Recent updates from ADF&G tagged bowhead whale tracking data show a tagged bowhead wintering south of 59°N latitude in the SW Bering Sea (Citta 2013) and tracking data from summer 2012 showed a tagged whale spent an extended period of time near 76 and 78°N latitude in the Chukchi Sea (Citta 2012a). They retain a close association with ice for most of the year. Most migrate annually from wintering areas in the northern Bering Sea, through the Chukchi Sea in the spring to summer in the Beaufort Sea before returning to the Bering Sea in the fall (Allen and Angliss 2010, 2012a) (Figure 3.2.-11). Some animals remain in the eastern Chukchi and western Beaufort seas during the summer (Clarke et al. 2011a, Ireland et al. 2008).

Recent satellite tagging studies provide a more detailed look at winter distribution of bowhead whales. Winter bowhead distribution was generally concentrated around the Bering Shelf north of Navarin Canyon and the 200 m (656 ft) isobath. During the winter of 2008-2009, areas of higher use extended from the Bering Strait through the Anadyr Strait to Navarin Canyon, and in the following winter (2009-2010), their distribution shifted south of St. Lawrence Island from Cape Navarin to St. Matthew Island

(Citta et al. 2012). Two whales migrated into the Chukchi Sea in March of 2009, though most did not begin migrating north into the Chukchi Sea until April (Quakenbush et al. 2010a). Satellite tagged whales (Citta et al. 2011) indicate a much greater use of continuously ice covered habitat in the Northern Bering Sea than previously believed, and the association of wintering bowhead whales with the marginal ice front and the polynyas near St. Matthew and St. Lawrence Islands and the Gulf of Anadyr appears to be not as strong as previously assumed (Moore and Reeves 1993, NMFS 2008b).

The spring migration from April to June follows leads in the sea ice through the Bering Strait to the Chukchi Sea and past Barrow and into the Beaufort Sea (Figure 3.2.-12). Tagged whales began migrating north in early April, passed into the Chukchi Sea by mid-April, on average, and all passed Barrow by May 7, during 2009 and 2010, travelling parallel to and within 40 km (24.8 mi) of the coast (Quakenbush et al. 2012). Once past Barrow, several of the tagged whales traveled directly to the Amundsen Gulf polyna (Quakenbush et al. 2010a) (Figure 3.2-13).

Temporal segregation by size and sex class occurs during the spring migration. The first wave consists of sub-adults, the second of larger whales, and the third is comprised of even larger whales and cows with calves (NMFS 2008b, Rugh 1990, Suydam and George 2004). Yupik whalers of St. Lawrence Island also note that the first to pass by are the smaller whales—*ingutuk* in both Yupik and Iñupiaq, which are rotund yearlings --then the mid-sized whales, followed by the largest whales and the mothers with calves (Noongwook et al. 2007).

Aerial surveys of bowhead whale distribution in the Beaufort Sea during summer-fall are conducted annually by the National Marine Mammal Laboratory (NMML). BWASP surveys were previously flown by the Minerals Management Service (now BOEM). In 2011, an Interagency Agreement between the BOEM and NMML combined BWASP with the Chukchi Offshore Monitoring in Drilling Area survey (COMIDA) under the auspices of a single survey called Aerial Surveys of Arctic Marine Mammals (ASAMM) (Clarke et al. 2012); both studies are funded by BOEM. The most recent survey years (2006 through 2011) were light ice years. Median distance of bowhead whales from shore ranged from as close as 6.6 to 16.9 km (4.1 to 10.5 mi) in 2009 to 34.3 to 39.2 km (21.3 to 24.4 mi) in 2006. The latter was significantly farther from shore than during other light ice years, possibly due to grounded ice near the coastline, locations of prey concentrations, or nearshore shallow hazards work. Median depth of sightings was relatively shallow all years, ranging from 15 to 44 m (49 to 144 ft) (Clarke et al. 2011b, 2011c). Bowhead distribution in 2011 was not noticeably different than that of other low ice years (Clarke et al. 2012). Behaviors included milling, swimming, and feeding, to a lesser degree. Highest numbers of sightings were in the central Beaufort and east of Point Barrow.

During the summer, most of the population is in the southern and eastern Beaufort Sea and Amundsen Gulf although recent tagging studies and aerial surveys indicate summer movements to areas outside the Canadian Beaufort. These include the central Alaskan Beaufort and Barrow, and as far as the northern coast of Chukotka, Russia (Clarke et al. 2012, Quakenbush et al. 2012). In August 2010, one whale traveled north and east from Amundsen Gulf to Viscount Melville Sound, a main route of the Northwest Passage, where it remained for about 10 days. A bowhead whale tagged off West Greenland arrived in the same area a few days after the Western Arctic bowhead departed, suggesting that the Western Arctic and Baffin Bay-Davis Strait stocks could intermingle during summer (Heide-Jørgensen et al. 2011). Bowheads have been noted in the northeastern Chukchi Sea during the summer (Ireland et al. 2008). In June and July 2009, a group of bowhead whales was observed feeding in nearshore waters between Point Franklin and Barrow along the Chukchi Sea coast, although no bowheads were observed there in 2008 or 2010 and few were sighted in the Chukchi Sea in August during surveys in 2008 through 2010 (Clarke et al. 2011a). Four bowheads were seen near Point Franklin in June 2011, but none were observed feeding (Clarke et al. 2012).

In September to mid-October bowheads begin their western migration out of the Canadian Beaufort Sea to the Chukchi Sea (Figure 3.2-15). Most westward travel across the Beaufort Sea by tagged whales was over the shelf, within 100 km (62 mi) of shore, although a few whales traveled farther offshore (Quakenbush et al. 2012).

Bowhead whales feed seasonally in response to food availability and abundance. Feeding occurs in the spring during migration but is not as common as later in the summer and fall when zooplankton abundance peaks. Feeding during the fall migration is most likely a result of whales encountering food resources where they can briefly stop to feed before continuing on past Point Barrow to the Chukchi Sea. Primary prey are copepods and euphausiids (krill). A greater preponderance of euphausiids is eaten in the Bering–Chukchi region, and more copepods are taken in the eastern Beaufort Sea (Lee et al. 2005). Based on visual observations and tagging data, important feeding areas include Amundsen Gulf, near Point Barrow, Wrangel Island, the northern coast of Chukotka, the western Bering Sea, and near Kaktovik (Clarke et al. 2011a, b, c, Koski and Miller 2009, Quakenbush et al. 2010a).

The Barrow area is used as a feeding area during spring and fall. A higher proportion of photographed individuals showed evidence of feeding in fall than in spring (Mocklin 2009). Opportunistic sampling of zooplankton near feeding bowhead whales suggest they were preying on dense swarms of euphausids (*T. raschii*) or copepods (*Pseudocalanus spp.*) (Moore et al. 2000). A bowhead whale feeding "hotspot" (Okkonen et al. 2011) commonly forms on the western Beaufort Sea shelf off Point Barrow in late summer and fall due to a combination of the physical and oceanographic features of Barrow Canyon, combined with favorable wind conditions (Ashjian et al. 2010, Moore et al. 2010, Okkonen et al. 2011). Data suggest that euphausiids were present in lower numbers than in 2009-2010 and that there might be a minimum threshold of abundance below which bowhead whales would not stay to feed (Shelden et al. 2012). The bowhead whale feeding aggregations may, therefore, have not been seen because of lack of prey or because the 2011 migration was late passing through the area, or both (Clarke et al. 2012). However, it is likely that bowhead whales feed annually in September and October between Smith Bay and Point Barrow, usually at depths less than 20 m and/or in Barrow Canyon (J. Clarke, pers. comm. 2013).

The area near Kaktovik appears appears to be one of the areas important to bowhead whales primarily during the fall (NMFS 2010b). BOEM-funded BWASP surveys show areas off Kaktovik as areas that are sometimes of high use by bowhead whales (Clarke et al. 2011b, NMFS 2010b). Data recently compiled by Clarke (2012) further illustrate the frequency of use of the area east of Kaktovik by bowhead mothers and calves during August, September, and October.

Historically, there have been few spring, summer, or autumn observations of bowheads in larger bays such as Camden, Prudhoe, and Harrison Bays, although some groups or individuals have occasionally been observed feeding around the periphery of or, less commonly, inside the bays as migration demands and feeding opportunities permit. Observations indicate that juvenile, sub-adult, and cow-calf pairs of bowheads are the individuals most frequently observed in bays and nearshore areas of the Beaufort, while more competitive whales are found in the Canadian Beaufort and Barrow Canyon, as well as deeper offshore waters (BWASP, ASAMM, BOWFEST, Koski and Miller 2009, Quakenbush et al. 2010). Industry funded aerial surveys of the Camden Bay area west of Kaktovik reported a number of whales feeding in that region in 2007 and 2008 (Christie et al. 2010); however, more recent ASAMM surveys have not noted such behavior in Camden Bay. These mostly recent observations of juvenile/sub-adult/cow-calf bowheads in these areas may also indicate a population that is approaching the carrying capacity of the environment, and less competitive individuals are being pushed to use sub-optimal habitat. While data indicate that bowhead whales might feed almost anywhere in the Alaskan Beaufort Sea within the 50-m isobath, feeding in areas outside of the area noted between Smith Bay and Point Barrow and/or in Barrow Canyon are ephemeral and less predictable (J. Clarke, pers. comm. 2013).

From mid-September to mid-October, bowheads occur in the northeast Chukchi Sea. Tagged whales passed Point Barrow between July 21 and November 2, with a median date of October 10 (Quakenbush et al. 2012). Most of the tagged whales in 2006 through 2010 traveled west from Point Barrow through the

Chukchi Sea between 71˚ and 74˚ N latitude. All but one traveled through the Chukchi Sea 193 Lease Sale area in the northeastern Chukchi Sea at least once (Figure 3.2-15) (Quakenbush et al. 2010b, Quakenbush et al. 2012). Brueggeman et al. (2009, 2010) sighted two and three bowhead whales in October 2008 and October 2009, respectively, on the Burger prospect of this lease sale area. More bowhead whales were sighted during the 2010 Chukchi Sea Environmental Study Program (CSESP) surveys of these lease sale prospects than in the previous two years. Two bowheads were sighted in the Statoil study area in mid-September, and 35 sightings of 52 whales were in the Burger study area and along the Burger to Wainwright transect in early October (Aerts et al. 2011).

The area of highest probability of use by satellite tagged whales in September was concentrated northeast of Point Barrow. The importance of this region as a feeding area is described above. The high probability use area also extended to the east, west and south of the shelf break and 200-m isobath (Quakenbush et al. 2010a). Most tagged whales were crossing the Chukchi Sea in September heading to Wrangel Island and Chukotka (Figure 3.2-14). The Chukchi Sea Lease Sale Area was most commonly used by tagged whales in September. However, the areas with the highest probability of use were in the northeastern section of the Lease Area, not in the area of the leased blocks. Leased blocks contained only two percent of the total probability of use by bowhead whales (Quakenbush et al. 2010a). Bowhead whales increased in the COMIDA survey in September and October 2008 through 2010, with sighting rates highest in October (Clarke et al. 2011a). This was similar to the previously observed distribution during surveys conducted from 1989 through 1991 (Clarke et al. 2011a). This differed in 2011, when there were few bowhead whale sightings, despite excellent survey effort (Clarke et al. 2012).

In October, the area of highest probability of use was northeast of Point Barrow and along the Chukotka coast. In November, highest probability of use was also along the Chukotka coast. By December, use concentrated along the Chukotka coast, from Cape Serdtse-Kamen to the Bering Strait (Quakenbush et al. 2010a).

The fall migratory corridor from Amundsen Gulf back to Barrow was less defined than during the spring migration. Some whales travel closer to shore (within 10-15 miles of the coastline) and some travel farther offshore. The migratory corridor across the Chukchi Sea, from Barrow to Chukotka, was the least defined, with whales crossing the Chukchi Sea between 71˚ and 74˚ N latitude. Some whales crossed farther to the north and some migrated down the Alaskan coast (Quakenbush et al. 2010a). Whales that stay later in the fall near to Barrow have not been observed to migrate to Wrangel Island, as they either cross the Chukchi Sea farther to the south or migrate down the Alaskan coast (Quakenbush et al. 2010a).

On February 22, 2000, NMFS received a petition to designate critical habitat in the nearshore areas from the U.S.-Canada border to Barrow for the Western Arctic stock of bowhead whales. On May 22, 2001, NMFS found the petition to have merit (66 FR 28141), but on August 30, 2002 (67 FR 55767), NMFS announced the decision to not designate critical habitat. NMFS determined that as the population is increasing and nearing its pre-commercial whaling population size, and no known habitat issues are impeding population growth, critical habitat designation was unnecessary (Allen and Angliss 2011, 2012a).

Reproduction and Growth

Bowheads likely mate in late winter or early spring, although mating behavior has been observed at other times of the year. Gestation is about 13 to 14 months, and calves are usually born between April and June, during the spring migration. The calving interval is about three to four years. Juvenile growth is relatively slow. Bowheads reach sexual maturity at about 15 years of age (12 to 14 m [39 to 46 ft] long) (Nerini et al. 1984). Growth for both sexes slows markedly at about 40 to 50 years of age (George et al. 1999).

Survival and Mortality

Bowhead whales are long-lived animals, likely living longer than any other mammals. Based on aspartic racemization of eye lenses, George et al. (1999) calculated ages greater than 150 years. Discoveries of traditional stone, ivory, and metal whale-hunting tools recovered from several harvested whales further corroborated longevity beyond 150 years.

Pelagic commercial whaling was the single greatest historical source of mortality for bowhead whales. The Bering Sea fishery primarily operated from 1848 to 1919. By 1870, 60 percent of the pre-whaling population was estimated to have been taken (Braham 1984). The estimated catch of 18,684 western Arctic bowhead whales by pelagic whalers (Woodby and Botkin 1993) was likely an underestimate due, in part, to under-reporting of Soviet catches (Yablokov 1994). Bowhead whales are an important subsistence resource for Alaska natives (see Section 3.3.2, Subsistence) and have been hunted by Eskimos for at least 2,000 years. Takes are regulated by quotas established under the authority of the IWC and average about 40 to 50 strikes per year (NMFS 2008b).

Incidental mortality or injury from entanglement in commercial fishing gear is known to occur. Scarring attributed to ropes or entanglements have been observed on approximately 10 percent of whales harvested from 1988 to 2008 (Reeves et al. 2012). Stranding reports document entanglements between 2001 and 2005, including a bowhead whale observed near Point Barrow with fishing net and line around the head (Allen and Angliss 2010). A dead bowhead whale found floating in Kotzebue Sound in July 2010 was entangled in crab pot gear similar to that used in the Bering Sea crab fishery. The entanglement through the mouth and around the tail stock may have been the cause of death (Suydam et al. 2011a).

Incidence of injury caused by vessel collisions appears to be low. Two to three percent of harvested whales examined between 1988 and 2007 had ship or propeller injuries (Reeves et al. 2012). The low incidence of observed injury or scarring could be due to either collisions resulting in death (and not accounted for) or a low incidence of co-occurrence of ships and bowhead whales (George et al. 1994).

Little is known about naturally occurring diseases, parasites, or other sources of natural mortality in bowhead whales. Periodic ice entrapment and predation by killer whales have been documented in most bowhead whale stocks (Nerini et al. 1984). The frequency of killer whale attacks is unknown, although a small percent (4 to 8 percent) of bowheads examined had scars indicative of killer whale attacks (George et al. 1994, NMFS 2008b).

Hearing and Other Senses

Bowhead whales are grouped among low frequency functional hearing baleen whales (Southall et al. 2007). Inferring from their vocalizations, bowhead whales should be most sensitive to frequencies between 20 Hz - 5 kHz, with maximum sensitivity between 100-500 Hz (Erbe 2002). Vocalization bandwidths vary. Whalers on St. Lawrence Island noticed that bowheads are sensitive to noise when traveling alone or in small groups, so they use sails to power their boats when hunting bowheads (Noongwook et al. 2007). Barrow whalers hunting bowheads in ice leads in the spring use umiaqs made of bearded seal skin and paddle silently so as not to scare the whales; aluminum boats produce too much noise (Rexford 1997).

Bowhead whales produce a broad repertoire of sounds. Bowhead calls have been distinguished by Würsing and Clark (1993): pulsed tonal calls, pulsive calls, high frequency calls, low-frequency FM calls (upsweeps, inflected, downsweeps, and constant frequency calls). However, no direct link between specific bowhead activities and call types was found. Bowhead whales have been noted to produce a series of repeating units of sounds up to 5000 Hz that are classified as songs, produced primarily by males on the breeding grounds (Delarue et al. 2011). Tonal FM modulated vocalizations have a bandwidth of 25 to 1200 Hz with the dominant range between 100 and 400 Hz and lasting 0.4- 3.8 seconds. Bowhead whale songs have a bandwidth of 20 to 5000 Hz with the dominant frequency at approximately 500 Hz and duration lasting from 1 minute to hours. Pulsive vocalizations range between 25 and 3500 Hz and last

0.3 to 7.2 seconds (Clark and Johnson 1984, Würsig and Clark 1993; Cummings and Holliday 1987 in Erbe 2002).

Bowhead whales appear to have good lateral vision. Recognizing this, whalers approach bowheads from the front or from behind, rather than from the side (Noongwook et al. 2007). In addition, whalers wear white parkas on the ice so that they are not visible to the whales when they surface (Rexford 1997).

Olfaction may also be important to bowhead whales. Recent research on the olfactory bulb and olfactory receptor genes suggest that bowheads not only have a sense of smell but one better developed than in humans (Thewissen et al. 2011). The authors suggest that bowheads may use their sense of smell to find dense aggregations of krill upon which to prey.

Humpback Whale

Species Description

Humpback whales are medium sized baleen whales, reaching lengths of 16 to 17 m (52.5 to 55.8 ft) (Clapham and Mead 1999). They are easily recognized at close range by their extremely long flippers, which may be one-third the length of the body. The flippers are white on the bottom and may be white or black on top, depending on the population. The body is black on top with variable coloration ventrally and on the sides. The head and jaws have numerous knobs which are diagnostic for the species. The dorsal fin is small and variable in shape. The underside of the tail exhibits a unique pattern of white to black that is individually identifiable (Clapham 2009).

Population Status and Trends

The three stocks of humpback whales in the North Pacific are: 1) the California/Oregon/Washington and Mexico stock, which migrates seasonally between coastal Central America and Mexico and the coast of California to southern British Columbia in summer/fall; 2) the Central North Pacific stock, that migrates between the Hawaiian Islands and northern British Columbia/Southeast Alaska, the Gulf of Alaska, and the Bering Sea/Aleutian Islands; and 3) the Western North Pacific stock, that migrates between Asia and Russia and the Bering Sea/Aleutian Islands (Allen and Angliss 2010, 2012a).

It is uncertain as to whether the individuals that venture into the Chukchi Sea are from the Central or Western North Pacific stock or both. The Western North Pacific stock may be the more likely of the two, given the known geographic range. Population estimates are provided for both stocks.

The most recent estimates derive from a large-scale study of humpback whales throughout the North Pacific conducted in 2004 through 2006 (Structure of Populations, Levels of Abundance, and Status of Humpbacks [SPLASH]). The abundance estimate for the entire North Pacific was 19,594 (Calambokidis et al. 2008). However, Barlow et al. (2011) revised the estimate based on capture-recapture methods using over 18,000 fluke identification photographs collected in 2004-2006. Their best estimation of abundance was 21,808. After using simulation models to estimate biases, Barlow et al. (2011) derived a best estimate of abundance of 21,063. Barlow et al. (2011) states, "Results confirm that the overall humpback whale population in the North Pacific has continued to increase and is now greater than some prior estimates of pre-whaling abundance."

Initial abundance estimates for the Kamchatka feeding ground area of the Western North Pacific stock in Russia ranged from about 100 to 700 individuals. Estimates for the other areas in Russia, the Gulf of Anadyr and the Commander Islands were included in the estimate of abundance of 6,000 to 14,000 for the Bering Sea and Aleutian Islands (Calambokidis et al. 2008). Point estimates of abundance for Asia were 938 to 1,107 individuals (Calambokidis et al. 2008). Trend data were unreliable for this stock (Allen and Angliss 2010). The estimated abundance for the Aleutian Islands, Bering Sea, and Gulf of Alaska combined ranged from 6,000 to 19,000 (Allen and Angliss 2010, 2012a).

The humpback whale is listed as endangered under the ESA and designated as depleted under the MMPA.

Distribution, Migration and Habitat Use

Humpback whales occur in all oceans of the world from the tropics to sub-polar regions (Perry et al. 1999). They undertake extensive seasonal migrations between low-latitude breeding and calving areas and high latitude feeding grounds (Perry et al. 1999). The summer feeding range of humpback whales in the North Pacific includes coastal and inland waters of California, the Gulf of Alaska, and Bering Sea, along the Aleutian Islands to the Kamchatka Peninsula and into the Sea of Okhotsk, and north of the Bering Strait. Wintering areas include Japan, the Phillipines, Hawaii, Mexico, and Central America (Allen and Angliss 2010, 2012a, Calambokidis et al. 2008).

Data from the SPLASH study suggests Russia is the migratory destination for whales breeding in Okinawa and the Philippines, although some Asian whales go to Ogasawara, the Aleutian Islands, Bering Sea, and Gulf of Alaska (Calambokidis et al. 2008).

Humpback whales photographed in Russia during SPLASH occurred along the Kamchatka Peninsula, near the Commander Islands between Kamchatka and the Aleutians Islands, and in the Gulf of Anadyr just southwest of the Bering Strait. Historical whaling data indicate catches of humpback whales were taken in the Bering Strait and Chukchi Sea from August through October (Allen and Angliss 2010).

Humpback whales have recently been observed in the Alaskan Beaufort and Chukchi seas. Historically (1930s-1960s), sightings were made by the Russian whaling flotilla and during studies from 1990-1996 in Chukchi Sea waters off the Russian Chukchi Peninsula (Melnikov 1999). In August 2007, a mother-calf pair was sighted from a barge approximately 87 km (54.1 mi) east of Barrow in the Beaufort Sea (Hashagen et al. 2009). Additionally, Ireland et al. (2008) reported three humpback sightings in 2007 and one in 2008 during surveys of the eastern Chukchi Sea. A single humpback was observed between Icy Cape and Wainwright feeding near a group of gray whales during aerial surveys of the northeastern Chukchi Sea in July 2009 as part of COMIDA (Clarke et al. 2011a). This may be a recent phenomenon as no humpback whales were sighted during the previous COMIDA surveys in the Chukchi Sea from 1982 through 1991 (Clarke et al. 2011a). Additional sightings of four humpback whales occurred in 2009 south of Point Hope, while transiting to Nome (Brueggeman 2010). Aerts et al. (2011) observed one humpback whale during the Nome transit in 2010. The COMIDA surveys conducted in 2012 observed 29 humpback whales on five different flight days with 24 of these observed during one flight on September 11 near Point Hope. The majority of observations were of single humpbacks; there were also five groups of two individuals and one group of four individuals. There were four recorded feeding events, three of which were observed on September 11 (Sims et al. 2013). Additionally, a number of humpback whales were observed by the ongoing Arctic Whale Ecology Study (ARCWEST) and ASAAM, as well as during other research cruise and monitoring efforts, during the 2012 open water season.

Humpback whales feed on euphausiids (krill) and various schooling fishes, including herring, capelin, sand lance, and mackerel (Krieger and Wing 1986, Nemoto 1957, 1959, Witteveen et al. 2008). They are considered “lunge feeders” that predate dense prey patches by engulfing the patch and distending the ventral grooves of the throat area. They also blow nets, or curtains, of bubbles around or below prey patches to concentrate the prey in one area, and then lunge with mouths open through the middle (Clapham 2009).

Reproduction and Growth

Humpbacks give birth and presumably mate on low-latitude wintering grounds in January to March in the Northern Hemisphere. Females attain sexual maturity at 5 years in some populations and exhibit a mean calving interval of approximately two years (Barlow and Clapham 1997, Clapham 1992). Gestation is about 12 months, and calves probably are weaned by the end of their first year (Perry et al. 1999).

Survival and Mortality

The greatest source of mortality of humpback whales was commercial whaling. An estimated 28,000 humpbacks were reportedly removed from the North Pacific during the 20th century (Rice 1978 cited in Allen and Angliss 2010). Reported catches in Asia totaled 3,277 whales from 1910 to 1964. Humpback whales were, ostensibly, awarded international protection from whaling in the North Pacific starting in 1965, but illegal takes by the Soviet Union continued until 1972 (Ivashchenko et al. 2007). The Soviet Union illegally killed 6,793 humpback whales between 1961 and 1971, many of which were taken from the Gulf of Alaska and Bering Sea (Doroshenko 2000 cited in Allen and Angliss 2010).

Subsistence hunters in Alaska reportedly took one humpback whale in South Norton Sound in 2006. This whale was in the process of stranding when taken, so was not included in the average annual mortality rate from subsistence takes for 2005-2010 (Allen and Angliss 2012a). There are no other reports of subsistence takes from the Western North Pacific stock. Subsistence hunters in Alaska are not authorized to take whales from the Central North Pacific stock, and none have been reported (Allen and Angliss 2010, 2012a).

Mortality or injury due to interactions with commercial fisheries is possible. Incidental mortality of one Western North Pacific humpback whale was reported in the Bering Sea/Aleutian Islands flatfish trawl fishery and one was reported in the Bering Sea/Aleutian Islands pollock trawl fishery between 2007 and 2010. The estimated annual mortality rate incidental to US commerical fisheries was calculated as 0.62 humpbacks from this stock. The estimated fishery-related minimum mortality and serious injury rate incidental to commercial fisheries for the northern part of the central North Pacific stock is 1.0 humpback whales per year (Allen and Angliss 2012a).

Natural sources of mortality include predation by killer whales and paralytic shellfish poisoning. The latter was a highly unusual event wherein 14 humpbacks died during a two month period in the vicinity of Cape Cod, Massachusetts (Geraci et al. 1990, NMFS 1991).

Hearing and Other Senses

Humpback whales are in the low-frequency functional hearing group, with an estimated auditory bandwidth of 7 Hz to 22 kHz (Southall et al. 2007). However, Au et al. (2006) note humpback whale songs having harmonics that extend beyond 24 kHz. In summary, humpback whales produce at least three classes of vocalizations: (1) Complex songs with components ranging from at least 20 Hz–5 kHz with estimated source levels from 144– 174 dB; these are mostly sung by males on the breeding grounds (Winn et al. 1970; Richardson et al. 1995; Frazer and Mercado 2000; Au et al. 2000, 2006); (2) Social sounds in the breeding areas that extend from 50Hz – more than 10 kHz with most energy below 3kHz (Tyack and Whitehead 1983, Richardson et al. 1995); and (3) Feeding area vocalizations that are less frequent, but tend to be 20 Hz–2 kHz with estimated sources levels in excess of 175 dB re 1 Pa at 1m (Thompson et al. 1986; Richardson et al. 1995).

<u>Fin Whale: Northeast Pacific Stock</u>

Species Description

Fin whales are baleen whales of the family Balaenopteridae. They are the second largest whale in the world reaching lengths of about 22 m (72 ft) in the northern hemisphere (Aguilar 2009). Females are larger than males (Gambell 1985). Fin whales are slender, with a narrow rostrum and prominent falcate dorsal fin. The pigmentation is uniquely asymmetrical. The right lower jaw and right side baleen plates are white to yellow-white, while the corresponding left side is dark gray, as are the upper body, flippers and flukes. They are considered “gulp” feeders and have a series of ventral groves that expand during feeding, enabling the whale to engulf large quantities of water and prey (Aguilar 2009).

Population Status and Trends

The IWC recognizes one stock of fin whales in the North Pacific, but NMFS recognizes three stocks in U.S. Pacific waters for management purposes: Alaska (Northeast Pacific); California/ Oregon/Washington; and Hawaii (NMFS 2010b, Allen and Angliss 2010, 2012a). The Northeast Pacific stock is the only one that may occur in the EIS project area.

There are currently no reliable estimates of abundance for the entire Northeast Pacific stock of fin whales. Surveys in the Bering Sea and coastal waters from southcentral Alaska to the central Aleutian Islands provide the only data from which estimates could be derived. The estimate of 5,700 whales is considered a minimum for this stock, since surveys only covered a small part of the range (Allen and Angliss 2010). Zerbini et al. (2006) estimated an annual rate of increase of 4.8 percent from 1987 through 2003 for fin whales in coastal waters south of the Alaska Peninsula.

For fin whales, the pre-commercial whaling population for the entire North Pacific was estimated to be 42,000 to 45,000, with the "American population" east of 180° W longitude estimated as 25,000 to 27,000 whales (Ohsumi and Wada 1974). By the early 1970s, there may have been as few as 8,000 to 11,000 remaining in the eastern North Pacific (Ohsumi and Wada 1974).

The fin whale is listed as endangered under the ESA and as depleted under the MMPA.

Distribution, Migration and Habitat Use

Fin whales occur throughout the North Pacific from Central Baja California to the Chukchi Sea (Mizroch et al. 2009, Nasu 1974, Rice 1974). Occurrence in Alaskan waters in summer and fall has been documented primarily in the Gulf of Alaska and Bering Sea (Mizroch et al. 2009). There are no reports of fin whales in the Beaufort Sea. In 2010, fin whales were among the species commonly detected acoustically in the Chukchi Sea during August and September (Crance et al. 2011, Hannay et al. 2011). Visual observations are rare. One fin whale was observed north of Cape Lisburne during COMIDA aerial surveys in July 2008 (Clarke et al. 2011a). Also in 2008, there were two sightings of four fin whales recorded by Marine Mammal Observers during Chukchi Sea seismic surveys (Funk et al. 2010). Observations made during the 2012 ASAAM surveys in the Chukchi Sea observed a total of five fin whales (including two calves) on September 11. Three individuals were observed lunge feeding (Sims et al. 2013).

Little is known of their migratory movements. There is evidence of fin whales year-round in high latitude regions, and they may occur at several different latitudes during any one season (Mizroch et al. 2009, NMFS 2010b, Stafford et al. 2007a). In the northern North Pacific and Bering Sea, fin whales generally occur along frontal zones or mixing zones, corresponding with the 200 m (656 ft) isobath (Nasu 1974).

In general, fin whales in the North Pacific prey on euphausiids (krill) and large copepods, as well as schooling fish such as herring, walleye pollock, and capelin (Nemoto 1970, Kawamura 1982).

Reproduction and Growth

Age at sexual maturity is between 5 and 15 years (Perry et al. 1999). Mating and calving occur primarily during winter (November to March, with a peak in December to January). Gestation is probably less than a year. Calves nurse for six to seven months, and the average calving interval is two to three years (Agler et al. 1993).

Survival and Mortality

Fin whales were heavily targeted by 20th century commercial whaling operations. More than 47,000 fin whales were reported killed throughout the North Pacific between 1925 and 1975 (unpublished IWC data cited in Allen and Angliss 2010). Commercial whaling for fin whales in the North Pacific ended in 1976. There is no subsistence whaling for fin whales in U.S. waters, and there are no reports of other direct human caused injury or mortality to fin whales in Alaska waters (Allen and Angliss 2010, 2012a).

Fin whales may, occasionally, be injured or killed incidental to commercial fishery operations. The incidence of occurrence is low in Alaska waters. One fin whale was reported incidentally killed in the Bering Sea/Aleutian Islands pollock trawl fishery between 2002 and 2006 (Allen and Angliss 2010, 2012a). There were no observed mortalities incidental to commercial fisheries in Alaska between 2007 and 2010 (Allen and Angliss 2012a). Ship strikes have, however, resulted in fin whale mortalities in Alaskan waters, with three reported between 2006 and 2010 (Allen and Angliss 2012a).

Causes of natural mortality are not well known. The rate of natural mortality for adult fin whales is estimated as 4 to 6 percent (Perry et al. 1999).

Hearing and Other Senses

Fin whales are in the low-frequency functional hearing group, with an estimated auditory range of 7 Hz to 22 kHz (Southall et al. 2007). Fin whales produce a variety of low-frequency sounds in the 10-200 Hz band (Watkins 1981; Watkins et al. 1987; Edds 1988; Thompson et al. 1992). The most typical signals are long, patterned sequences of short duration (0.5-2s) infrasonic pulses in the 18-35 Hz range (Patterson and Hamilton 1964). Estimated source levels for fin whales are 140-200decibels (dB) re 1 µPa m (Patterson and Hamilton 1964; Watkins et al. 1987; Thompson et al. 1992; McDonald et al. 1995; Clark and Gagnon 2004).

Minke Whale: Alaska Stock

Species Description

The minke whale is in the family Balaenopteridae and is the second smallest baleen whale in the world. Females, at 8.5 m (27.9 ft), are somewhat larger than males at 7.9 m (25.9 ft) (Perrin and Brownell 2009). Minkes weigh about 10 tons. The body is dark gray to brownish above and white to cream colored below. The flipper has a distinctive white patch and the dorsal fin is relatively tall and falcate. The rostrum is very narrow and pointed (thus the species name *acutorostrata*) (Perrin and Brownell 2009).

Population Status and Trends

Minke whales are widely distributed in all oceans with three recognized subspecies: in the North Atlantic (*B. a. acutorostrata*); in the southern hemisphere (*B. a. bonaerensis*); and in the North Pacific (*B. a. scammoni*) (Rice 1998). The two stocks of North Pacific minke whales recognized in U.S. waters are the Alaska Stock and the California/Washington/Oregon stock (Allen and Angliss 2010, 2012a).

There are no abundance estimates for minke whales in the entire North Pacific, or for the Alaska stock. Provisional estimates exist for minke whales in the central-eastern (810) and southeastern (1,003) Bering Sea (Moore et al. 2002). These numbers include only a portion of the stock's range, so could not be extrapolated out to the entire stock. There are no data on abundance trends in Alaska waters (Allen and Angliss 2012b). There will be some level of incomplete information on population status of minke whales in Alaska waters. However, sufficient information is available to support sound scientific judgments and reasoned managerial decisions. More accurate counts are not essential for a reasoned choice among alternatives. Furthermore, the missing information pertains to impacts that are common to all alternatives, limiting the utility of this information to the decision maker.

Minke whales are not listed as depleted under the MMPA or listed as threatened or endangered under the ESA.

Distribution, Migration and Habitat Use

Minke whales are common and the most numerous baleen whales found throughout the world. In the Northeast Pacific Ocean, minke whales range from the Chukchi Sea south to Baja California (Perrin and Brownell 2009). Until recently, there were only a few documented sightings of minke whales in the Chukchi Sea during summer (Ireland et al. 2008). Ship-based surveys of the Klondike and Burger areas of the northeastern Chukchi Sea sighted one and two minke whales in 2008 and 2009, respectively

(Brueggeman 2009, 2010). Fourteen sightings of 16 minke whales were documented during Joint Monitoring Program ship-based surveys in the Chukchi Sea, 2006 through 2008, with 3 in 2006, 3 in 2007, and 8 sightings in 2008 (Funk et al. 2010). Minke whales were not sighted during aerial surveys of the northeastern Chukchi Sea study area in 2008-2010, but in 2011, there were five sightings of six minkes (plus an additional four sightings of probable minke whales) from July to September during ASAMM surveys. One minke whale seen during September at 71.89°N, 163°W (approximately 180 km [112 mi] northwest of Wainwright) is thought to be the farthest north confirmed sighting of a minke whale in the northeastern Chukchi Sea (Clarke et al. 2012). A total of seven minke whales were observed during four separate ASAMM surveys in July, August, and September of 2012 in the Chukchi Sea. Sightings of minke whales are becoming more common in the eastern Chukchi Sea, especially south of Point Lay (Clarke et al. 2012). Roseneau (2010) indicates minke whales started occurring in the waters off Cape Lisburne in the mid-1990s and observed one to three individuals each summer through 2009. They are rare in the Beaufort Sea, with only one observation in 2007 during vessel surveys in the region (Funk et al. 2010).

Minke whales in the North Pacific typically consume euphausiids, anchovies, Pacific saury, walleye pollock, small fish, and squid (Perrin and Brownell 2009).

Reproduction and Growth

Little is known of the natural history of minke whales. They presumably breed in winter in warm, low latitude waters, give birth to a single calf every other year, and reach sexual maturity when 7 to 9 m (23 to 30 ft) long (Perrin and Brownell 2009).

Survival and Mortality

Minke whales were never targeted by the modern shore-based whale fishery in the eastern North Pacific (Rice 1974). Subsistence takes by Alaska Natives are rare, but have occurred, with seven minke whales reported taken for subsistence between 1930 and 1987 (C. Allison, International Whaling Commission, United Kingdom, pers. comm. cited in Allen and Angliss 2010).

Incidental mortality in commercial fisheries is known to occur at a low level. There was one mortality of a minke whale reported in the Bering Sea/Aleutian Islands groundfish trawl fishery in 2000 (Allen and Angliss 2010). The total estimated mortality and serious injury due to interactions with U.S. commercial fisheries was zero for 2006 to 2010 (Allen and Angliss 2012a).

Minke whales are preyed upon by killer whales (Perrin and Brownell 2009). Roseneau (2010) observed an adult minke killed and eaten by a pod of five male killer whales just north of Cape Lisburne in 1997.

Hearing and Other Senses

Minke whales are in the low-frequency functional hearing group with an estimated auditory bandwidth of 7 Hz to 22 kHz (Southall et al. 2007). Minke whales produce a variety of calls ranging from 60 Hz to 20 kHz (DoN 2011). Common sounds include clicks, tonals, and FM signals that range in frequency from 80 to 800 Hz. North Pacific minke whales were recently discovered to be the source of the "boing" sound that has been recorded since the 1950s (Frankel 2009, Rankin and Barlow 2005).

Gray Whale: Eastern North Pacific Stock

Species Description

The gray whale is a robust, slow-moving baleen whale recognized by a mottled gray color with numerous light patches scattered along the body and lack of a dorsal fin (Jones and Swartz 2009). They have more external parasites than other cetaceans (Jones and Swartz 2009). Instead of a dorsal fin, they have a low hump, followed by a series of 10 or 12 knobs along the dorsal ridge of the tail. Adults are 10 to 15 m (33 to 49 ft) long and weigh between 16 and 45 tons (Jones and Swartz 2009).

Population Status and Trends

There are two populations of gray whales in the North Pacific. The eastern North Pacific population migrates along the coasts of eastern Siberia, North America, and Mexico (Allen and Angliss 2010, Weller et al. 2002). The western North Pacific population migrates primarily between the South China Sea and the Okhotsk Sea. Some members of the western North Pacific stock may occasionally migrate to the eastern Pacific. A 13 year old male from the western population satellite-tagged off Sakhalin Island, Russia in 2010 departed Russia in mid-December, traveled across the Okhotsk Sea, the Bering Sea and Gulf of Alaska to the coast of Oregon by early February 2011. The last location overlapped in time and space with the end of the typical eastern North Pacific population's southbound migration. Photo-identification and genetics studies revealed that this individual and others from the western population were previously identified off southern Vancouver Island, British Columbia, Canada and Laguna San Ignacio, Mexico in the eastern North Pacific (Mate et al. 2011, Weller et al. 2012). A gray whale tagged by ADF&G in 2012 moved from the nearshore Chukchi Sea between Barrow and Wainwright to the vicinity of Khatyrka, Russia (approximately 62º N., 176º E.) when the tag stopped transmitting (Citta 2012b). The eastern North Pacific stock, however, is the only one considered in this EIS.

The eastern North Pacific gray whale population has been increasing over the past several decades. Abundance estimates from southbound migration population surveys reached a high of 21,135 whales in 1997/98 (Laake et al. 2009). The most recent population estimates were 16,369 in 2000/01, 16,033 in 2001/02, and 19,126 in 2006/07 (Laake et al. 2009). The lower estimates in 2000 to 2002 were likely related to high levels of mortality during an unusual mortality event in 1999 and 2000 (Rugh et al. 2005). An unusually high number of gray whales, 60 percent of which were adults, stranded along the west coast of North America. Many were emaciated, suggesting that starvation was a contributing factor. This was considered a short-term, acute event from which the population appears to have rebounded (Allen and Angliss 2012a). Buckland and Breiwick (2002) estimated a population increase of 2.5 percent per year between 1967/68 and 1995/96. Rugh et al. (2005) incorporated the more recent survey data to estimate a 1.9 percent rate of increase from 1967/68 through 2001/02.

These abundance trends are consistent with a population approaching carrying capacity (Allen and Angliss 2010, 2012a), which Wade and Perryman (2002) calculated as 19,830 to 28,740 whales for the eastern North Pacific stock. Abundance estimates will likely rise and fall in the future as the population finds a balance with the carrying-capacity of the environment (Rugh et al. 2005).

The steadily increasing population abundance warranted delisting of the eastern North Pacific gray whale stock in 1994, as it was no longer considered endangered or threatened under the ESA (Rugh et al. 1999). A five-year status review determined that the stock was neither in danger of extinction nor likely to become endangered in the foreseeable future, thus, retaining the non-threatened classification (Rugh et al. 1999).

Distribution, Migration and Habitat Use

The gray whale migration may be the longest of any mammalian species. They migrate over 8,000 to 10,000 km (5,000 to 6,200 mi) between breeding lagoons in Mexico and Arctic feeding areas each spring and fall (Rugh et al. 1999). The southward migration out of the Chukchi Sea generally begins during October and November, passing through Unimak Pass in November and December, then continues along a coastal route to Baja California (Rice et al. 1984). The northward migration usually begins in mid-February and continues through May (Rice et al. 1984).

The summer feeding range for eastern North Pacific gray whales extends from California to the high-latitude waters of the Arctic. Most feed in the northern and western Bering and Chukchi Seas (Figure 3.2-17). Feeding also occurs near Kodiak Island, Southeast Alaska, British Columbia, Washington, Oregon, and California (Calambokidis et al. 2002, Darling 1984, Moore et al. 2007, Nerini 1984, Rice and Wolman 1971, Rice et al. 1984). Those remaining throughout the summer and fall along the

Canadian/Washington/Oregon coast are known as the Pacific Coast Feeding Aggregation (Allen and Angliss 2010, 2012a).

Sightings of gray whales in the Beaufort Sea near Point Barrow increased in recent years. Native hunters observed growing numbers of gray whales during late summer and autumn (Moore et al. 2006). Gray whales were observed in all survey months and years (2008 through 2011) during COMIDA and ASAMM aerial surveys of the northeastern Chukchi Sea (Clarke et al. 2011a, 2012). They were consistently observed within 50 km (31.1 mi) of shore between Wainwright and Barrow. (Clarke et al. 2011a, 2012). Most were feeding. Low numbers of gray whales were dispersed throughout the survey area beyond 50 km (31.1 mi) of shore; there was little indication they were feeding. In 2011, gray whales were seen very close to shore from east of Cape Lisburne to south of Point Hope, where they regularly occurred in the 1980s to early 1990s, but not during 2008 to 2010. Also, unlike previous years, few gray whales were seen offshore west of Point Hope in 2011, while they were observed 50 to 100 km (31 to 60 mi) offshore between Point Franklin and Icy Cape (Clarke et al. 2012). Similar to 2008 to 2010, gray whales were absent from Hanna Shoal during all survey months in 2011. This differed markedly from surveys of 1982 through 1991 when gray whales frequented Hanna Shoal (Clarke et al. 2011a, 2012). Gray whales were regularly feeding in the vicinity of Barrow during 2006-2007 fall BWASP aerial surveys of the Beaufort Sea coast. Only two were seen in 2008, and none were seen in 2009 (Clarke et al. 2011b, 2011c). In 2011, there were no sightings of gray whales east of Point Barrow during ASAMM aerial surveys (Clarke et al. 2012). Throughout the summers of 2010 and 2011, gray whales regularly occurred in small groups north of Point Barrow and west of Barrow (George et al. 2011, Shelden et al. 2012). Calls recorded by moored autonomous acoustic recorders northeast of Barrow throughout the winter of 2003/2004 provide evidence of gray whales overwintering in the Beaufort Sea (Stafford et al. 2007b). Increasing population size and habitat changes associated with decreased sea ice may be contributing to the northward shift in distribution.

Gray whales are the most coastal of all the large whales and inhabit primarily inshore or shallow, offshore continental shelf waters (Jones and Swartz 2009). They prefer shoal areas (<60 m [197 ft] deep) with low (<7 percent) ice cover (Moore and DeMaster 1997). These areas provide habitat rich in gray whale prey. Gray whales are suction-feeders and prey upon a variety of benthic amphipods, decapods, and other invertebrates in the Bering and Chukchi Seas. Ampeliscid amphipods were the predominant prey targeted in Chirikov Basin in the northern Bering Sea (Moore et al. 2003). There are indications that this resource was being stressed by overgrazing and that gray whales may be expanding their summer range in search of alternative feeding grounds (Rugh et al. 1999).

Reproduction and Growth

Female gray whales usually breed once every two years. The breeding season is limited primarily to a three-week period in late November and early December during the southbound migration (Jones and Swartz 2009). Gestation lasts approximately 13.5 months (Rice et al. 1984), with an estimated median calving date of January 13 (Perryman and Lynn 2002). Weaning occurs approximately seven months later on the feeding grounds (Rice et al. 1984).

Calf production indices (calf estimate/total population estimate) fluctuated broadly between 1994 and 2000, from a high of 5.8 percent in 1997 to a low of 1.1 percent in 2000. These fluctuations positively correlated with how long the primary feeding area was free of seasonal ice during the previous year (Perryman et al. 2002). More calves were observed during the 2012 ASAMM surveys than anytime since 1979 (Bower et al. 2013).

Survival and Mortality

Gray whales suffered heavy exploitation through commercial whaling in the 19th and early 20th centuries, resulting in a dwindled population of only a few thousand whales. Protection from commercial whaling began in 1937 (Rugh et al. 2005). As described above, the population now appears fully recovered.

Current sources of human-caused mortality and serious injury include commercial fisheries, subsistence harvest, and ship strikes. An estimated minimum 3.3 gray whales died annually from interactions with commercial fishing gear between 2003 and 2007 (Allen and Angliss 2012b). From 2005 to 2009, stranding data indicate a minimum annual mean of 2.4 gray whale mortalities resulting from interactions with commercial fishing gear. This includes the entire U.S. west coast from California to Alaska and is a minimum estimate due to lack of observer coverage for most Alaska gillnet fisheries known to interact with gray whales (Allen and Angliss 2012b).

Russian and Alaskan subsistence hunters traditionally harvested whales from this stock. Most are taken by Russian hunters. Alaska Natives reportedly took two gray whales in 1995 (IWC 1997). In 1997, the IWC approved a five-year quota (1998 through 2002) of 620 gray whales, with an annual limit of 140 whales. The U.S. and Russia share the quota, with an average annual allowable take of 120 whales by the Russian Chukotka people and four whales by the Makah Indian Tribe of Washington State (U.S.) (IWC 1998). The annual subsistence take averaged 121 whales from 2003 to 2007; all were taken in Russia (Allen and Angliss 2012b).

The coastal habitat use and migrations of gray whales leaves them vulnerable to ship strikes, although this is not currently a major source of mortality. In 1997, one fatal ship strike of a gray whale was reported in Alaska (B. Fadely, AFSC-NMML, pers. comm., cited in Allen and Angliss 2010).

Predation by killer whales has been well documented and is the primary natural, non-human cause of mortality in gray whales (Rice et al. 1984). Iñupiat Eskimo hunters have observed killer whale attacks on gray whales off Point Hope and between Point Franklin and Barrow. In addition, several young gray whales stranded along the Chukchi Sea coast have had injuries indicative of killer whale attacks (George and Suydam 1998). Weller et al. (2002) observed that at least 1/3 of identified western gray whales bore killer whale tooth rake marks on their bodies.

Hearing and Other Senses

Gray whales are in the low-frequency cetacean functional hearing group, with an estimated auditory bandwidth of 7 Hz to 22 kHz (Southall et al. 2007). Gray whales produce broadband signals ranging from 100 Hz to 4 kHz (and up to 12 kHz). The most common sounds on the breeding and feeding grounds are knocks, which are broadband pulses from about 100 Hz to 2 kHz and most energy at 327 to 825 Hz. The source level for knocks is approximately 142 dB re 1 μPa-m (Jones and Swartz 2009, Richardson et al. 1995).

Beluga Whale: Beaufort Sea and Eastern Chukchi Sea Stocks

Species Description

The beluga whale is a toothed whale of the family Monodontidae. The white coloring and lack of dorsal fin are two distinguishing characteristics for which the scientific name derives ("…apterus" means without a fin and "leucas," from the Greek leukos, means white). Unlike other toothed whales, beluga neck vertebrae do not fuse, allowing for flexibility of the head and neck (O'Corry-Crowe 2009). They are medium sized, growing to 3.5 to 4.5 m (11 to 15 ft) in length and weigh up to 1,500 kg (3,307 lbs) (Burns and Seaman 1986). Calves are dark gray when born and grow progressively lighter with age, until they are pure white at about age 14 for females and 18 for males (O'Corry-Crowe 2009). In northwest Alaska, age at which animals become all white is highly variable. For males, it ranged from 9 to 38 years and from 6 to 33 years for females (Burns and Seaman 1986).

Population Status and Trends

There are five stocks of beluga whales recognized in U.S. waters: Cook Inlet; Bristol Bay; eastern Bering Sea; eastern Chukchi Sea; and Beaufort Sea (Allen and Angliss 2010, 2012a). The latter two are of interest here, as both of these stocks are likely to occur in the EIS project area.

Opportunistic and systematic observations have been used to estimate abundance for belugas off northern Alaska and western Canada. Based on the most recent aerial surveys in 1992 (Harwood et al. 1996) and correction factors to account for availability bias, the best available abundance estimate for the Beaufort Sea stock is 39,258 (Allen and Angliss 2010, 2012a). Telemetry data from 1993 and 1995 showed belugas ranging well beyond the aerial survey area, suggesting the 1992 abundance may have been greatly underestimated (Richard et al. 2001).

Survey data are also outdated for the eastern Chukchi stock. It was not possible to estimate abundance from the most recent survey in 1998, but, in 2012, efforts to estimate abundance of this stock took place. Data are currently being analyzed. The most reliable estimate continues to be 3,710 whales derived from 1989-91 survey counts corrected for animals diving and not visible at the surface and for newborns and yearlings missed due to their small size and dark coloring. There is currently no evidence that the eastern Chukchi Sea stock of beluga whales is declining (Allen and Angliss 2010, 2012a).

Neither the Beaufort Sea beluga whale stock nor the eastern Chukchi Sea stock is listed as depleted under the MMPA or threatened or endangered under the ESA.

Distribution, Migration and Habitat Use

Beluga whales closely associate with open leads and polynyas in ice-covered regions throughout Arctic and sub-Arctic waters of the Northern Hemisphere. Distribution varies seasonally. Whales from both the Beaufort Sea and eastern Chukchi Sea stocks overwinter in the Bering Sea. Belugas of the eastern Chukchi may winter in offshore, although relatively shallow, waters of the western Bering Sea (Richard et al. 2001), and the Beaufort Sea stock may winter in more nearshore waters of the northern Bering Sea (R. Suydam, pers. comm. 2012c). In the spring, belugas migrate to coastal estuaries, bays, and rivers. Annual migrations may cover thousands of kilometers (Figure 3.2-16) (Allen and Angliss 2010, 2012a).

Belugas of the eastern Chukchi Sea stock congregate in nearshore waters of Kotzebue Sound and Kasegaluk Lagoon (near Point Lay) in June and July (Frost et al.1993, Huntington et al. 1999). Iñupiat hunters in Point Lay describe Omalik Lagoon, south of Kasegaluk Lagoon, as an important gathering area for belugas in June, except in years when there is heavy ice along the shore. Hunters also note that belugas enter inlets to Kasegaluk Lagoon when tides or currents are outgoing (possibly following fish), then stay in the deeper channels near the inlets (Huntington et al. 1999).

Satellite telemetry data from 23 whales tagged in Kaseguluk Lagoon in 1998 through 2002 provided information on movements and migrations of eastern Chukchi Sea belugas. Animals initially traveled north and east into the northern Chukchi and western Beaufort Seas after capture (Suydam et al. 2001, 2005).

Movement patterns between July and September vary by age and/or sex classes. Adult males frequent deeper waters of the Beaufort Sea and Arctic Ocean (79-80°N), where they remain throughout the summer. All of the belugas that moved into the Arctic Ocean (north of 75°N) were adult males that traveled through 90 percent pack ice cover to reach the higher latitudes by late July through early August. Females, both adult and immature, remained mostly in the vicinity of the Beaufort and Chukchi seas shelf break.

Immature males moved farther north than immature females but not as far north as adult males. All of the belugas frequented water deeper than 200 m (656 ft) along and beyond the continental shelf break. Use of the inshore waters within the Beaufort Sea Outer Continental Shelf lease sale area was rare (Suydam et al. 2005).

Most information on distribution and movements of belugas of the Beaufort Sea stock was similarly derived using satellite tags. A total of 30 belugas were tagged in the Mackenzie River Delta, Northwest Territories, Canada, during summer and autumn in 1993, 1995, and 1997 (Richard et al. 2001). In 1993 and 1995, most of the tagged males left the estuary and traveled farther north than expected into the permanent pack ice of the Beaufort Sea and Arctic Ocean. In late July, most males were in Viscount Melville Sound, while most of the females were in Amundsen Gulf. This differed in 1997, when the males' movements were more similar to the females in 1993 and 1995 (Richard et al. 2001).

Beaufort Sea belugas migrate westward in September. Approximately half of the tagged whales traveled far offshore of the Alaskan coastal shelf, while the remainder traveled on the shelf or near the continental slope (Richard et al. 2001). Migration through Alaskan waters lasted an average of 15 days. In 1997, all of the tagged belugas reached the western Chukchi Sea (westward of 170°W) between September 15 and October 9. Belugas remained north and east of Wrangel Island until mid- to late-October. Two tags transmitted into November revealing movements along and offshore of the Chukotka Peninsula and, for the male, across the Bering Strait and into the Bering Sea (Richard et al. 2001).

Beluga whales are regularly sighted during the September-October BWASP aerial surveys of the Alaska Beaufort Sea coast. In 2006, distribution offshore along the shelf-break and slope overlapped with that observed in previous years. Sighting rates were much lower in 2007 and 2008 (117 and 15, respectively, compared to 525 in 2006), possibly because of the absence of sea ice in the area or survey effort offshore. Sighting rates in 2009 were similar to years prior to 2007, with distribution highest in Barrow Canyon and offshore shelf break and slope areas (Clarke et al. 2011b, 2011c). In 2011, belugas were also seen along the Beaufort Sea continental slope and near Barrow Canyon, with a few scattered sightings nearshore, in all months (July through October) during which ASAMM surveys were flown (Clarke et al. 2012). Sighting rates were highest along the Alaskan Beaufort Sea slope, in the 201 to 2,000 m (659 to 6,562 ft) depth zone near Barrow Canyon, and in the >2000 m (>6562 ft) depth zone in the Alaskan Beaufort Sea. Distribution patterns of belugas in the Alaskan Beaufort Sea have remained relatively consistent for the past 30 years (Clarke et al. 2012). Belugas seen during these surveys could be from either the Beaufort Sea or Chukchi Sea stocks.

In fall, most belugas migrate to the Bering Sea where they spend the winter. Satellite tag transmissions from one male suggest that the area northwest of St. Lawrence Island is used as an overwintering area for the Chukchi Sea stock (Suydam et al. 2005, Robert Suydam, Department of Wildlife Management, NSB, Barrow, AK, pers. comm.), although determining what a population does from a sample of one should be done cautiously.

Acoustic detections of beluga whales provide additional insight into distribution and movements of belugas in the northeastern Chukchi Sea. Belugas were detected during every month from April to November in 2007 and 2008 (Delarue et al. 2011). Detections were more restricted in summer and ranged more broadly in the spring. Calls in July and August were concentrated near Barrow Canyon. Calls were detected between mid-April and June 2008 over a large area 90 to 150 km (60.0 to 93.2 mi) off Point Lay and Wainwright. These spring detections of belugas may have included whales from both the eastern Beaufort and Chukchi Sea stocks (Delarue et al. 2011). Calls were also detected in November 2007 off Point Lay (Delarue et al. 2011). It is not clear from which stock those animals originated. Most acoustic detections of belugas from late-October to late-November 2008 were at stations located 56.3 km (35 mi) and 80.5 km (50 mi) off Wainwright (Hannay et al. 2011). Detections in spring 2009 began in mid-April 177 km (110 mi) off Point Lay, suggesting that migrating belugas may travel in offshore leads that form southwest of Hanna Shoal before inshore leads form (Hannay et al. 2011). High call counts shifted from the southwest to the northeast from April to June, as belugas migrated to the Beaufort Sea. Spring detections ended mid-June 144.8 km (90 mi) off Wainwright. Belugas were only detected on 4 occasions during summer 2009 (Hannay et al. 2011). There were no recorders deployed inshore.

Despite being acoustically detected in the Chukchi Sea, no beluga whales were visually detected by observers aboard vessels surveying the Burger and Klondike prospects from July to October 2008 and August to October 2009 (Brueggeman 2009, 2010), or during surveys of Burger, Klondike, or Statoil leases from July to October 2010 (Aerts et al. 2011), possibly because the observation vessels influenced the distribution, behavior, and sightability of animals.

Belugas were seen, however, during aerial surveys conducted from June through November in the northeastern Chukchi Sea, 2008 to 2012, as part of the COMIDA project and from June through October 2011 and 2012 during ASAMM surveys. They were sighted every month except September, and none were sighted within Lease Sale Block 193 during 2008 to 2010 (Clarke et al. 2011a, 2013, Ferguson et al. 2013). In 2011, belugas in the Chukchi Sea were scattered both offshore and nearshore in June, September and October, were consistently within approximately 100 km (62 mi) of shore in July, and were primarily along the northwestern Alaskan coast in August. The highest sighting rate per depth zone was in shallow water (≤35 m [≤114 ft] depth) (Clarke et al. 2011a, 2012). The large groups (>150 whales) frequently seen near the coast south of Point Lay in June and mid-July in 2011 were reminiscent of large groups seen during surveys of the late 1970s through the early 1990s (Clarke et al. 2012). One group of 400 belugas, observed on June 25 south of Point Lay, was feeding. Such groups were not seen in this area in 2008 to 2010; there were also more sightings in 2011 (299) than in 2008 to 2010 combined (153) in the ASAMM study area (Clarke et al. 2012). More beluga whales (127 sightings) were seen near Barrow during the summer of 2010 than in previous years. They were observed feeding inside and near to Elson Lagoon in July through August and September, with over 500 belugas reported on July 25 (George et al. 2011).

The diet of beluga whales appears to be quite varied. Fish, including Arctic cod and saffron cod, and invertebrates, such as cephalopods and shrimp, seem to be important in the diet of belugas along the Alaskan Chukchi Sea coast (Seaman et al. 1982). Belugas in the eastern Beaufort Sea appear to feed predominantly on Arctic cod (Loseto et al. 2009). The stomachs of belugas harvested at Point Lay are often empty (Huntington et al. 1999). Prey available to, and likely consumed by, belugas in the area include herring, smelt, salmon, flounder, and capelin (Huntington et al. 1999). Subsistence hunters also noted shrimp in the stomachs of some harvested beluga whales in Kotzebue Sound (Whiting et al. 2011). Belugas harvested along the Chukotka coast of the northern Bering Sea often had Arctic cod or Arctic char in their stomachs (Mymrin et al. 1999).

Reproduction and Growth

Females become sexually mature at 9 to 12 years old; males at a later age (O'Corry-Crowe 2009), although this varies by population. Heide-Jøregensen and Teilmann (1994) estimated age of sexual maturity at 6 to 7 years for males and 4 to 7 years for females off West Greenland. Suydam (2009) estimated that 50 percent of females were sexually mature at age 8.25 and the average age at first birth was 8.27 years for belugas sampled near Point Lay.

The gestation period calculated for the eastern Chukchi stock is 14.9 months, and the calving interval is 2 to 3 years. The pregnancy rate of 0.41 for females harvested at Point Lay is consistent with this interval (Suydam 2009). Pregnancy rates decline after females reach 25 years old (Suydam 2009). A single calf is born in late spring to mid-summer and may remain with its mother until 2 years old (Brodie 1971, Suydam 2009). Most births occur from mid-June to mid-July (Burns and Seaman 1986). Length at birth for eastern Chukchi belugas was estimated to be 1.57 m (5.15 ft) and length at separation from mothers was estimated as 2.46 m (8.07 ft) (Suydam 2009). Mating is thought to occur from late-February to June, with a peak in March. Some breeding may occur in late-June to early-July (Burns and Seaman 1986, Suydam2009).

Survival and Mortality

The primary sources of human caused mortality in beluga whales are subsistence hunting and, possibly, interactions with commercial fisheries. The average annual subsistence take from the Beaufort Sea beluga stock by Alaska Natives was 41 during 1987 to 2006. For the eastern Chukchi Stock, annual subsistence take by Alaska Natives averaged 62 belugas during 1987 to 2006 (Frost and Suydam 2010). These annual harvests represent 0.1 percent and 1.7 percent of the estimated stock sizes for the Beaufort Sea stock and eastern Chukchi Sea stock, respectively (Frost and Suydam 2010). Subsistence is further discussed in Section 3.3.2.

The total commercial fishery mortality and serious injury is estimated to be zero for both the Beaufort Sea and eastern Chukchi Sea stocks (Allen and Angliss 2010, 2012a). Beluga whales are occasionally entangled in subsistence nets (R. Suydam pers. comm. 2012b). Killer whale predation on large whales is well documented in other populations and is likely to occur, at least seasonally, to these stocks as well (Shelden et al. 2006).

Hearing and Other Senses

Beluga whales are in the mid-frequency hearing group with an estimated auditory bandwidth of 150 Hz to 160 kHz (Southall et al. 2007). Average hearing thresholds of captive belugas were measured at 65 and 120.6 dB re 1 µPa at frequencies of 8 kHz and 125 Hz, respectively (Awbrey et al. 1988). Belugas create a diverse repertoire of sounds, earning them the name "sea canary." Sounds are divided into whistles and pulsed calls, typically at frequencies between 0.1 and 12 kHz. Nearly 50 different call types have been recognized, including groans, whistles, buzzes, trills, and roars (Bel'kovitch and Sh'ekotov 1990). Call types recorded in the Chukchi Sea include low and high whistles, buzzes, chirps, and clicks (Hannay et al. 2011).

Narwhal

Species Description

The narwhal is a toothed whale in the family Monodontidae, along with beluga whales. This species was given its scientific name for its most unique feature -- the up to 3 m (9.8 ft) long spiraled tusk. Adult narwhals only have two teeth, and, in males, the left tooth develops into a tusk. Some females grow tusks, some males lack tusks, and some grow double tusks. The tusk is likely a secondary sexual characteristic (Heide-Jørgensen 2009).

Narwhals lack dorsal fins. Calves are uniformly dark in coloration, while adults are mottled in appearance. Adult females are approximately 400 cm (157.5 in) long and weigh 1,000 kg (2,205 lbs), and males are 450 cm (177.2 in) and 1,600 kg (3,527 lbs) (Garde et al. 2007).

Population Status and Trends

Abundance surveys of narwhals in the Canadian High Arctic (Prince Regent Inlet, Barrow Strait, and Peel Sound) were conducted during summer 1996. The resulting estimated total abundance for that area was 45,358 (Innes et al. 2002).

Distribution, Migration and Habitat Use

Narwhals predominantly inhabit Arctic waters of the Atlantic Ocean—the Canadian high Arctic, northern Hudson Bay, Davis Strait, Baffin Bay and the Greenland Sea, and the Arctic Ocean between Svalbard and Franz Josef Land. There are a few records of sightings in the Pacific side of the Arctic (Heide-Jørgensen 2009).

Occurrence of narwhals in the Alaskan Beaufort and Chukchi seas is rare and, likely, extralimital. The NSB Department of Wildlife Management collected about a dozen incidental observations of narwhals made by Alaska Native hunters. Two were sighted in the spring leads off of Barrow with a group of belugas in 1989. Between 2001 and 2006, there were nine narwhal sighted in July and August from Wainwright to off Point Barrow. In 2008, a narwhal tusk was found on Cape Sabine. Most of the narwhals sighted live were associated with beluga whales (JC George pers. comm.). Incidental sightings of narwhals in the Beaufort and Chukchi seas are thought to be from the Baffin Bay population that are known to move into the Canadian Arctic Archipelago and as far north and west as ice conditions will permit (COSEWIC 2005).

Reproduction and Growth

Age at sexual maturity is estimated as six to seven years for females and nine years for males (Garde et al. 2007). Mating likely occurs in April through May, and, at least in Greenland and Canada, calving occurs from June through August, suggesting a gestation of 13 to 16 months. Lactation lasts one to two years, and females are thought to calve every three years (Heide-Jørgensen 2009).

Survival and Mortality

Recent studies using aspartic racemization suggest that female narwhals can reach 115 years of age (Garde et al. 2007).

Killer whales and polar bears are the only non-human predators of narwhals (Heide-Jørgensen 2009).

Narwhals are hunted for their tusks and skin in Greenland and Canada, with 433 taken during 2000 to 2004 in Canada. Narwhals appear susceptible to ice entrapment, particularly in areas of unpredictable ice conditions, such as Disko Bay in West Greenland (Heide-Jørgensen 2009).

Hearing and Other Senses

Narwhals are in the mid-frequency hearing group with an estimated auditory bandwidth of 150 Hz to 160 kHz (Southall et al. 2007). Narwhals produce a variety of sounds. Echolocation clicks have been measured at maximum amplitudes of 48 kHz. Whistles have also been recorded with frequencies of 300 Hz to 18 kHz (Ford and Fisher 1978, Miller et al. 1995).

Narwhals are called “unicorns” of the sea because of the tooth, or tusk, that emerges from its upper jaw. Researchers have come up with several explanations over the decades as to its function. A recent theory proposed by Nweeia et al. (2009) that it may in fact be a chemoreceptor capable of reacting and responding to varying salinity gradients. Being able to detect salinity gradients could help these animals survive in the Arctic environment. Additionally, it could also allow the animals to detect water particles characteristic of the fish upon which they prey (Science Daily 2005).

Killer Whale: Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock

Species Description

Killer whales are toothed whales and the largest member of the dolphin family. Adults are sexually dimorphic. Males reach a maximum body length of 9 m (30 ft) and a maximum weight of 6,600 (14,550 lbs). Females reach lengths of 7.7 m (25.5 ft), with a maximum measured weight of 4,700 kg (10,361 lbs) (Ford 2009, Yamada et al. 2007). In addition to being overall larger than females, the prominent dorsal fin on males can be as tall as 1.8 m. Directly behind the dorsal fin is a gray area of variable shape called the saddle patch. Killer whales are strikingly black and white in coloration with a conspicuous elliptically shaped white patch behind the eye. Individuals can be identified using variation in the shape and color of the eye patch, saddle patch, and the size and shape of the dorsal fin (Ford 2009).

Population Status and Trends

The three recognized ecotypes of killer whales—resident, transient, and offshore—are distinguished based on morphology, ecology (including prey preferences), genetics, acoustics, and behavior (Baird and Stacey 1988, Baird et al. 1992, Ford and Fisher 1982, Hoelzel and Dover 1991, Hoelzel et al. 1998, 2002).

Within these three ecotypes, there are six putative stocks of killer whales in Alaska: the Alaska Resident stock, occurring from southeastern Alaska to the Aleutian Islands and Bering Sea; the Northern Resident stock, occurring from British Columbia through part of southeastern Alaska; the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock, occurring mainly from Prince William Sound through the Aleutian Islands and Bering Sea; the AT1 transient stock, occurring in Alaska from Prince William Sound through the Kenai Fjords; the West Coast transient stock, occurring from California through southeastern

Alaska; and the Offshore stock, occurring from California through Alaska (Allen and Angliss 2010, 2012a).

The Gulf of Alaska, Aleutian Islands, and Bering Sea Transient stock is the one most likely to occur in the Beaufort and Chukchi seas. The minimum population estimate for this stock is 552, based on photographic identification of individuals (Allen and Angliss 2012a). Data are currently not available for determining trends in abundance.

The Gulf of Alaska, Aleutian Islands, and Bering Sea transient stock of killer whales is not listed as threatened or endangered under the ESA or considered depleted under the MMPA.

Distribution, Migration and Habitat Use

Killer whales are a cosmopolitan species found in all oceans and most seas. They are most commonly found in coastal and temperate waters of high productivity (Forney and Wade 2006). Killer whales range throughout the North Pacific. Along the west coast of North America, they occur from Alaska to California. Seasonal and year-round occurrence has been noted for killer whales throughout Alaska (Barlow 1995, Bigg et al. 1990, Braham and Dahlheim 1982, Forney et al. 1995).

Killer whales are occasionally reported in the northeastern Chukchi and western Beaufort Seas. Iñupiat Eskimo hunters reported observing killer whale attacks on gray whales in Peard Bay, northwest of Barrow and Point Hope. Other observations include attacks on beluga whales and bearded seals and possible foraging on whitefish and chum salmon near Peard Bay (George and Suydam 1998). Vessel-based sightings of three groups of killer whales were recorded in the Chukchi Sea during two industry-sponsored surveys in 2010 (Aerts et al. 2011, Reiser et al. 2011). In August 2011, two large groups of killer whales were sighted during marine mammal surveys. A group of 13 whales was sighted during an ASAMM aerial survey northeast of Barrow, followed five days later by a sighting of 25 to 30 whales by a CSESP survey vessel near Hanna Shoal (Joling 2012).

Killer whales were acoustically detected throughout the 2007 and 2009 Chukchi Sea open water season (Hannay et al. 2011). They were detected primarily off Cape Lisburne and Point Lay, with a few detections off Wainwright, plus one off Barrow in fall 2007. Analysis of the 2007 data indicated that the sounds were produced by transient killer whales (Hannay et al. 2011).

The killer whale is an apex marine predator with a diverse prey base. Transient killer whales are mammal-hunters whose prey includes various seal species. They are also known to attack minke whales and gray whale calves, as well as other large whale species, as evidenced by scars incurred during attacks (Ford 2009, George et al. 1994).

Reproduction and Growth

Births may occur in any month but most are in October through March. Females become reproductively mature between 11 and 16 years of age with a 5-year interval between births. Gestation is 15 to 18 months (Ford 2009) and weaning is about 1 to 2 years after birth. Females typically give birth for the first time at about 12 to 14 years of age (Olesiuk et al. 2005). Males attain sexual maturity at about 15 years of age (Ford 2009).

Killer whales are very social. The basic social unit is based on matriline relationships and linked by maternal decent. A typical matriline is composed of a female, her sons and daughters, and the offspring of her daughters (Ford 2009).

Survival and Mortality

Killer whales are long-lived. Life expectancy for females is about 50 years with a maximum of 80 to 90; males typically live to about 29 years of age (Ford 2009).

Sources of human-caused mortality include entanglement in fishing gear and ship strikes. Mortality has been reported in the Bering Sea/Aleutian Islands flatfish trawl fishery. The mean annual estimated level of serious injury and mortality for Gulf of Alaska, Aleutian Islands, Bering Sea transient stock of killer whales for 2007 to 2009 is 1.5 per year (Allen and Angliss 2012a). One ship strike of a killer whale was reported in the Bering Sea groundfish trawl fishery in 1998 (Allen and Angliss 2010). Killer whales have no known predators other than humans.

There is no subsistence harvest of killer whales in Alaska.

Hearing and Other Senses

Killer whales are highly vocal and use sound for social communication and to find and capture prey. The sounds include a variety of clicks, whistles, and pulsed calls (Ford 2009). Most of the pulsed sound frequencies range from 0.5 to 25 kHz. Source levels for echolocation clicks range from 195 to 224 dB re 1 μPa-m, with dominant frequencies from 20 to 60 kHz. Source levels associated with social sounds range from 131 to 168 dB re 1 μPa-m (DoN 2011). Acoustic studies of resident killer whales in British Columbia have found there to be dialects, which are likely used to maintain group identity and cohesion, and may serve as indicators of relatedness (Ford 1989, 1991). The vocal behavior of transient killer whales differs from residents, which is likely related to the hearing capabilities of their prey. They remain silent much of the time and communicate less frequently than residents (Barrett-Lennard et al. 1996, Saulitis et al. 2005). The killer whale has the lowest frequency of maximum sensitivity and one of the lowest high frequency hearing limits known among toothed whales. The frequency range of hearing is 1 to 100 kHz, with highest sensitivity at 20 kHz (DoN 2011).

Harbor Porpoise: Bering Sea Stock

Species Description

Harbor porpoise are toothed whales of the family Phocoenidae. They are one of the smaller porpoises in the world and the smallest cetacean in Arctic waters. They are characterized by a short, stocky body and a small, triangular dorsal fin. Females average 1.6 m (5.2 ft) in length and 60 kg (132.3 lbs), while males reach 1.4 m (4.6 ft) and 50 kg (110 lbs) (Bjørge and Tolley 2009). They have dark gray backs and light undersides. Harbor porpoise tend to avoid ships and rarely bow ride (Bjørge and Tolley 2009).

Population Status and Trends

There are currently three stocks of harbor porpoise recognized in Alaska: the Southeast Alaska stock; the Gulf of Alaska stock; and the Bering Sea stock (Allen and Angliss 2010). The latter occurs throughout the Aleutian Islands and all waters north of Unimak Pass.

The most recent population estimate for the Bering Sea stock is 48,215. This was based on surveys of the Bristol Bay area in 1997 through 1999 (Hobbs and Waite 2010). There is no reliable information on trends in abundance for this stock (Allen and Angliss 2012a).

Harbor porpoise are not listed as depleted under the MMPA or listed as threatened or endangered under the ESA.

Distribution, Migration and Habitat Use

Harbor porpoise in the eastern North Pacific range from Point Barrow and along the west coast of North America from Alaska to Point Conception, California (Gaskin 1984). The harbor porpoise are primarily coastal and most commonly occur in waters less than 100 m (328 ft) deep (Hobbs and Waite 2010). Harbor porpoise often feed on bottom-dwelling fishes and small pelagic schooling fishes with high lipid content; herring and anchovy are common prey (Bjørge and Tolley 2002, Leatherwood et al. 1982).

Harbor porpoise are seen in both the Beaufort and Chukchi seas. Incidences of entanglement in subsistence nets, beached carcasses, and live sightings near Point Barrow suggest regular use of, at least, the northeast Chukchi and far western Beaufort Seas (Suydam and George 1992). They are also occasionally seen during the fall BWASP aerial surveys (Clarke et al. 2011c). Harbor porpoise were sighted during vessel surveys of the Chukchi Sea in 2006 through 2010 (Aerts et al. 2011, Brueggeman 2009, 2010, Ireland et al. 2008) in higher numbers and farther offshore than previously documented (Ireland et al. 2008). Harbor porpoise comprised 14 percent of cetacean sightings in the offshore areas (>37 km, or 23 mi, from shore) of the Chukchi Sea during Joint Monitoring Program surveys in 2006 through 2008 (Funk et al. 2010) and was the third most commonly identified cetacean species (after gray whales and bowhead whales) in the Chukchi Sea in 2010 (Reiser et al. 2011). More harbor porpoise (five sightings of 10 individuals) were also seen during boat surveys off Barrow in 2010 than in any previous year (George et al. 2011). The increased frequency of occurrence was also noted by Iñupiaq of Kotzebue Sound:

> "*It seems like they're getting more and more of this porpoise. I'm getting to see more and more every year*" (Whiting et al. 2011).

The increased number of harbor porpoise may represent a range extension (Funk et al. 2010).

Reproduction and Growth

Harbor porpoise become sexually mature at 3 to 4 years old. Females generally give birth in summer from May through July. Mating occurs about one and a half months later. Calves remain dependent for at least six months and are generally weaned by 1-year of age (Bjørge and Tolley 2009, Leatherwood et al. 1982).

Survival and Mortality

Mortality incidental to fisheries is possible. One harbor porpoise mortality was observed in 2007 in the Bering Sea/Aleutian Islands flatfish trawl fishery; this is the only harbor porpoise mortality observed from 2007 to 2010. The estimated minimum annual mortality rate for the Bering Sea stock of harbor porpoise incidental to commercial fisheries is, therefore, 0.53 (Allen and Angliss 2012a). That estimate is, however, unreliable due to lack of observers on several gillnet fisheries in Alaska (Allen and Angliss 2010, 2012a).

Subsistence fishermen in Barrow occasionally catch harbor porpoise in their nets during the summer (Suydam & George 1992).

Hearing and Other Senses

Harbor porpoise are in the high-frequency functional hearing group, whose estimated auditory bandwidth is 200 Hz to 180 kHz (Southall et al. 2007). Their vocalizations range from 110 to 150 kHz, and echolocation signals are in the 1.4 to 2.5 kHz range (DoN 2011).

3.2.4.3 Ice Seals

<u>Ringed Seal</u>

Species Description

Ringed seals are one of the smallest of the true seals (family Phocidae). Adults reach 1.5 m (4.9 ft) in length and 70 kg (154 lbs) in weight. They have a small head, short cat-like snout, and a plump body. Ringed seal pelage can be either light or dark phase, and they have silver rings on their back and sides with a silver belly (McLaren 1966, Murdoch 1885, Ognev 1935).

Population Status and Trends

The five recognized subspecies of ringed seals are the Arctic ringed seal (*Phoca hispida hispida*), the Baltic ringed seal (*Phoca hispida botnica*), the Okhotsk ringed seal (*Phoca hispida ochotensis*), the Ladoga ringed seal (*Phoca hispida ladogensis*), and the Saimaa ringed seal (*Phoca hispida saimensis*).

The Arctic ringed seal is the most abundant of the subspecies and is further subdivided by geographical region: Greenland Sea and Baffin Bay; Hudson Bay; Beaufort and Chukchi seas; and the White, Barents and Kara Seas. Arctic ringed seals of the Beaufort and Chukchi seas will be discussed here, as they are the only ones anticipated to occur in the EIS project area.

Several factors—from the seals' distribution and ecology to cross political boundaries--make assessing the population difficult. Recent surveys estimated a population of at least 300,000 ringed seals in the Alaskan Beaufort and Chukchi seas, although this was likely an underestimate (Bengtson et al. 2005, Frost et al. 2004). Accounting for seals inhabiting the pack ice and the eastern Beaufort and Amundson Gulf areas, the total population of ringed seals in the Beaufort and Chukchi seas was estimated to be 1 million (Bengtson et al. 2005, Frost et al. 2004). Kelly et al. (2010a) estimates that over 1,000,000 ringed seals inhabit the Beaufort, Chukchi, and Bering Seas based on information from existing surveys and studies. Kelly et al. (2010) placed their maximum density estimate of ringed seals at Prudhoe Bay and along the coast south of Kivalina at 1.62 seals/km^2. A minimum population estimate could not be determined as current reliable estimates of abundance are not available (Allen and Angliss 2012a).

On December 10, 2010, NMFS announced a proposed rule and a 12-month finding on a petition to list the ringed seal as a threatened or endangered species in the *Federal Register* (75 FR 77476). In this *Federal Register* notice, NMFS determined that all of the subspecies, except for the Saimaa ringed seal, are likely to become endangered throughout all or a significant portion of their range in the foreseeable future and therefore proposed to list them as threatened under the ESA. The basis for the determination was the likelihood of sea-ice habitat modification due to climate change and marine habitat modification due to ocean acidification. On December 28, 2012, NMFS published the final rule in the *Federal Register* (77 FR 76706) listing the Arctic subspecies of ringed seal as threatened.

Distribution, Migration and Habitat Use

Ringed seals are circumpolar and occur in all seasonally ice-covered seas of the northern hemisphere (King 1983) (Figure 3.2-18). Ringed seals are strongly ice-associated, and the seasonality of ice cover dictates their movements, feeding, and reproductive behavior. The ringed seal year consists of three distinct periods: the "foraging period" during the open water season when foraging is most intensive; the "subnivean period" from early winter through late May or early June when seals are using subnivean lairs on the ice; and the "basking period" between the time seals leave their lairs in May or June and the ice breaks up in June or July (Kelly et al. 2010b).

Ringed seals breed on either shorefast ice or pack ice. Some suggest that these breeding populations may represent different ecotypes (Kelly et al. 2010a). Ringed seals that breed on shorefast ice may either forage within 100 km (62.1 mi) of their breeding habitat or undertake extensive foraging trips to more productive areas at distances of 100s to 1,000s of kilometers (Kelly et al. 2010b). Adult Arctic ringed seals return to the previously used subnivean site after the foraging period ends. Movements are limited during the subnivean period.

The Arctic subspecies typically hauls out exclusively on sea ice for resting, pupping, and molting. In the Beaufort and Chukchi seas, time spent on the ice increased from 12 percent in March to 43 percent in early June to more than 60 percent while molting in June (Kelly and Quakenbush 1990, Kelly et al. 2010b). After molting, and, as the sea ice breaks up in summer, ringed seals spend less time on the ice and more time in the water foraging. Time on the ice was 10 percent or less from August to November and remained less than 20 percent from December to March (Kelly et al. 2010b).

Ringed seals are able to remain in areas of dense ice cover throughout the fall, winter, and spring by maintaining breathing holes in the ice. They excavate lairs in the snow (subnivean) over their breathing holes as pupping season approaches (Helle et al. 1984). Recent satellite telemetry data showed adult seals remained in localized areas of the southern Chukchi and northern Bering seas in high concentrations of pack ice or at the periphery of the shorefast ice from December through April. Sub-adults, however, were not constrained by the need to defend territories or maintain birthing lairs and followed the advancing ice southward to winter along the Bering Sea ice edge where there may be enhanced feeding opportunities and less exposure to predation (Crawford et al. 2012). Sub-adult ringed seals tagged in the Canadian Beaufort Sea similarly undertook lengthy migrations across the continental shelf of the Alaskan Beaufort Sea into the Chukchi Sea, passing Point Barrow prior to freeze-up in the central Chukchi Sea (Harwood et al. 2012).

Factors most influencing seal densities during May through June in the central Beaufort Sea between Oliktok Point and Kaktovik were water depth, distance to the fast ice edge, and ice deformation. Highest densities of seals were at depths of 5 to 35 m (16 to 144 ft) and on relatively flat ice near the fast ice edge (Frost et al. 2004).

Ringed seals are relatively common in May and June in the eastern Chukchi Sea (north of the Bering Strait to Point Barrow), with average densities of 1.62 to 1.91 seals/km^2 (Bengston et al. 2005). Although found in both locations, densities of ringed seals were higher on nearshore fast ice and pack ice than on offshore pack ice. Highest densities of ringed seals were in the coastal waters south of Kivalina and near Kotzebue Sound (Bengston et al. 2005). Satellite tagging data also indicate regular use of Peard Bay along the Chukchi coast and Admiralty Bay/Dease Inlet along the western Beaufort Sea east of Barrow during summer and fall (NSB 2012a)

Ringed seals are thought to be primarily pelagic foragers. Their diet varies by season, age, and location. Ringed seals typically prey on small schooling fish and crustaceans (Kovacs 2007). Arctic cod, polar cod and saffron cod, plus sculpins in the Chukchi Sea, are among preferred fish prey of ringed seals (Kelly et al. 2010a). Shrimp, amphipods, euphausiids, and mysids were also found in stomachs of ringed seals from the Chukchi Sea (Quakenbush and Sheffield 2007). Quakenbush et al. (2011b) found that general fish consumption increased and consumption of invertebrates decreased from the 1960s and 1970s to the 2000s. Among the fish consumed were, as noted above, Arctic cod and saffron cod, as well as Pacific herring, capelin, sand lance, prickleback, and eelblennny. A decrease in crustacean and shrimp consumption accounted for the decreased frequency of invertebrates in stomach contents. Amphipods and mysids were among the other invertebrates regularly consumed (Quakenbush et al. 2011b). Dominant prey (based on frequency of occurrence) in stomachs of ringed seals harvested off Barrow included cod (Arctic and saffron) sand lance, euphausiids, mysids, amphipods, and shrimp (Dehn et al. 2007). Consumption of Arctic cod increased with age and females ate more fish and males more zooplankton (Dehn et al. 2007).

Reproduction and Growth

Female ringed seals reach sexual maturity at 4 to 8 years old and males at 5 to 7 years. They breed annually and produce a single pup each year. Mating typically occurs in May. Gestation lasts about 240 days after a 3 to 3.5 month period of delayed implantation (Smith 1987). Pupping occurs in late winter to early spring in subnivean lairs on the sea ice (Finley et al. 1983).

Pups are 60 to 65 cm (23.6 to 25.6 in) long and weigh 4.5 to 5.0 kg (10 to 11 lbs) at birth (McLaren 1958a, Smith and Stirling 1975, Tikhomirov 1968). Pups nurse for 5 to 9 weeks and, when weaned, are four times their birth weights. Ringed seal pups are more aquatic than other ice seal pups and spend roughly half their time in the water during the nursing period (Lydersen and Hammill 1993b).

Survival and Mortality

Survival rates are not well known. The average life span is 15 to 28 years (Holst et al. 1999), but ringed seals can live longer than 40 years (Lydersen and Gjertz 1987, McLaren 1958a).

Sources of mortality include commercial fisheries, subsistence harvests, and predation. Mortality incidental to commercial fishing operations is low, with one report during 2002 to 2006 (Allen and Angliss 2010).

Ringed seals are hunted for subsistence by Alaska Natives from communities along the coasts of the northern Bering, Beaufort, and Chukchi seas. See Section 3.3.2, Subsistence Resources and Uses, for further discussion.

Common predators of ringed seals are polar bears and Arctic foxes, and, occasionally, other terrestrial carnivores, sharks, walrus and killer whales (Stirling and McEwan 1975, Stirling and Øritslsand 1995, Burns and Eley 1976, Heptner et al. 1976a, Sipila 2003). Ringed seals constitute 98 percent of the polar bear diet in the Beaufort Sea (Iverson et al. 2006). Gulls and ravens will prey on newborn pups, but concealment in subnivean lairs usually prevents that from occurring (Kelly et al. 2010a).

Ringed seals co-evolved with numerous parasites and diseases, and distemper virus has been reported in Arctic ringed seals. There is currently no evidence of impacts of disease or pathogen on ringed seal populations (Kelly et al. 2010a).

In 2011, over 60 dead and 75 diseased seals (mostly ringed seals) were reported in the Arctic (Chukchi and Beaufort seas) and Bering Straits regions of Alaska (NOAA 2011c). Characteristics of the disease include hair loss, skin sores on the hind flippers and face, and, for some, labored breathing and lethargy. In December, 2011, NOAA declared the deaths an unusual mortality event (UME) (NOAA 2011d). In February 2012, a young seal originally thought to be a ringed seal was found in Yakutat sick with symptoms consistent with this disease (NOAA 2012a). Results of DNA analyses subsequently determined this was a young ribbon seal that was misidentified due to excessive hair loss (Suydam pers. comm. 2012b). In 2012, Native subsistence hunters in the Bering Strait region have documented over 40 seals with clinical signs of the disease (NOAA 2012b).

The underlying cause is still unknown. Despite numerous tests for viral, bacterial pathogens, and biotoxins, no specific disease agent or process has been identified. The following have been ruled out, so far: Phocine distemper, influenza, Leptospirosis, Calicivirus, orthopoxvirus, and poxvirus, foot and mouth disease, VES, pan picornavirus, and Rickettsial agents (NOAA 2012a, 2012b). Tissue samples were also collected to analyze heavy metals, radionuclides (radiation), and persistent organic pollutant levels (NOAA 2012b). Results are pending, although preliminary screening showed radiation levels within the typical background range for Alaska and not of a level that would cause the observed symptoms (NOAA 2012c).

Hearing and Other Senses

The estimated auditory bandwidth of ringed seals is 75 Hz to 75 kHz in water and 75 Hz to 30 kHz in air (Southall et al. 2007). Ringed seals produce at least six types of underwater calls. These include clicks (2 to 6 kHz), burst pulses, knocks (150 Hz to 2 kHz), chirps (500 to 1000 Hz), yelps (modulate around 1 kHz), and other low-frequency sounds (as summarized in Frankel 2009). Call activity varies seasonally in the Arctic. Most noises produced by ringed seals consist of sounds from scratching ice to maintain their breathing holes in the ice, otherwise they produce much less noise than other seal species (Cummings and Holliday 1984). Seals do not echolocate; however they can hear low-frequency sounds. Foraging by seals is believed to integrate vision and tactile senses such that they can see in almost total darkness, having the ability to track moving prey from as far as 100+ ft (30+ m) away using their vibrissae (Schusterman et al. 2004, Riedman 1990, Wieskotten et al. 2010, Dehnhardt et al. 2001, Schulte-Pelkum et al. 2007).

Spotted Seal

Species Description

Spotted seals, also called largha seals, are true seals of the family Phocidae. Males and females are similar in size and appearance. Adult females in the Bering Sea and Sea of Okhotsk typically weigh 65 to 115 kg (143.3 to 253.5 lbs) and are 151 to 169 cm (59.4 to 66.5 in) long. Adult males typically weigh 85 to 110 kg (187.4 to 242.5 lbs) and are 161 to 176 cm (63.4 to 69.3 in) long. They are generally light-colored with densely scattered dark grey and black spots (Heptner et al. 1976b, Wilke 1954).

Population Status and Trends

Spotted seals are divided into three Distinct Population Segments (DPSs) based on genetics, geography and breeding groups: the Bering DPS; the Okhotsk DPS; and the Southern DPS (Boveng et al. 2009). The Southern DPS includes spotted seals breeding in the Yellow Sea and Peter the Great Bay in the Sea of Japan.

There are no accurate abundance estimates for spotted seals across their entire range or for the Bering DPS, specifically. Data from 2007 and 2008 surveys are being analyzed to estimate abundance for the central and eastern Bering Sea. A provisional estimate of 101,568 spotted seals was provided in the interim by the National Marine Mammal Laboratory (Goodman 1960, Ver Hoef et al. 2010). Population trend assessments are currently unavailable.

In response to a petition to list the spotted seal as threatened or endangered under the ESA due to concerns over impacts of habitat loss due to climate change, NMFS conducted a status review of the species (Boveng et al. 2009). NMFS determined that only the Southern DPS is likely to become endangered throughout all or a significant portion of its range in the foreseeable future and should be listed as threatened. A proposed rule to list the Southern DPS of the spotted seal as a threatened species was published in the *Federal Register* on October 20, 2009 (74 FR 53683). NMFS published the final rule for the listing in the *Federal Register* on October 22, 2010 (75 FR 65239).

No listing action was proposed for the Okhotsk and Bering Sea DPSs (74 FR 53683, October 20, 2009). The Okhotsk and Bering Sea DPSs are not considered in danger of extinction or likely to become endangered in the foreseeable future.

Distribution, Migration and Habitat Use

Spotted seals are widely distributed on continental shelf areas of the Beaufort, Chukchi, southeastern East Siberian, Bering, and Okhotsk Seas, and south through the Sea of Japan and the northern Yellow Sea. This encompasses more than 40 degrees of latitude from Point Barrow in Alaska to the Yangtze River in China (Burns and Fay 1972, Lowry 1985, Naito and Konno 1979, Naito and Nishiwaki 1972).

Habitat use and distribution are closely linked to seasonal sea ice from late fall through spring (November/December to March in the Bering Sea). The seals haul out on the ice during the whelping, nursing, breeding, and molting periods. Before whelping and breeding, spotted seals are scattered among drifting ice floes (Heptner et al. 1976b).

Spotted seals congregate in herds on ice floes as the ice begins to disappear in late spring. Adults molt, and pups are weaned during this time. Adult spotted seals in the Bering Sea molt over a 2 to 2.5 month period from late April or early May to mid-July (Boveng et al. 2009). In summer, when the usable sea ice disappears, herds disperse, and seals move toward the ice-free coastal waters (Heptner et al. 1976a).

Spotted seals in the eastern Bering Sea use coastal haul-out sites from Kuskokwim Bay to the Bering Strait from May to July. Primary haul-outs in the eastern Chukchi Sea are along the coast of Kotzebue Sound and in Kasegaluk Lagoon (near Point Lay) during summer and fall (Figure 3.2-19) (Frost et al. 1982, Frost et al. 1983). Counts in excess of 1,000 spotted seals hauled out in Kasegaluk Lagoon are not uncommon from late-July through late-September (Frost et al. 1993). Other major haul-outs along the Chukchi Sea coast include the mouth of the Kuk River (near Wainwright), and the mouth of the Kugrua River (Peard Bay area) (Frost et al. 1993).

Spotted seals in the eastern Bering Sea use coastal haul-out sites from Kuskokwim Bay to the Bering Strait from May to July. Primary haul-outs in the eastern Chukchi Sea are along the coast of Kotzebue

Sound and in Kasegaluk Lagoon (near Point Lay) during summer and fall (Figure 3.2-19) (Frost et al. 1982, Frost et al. 1983).

Based on satellite tagging studies, spotted seals in the Chukchi Sea migrated south to breeding and whelping areas in the Bering Seas in October, passing through the Bering Strait in November. In summer, the seals either traveled to nearshore areas of the Bering Sea or headed north into the Beaufort and Chukchi seas. Tagged seals undertook foraging trips from haul-out sites in Kasegaluk Lagoon that averaged 9 days in length and ranged over 1,000 km (621 mi) towards the Bering Strait, Beaufort Sea, or the Russian coast (Lowry et al. 1998).

Spotted seals are generalists that eat a broad array of fish, crustaceans and cephalopods from continental shelf and shelf break waters (Dehn et al. 2007). Among the fish commonly consumed are Pacific herring, smelt, Arctic cod, and saffron cod. Arctic cod were consumed more often by spotted seals in the Bering Sea than in the Chukchi Sea and saffron cod was more common in stomachs of harvested seals taken in the Chukchi Sea than in the Bering Sea (Quakenbush et al. 2009a). Spotted seals tend to feed more pelagically than benthically (Dehn et al. 2007).

Reproduction and Growth

The annual timing of reproduction coincides with the period of maximum sea ice extent. In the Bering Sea, whelping generally occurs between late March and the end of April. Breeding occurs from late April to mid-May. Gestation lasts seven to nine months, after a two to four month period of delayed implantation. Males and females become sexually mature at about four to five years old. Most mature females annually give birth to a single pup (Heptner et al. 1976b).

Pups weigh 7 to 12 kg (15.4 to 26.5 lbs) at birth and 75 to 92 cm (29.5 to 32.6 in) long. Nursing lasts two to four weeks. Pups may more than triple their weight by the time of weaning. Pups are dependent on the sea ice and rarely enter the water while nursing, and early break up of ice can lead to high levels of pup mortality. Weaning occurs abruptly when the mother abandons the pup (Boveng et al. 2009).

Survival and Mortality

Spotted seals may live 30 to 35 years. Potential sources of mortality are commercial fisheries, subsistence hunts, and predation. No incidental serious injuries or mortalities of spotted seals were reported in any of the observed commercial fisheries in Alaska prior to 2004. The Bering Sea/Aleutian Islands flatfish trawl fishery is the only observed commercial fishery known to have taken spotted seals, averaging 1.0 seals per year from 2007 to 2009 (Allen and Angliss 2012a).

Spotted seals are an important species for Alaskan subsistence hunters, primarily in the Bering Strait and Yukon-Kuskokwim regions (see Section 3.3.2, Subsistence Resources and Uses).

There is little evidence of predation on spotted seals, and they are not considered primary prey of any predators. Predators include polar bears, brown bears, walrus, killer whales, Pacific sleeper sharks, foxes, wolves, sea lions, eagles, and gulls (Quakenbush 1988).

A variety of pathogens, diseases, helminthes, cestodes, and nematodes have been found in spotted seals, yet the prevalence is not unusual for seals (Boveng et al. 2009). Symptoms characteristic of the disease outbreak described above for ringed seals were documented in low numbers of spotted seals in the Bering Strait/Chukchi Sea region in 2011. The disease outbreak predominantly affected ringed seals; the number of affected spotted seals was small and below the level that warranted a UME declaration (NOAA 2011d, Stimmelmayr pers. comm. 2012b)

Hearing and Other Senses

The estimated auditory bandwidth of spotted seals is 75 Hz to 75 kHz in water and 75 Hz to 30 kHz in air (Southall et al. 2007). Spotted seals in captivity produced six underwater sounds, including growls, clicks, snorts, and “cranky door U.” Frequencies ranged from 500 Hz to 3.5 kHz (summarized in Frankel

2009). Additional information on hearing and other senses for seals in general can be found in the ringed seal description above.

Ribbon Seal: Alaska Stock

Species Description

Ribbon seals are one of the most strikingly marked and easily recognizable seals in the world. The distinctive ribbon pattern consists of four light-colored bands on a background of darker pelage. One band encircles the neck and nape, another the trunk around the lower back and hips, and two ovals encircle each front flipper. Adult males are more brightly patterned than adult females (Boveng et al. 2008).

Ribbon seals are medium-sized seals. Adults reach lengths of 150 to 175 cm (59.0 to 68.9 in) and weights of about 70 to 90 kg (154 to 198.4 lbs) (Burns 1981, Lowry and Boveng 2009).

Population Status and Trends

The two main breeding areas for ribbon seals are in the Sea of Okhotsk and the Bering Sea. They are not separated into DPSs.

Data from aerial surveys in the eastern Bering Sea in 2003, 2007, and 2008 are currently being analyzed to develop abundance estimates for that region. An interim provisional population estimate of ribbon seals in the eastern and central Bering Sea (i.e. the EEZ) is 49,000 individuals (Boveng et al. 2008).

NMFS received a petition to list ribbon seals under the ESA in December 2007 due to loss of sea ice habitat caused by climate change in the Arctic. NMFS published a notice in the *Federal Register* on March 28, 2008 (73 FR 16617) indicating that there were sufficient data to warrant a status review of the species (Boveng et al. 2008). Findings of the review were published in the *Federal Register* on December 30, 2008 (73 FR 79822), wherein it was determined that listing of the ribbon seal was not warranted at the time, as it is not in danger of extinction or likely to become an endangered species within the foreseeable future. In response to new information and ongoing litigation regarding ribbon seals, NMFS published a notice of intitiation of a new status review in the *Federal Register* on December 13, 2011 (76 FR 77467). The findings of the new review are expected to be announced in June 2013.

Distribution, Migration and Habitat Use

Ribbon seals occur in the northern North Pacific Ocean and adjoining sub-Arctic and Arctic seas, primarily the Sea of Okhotsk and Bering Sea. They are strongly associated with sea ice during whelping, mating, and molting from mid-March through June (Burns 1970). The rest of the year is mostly spent at sea. Ribbon seals are rarely observed on land or near land and appear to prefer the continental shelf slope (Heptner et al. 1976c).

In Alaska, ribbon seals are found in the open sea, on pack ice, and only rarely on shorefast ice. They range from Bristol Bay in the Bering Sea to the Chukchi and western Beaufort Seas (Figure 3.2-20). From late March to early May, they inhabit the Bering Sea ice front (Braham et al. 1984, Burns 1970). During May and June, ribbon seals haul out on ice floes where weaned pups become self–sufficient and adults molt. As summer progresses and ice melts, at least part of the Bering Sea population migrates into the Bering Strait and Chukchi Sea (Fay 1974, Lowry 1985).

Research from the 1970s through 1980s, including observations by subsistence hunters, concluded that few ribbon seals passed through the Bering Strait. Ribbon seals were rarely seen by subsistence hunters from villages along the southern Chukchi Sea coast in Alaska and were rare in the northern Chukchi Sea (Burns 1981).

Satellite tag data from 2005 and 2007 indicated that ribbon seals disperse widely and into the Chukchi Sea. Eight seals tagged in the central Bering Sea in 2007 moved to the Bering Strait, Chukchi Sea, or

Arctic Basin as ice retreated northward and remained there for at least part of the summer and autumn. Three moved south of the Bering Strait before ice reformed in the Chukchi Sea. Most of the seals tagged in the central Bering Sea did not travel north of the Bering Strait (Boveng et al. 2008).

Ribbon seals primarily consume pelagic and nektobenthic prey, including demersal fishes and cephalopods. Arctic cod were important prey in the northern Bering Sea (Ziel et al. 2008).

Reproduction and Growth

Ribbon seals reach sexual maturity at one to five years of age, depending on environmental conditions. Adult females annually give birth to a single pup (Boveng et al. 2008). Whelping in the Bering Sea occurs from late March to mid-May, with a peak in early to mid-April (Burns 1981). Pups are nursed for three to four weeks, during which time their weight may triple from about 9.5 to 28.5 kg (20.9 to 62.8 lbs) (Burns 1981). Breeding takes place after weaning, at the end of April to early May (Boveng et al. 2008).

Survival and Mortality

Very little is known about survival rates, but ribbon seals may live 20 to 30 years. An estimated 25 percent of ribbon seals survive to reach sexual maturity at age five. Mortality for pups in their first year was estimated to be 45 percent; this decreased to 8 to 10 percent for adults annually (Boveng et al. 2008).

Ribbon seals were commercially harvested by the Soviet Union beginning in the Sea of Okhotsk in the 1930s. Catches increased to approximately 20,000 ribbon seals annually during the 1960s (Heptner et al. 1976c).

Commercial sealing expanded to the Bering and Chukchi Seas in 1961. Due to overharvest, the Bering Sea ribbon seals declined (Burns 1981) from an estimated 80,000 to 90,000 in 1963 through 1964 (Fedoseev 2000) to about 60,000 to 70,000 in 1969. Harvest restrictions were imposed in 1969 (Fedoseev 2000).

Ribbon seals are harvested by Alaska Native subsistence hunters, primarily from villages along the Bering Strait and to a lesser extent at villages along the Chukchi Sea coast (See Section 3.3.2, Subsistence Resources and Uses).

Incidental mortality in commercial fisheries is minimal. There were observed mortalities of ribbon seals incidental to the Bering Sea/Aleutian Islands flatfish trawl fishery, the Bering Sea/ Aleutian Islands Atka mackerel trawl fishery, and the Bering Sea/ Aleutian Islands pollock trawl fishery between 2007 and 2009, for an estimated annual mortality rate of 2.25 seals (Allen and Angliss 2012b).

There is little evidence of predation on ribbon seals, and they are not considered primary prey of any predators. Polar bears and killer whales are the most likely opportunistic predators (Boveng et al. 2008).

A variety of pathogens, diseases, helminthes, cestodes, and nematodes have been found in ribbon seals, yet the prevalence is not unusual for seals (Boveng et al. 2008).

Hearing and Other Senses

The estimated auditory bandwidth of ribbon seals is 75 Hz to 75 kHz in water and 75 Hz to 30 kHz in air (Southall et al. 2007). There is some information available about the vocalizations of ribbon seals. The only recordings of underwater sounds were off St. Lawrence Island in the 1970s (Watkins and Ray 1977 cited in Frankel 2009). The two recorded sounds were described as “intense downward frequency sweeps” and a “broadband puffing” sound. The downsweeps were of three types: long (from 7100 to 200 Hz); medium (from 5300 to 100 Hz); and short (from 2000 to 300 Hz). The puffing sounds were below 5 kHz (Frankel 2009). Additional information on hearing and other senses for seals in general can be found in the ringed seal description above.

Bearded Seal: Alaska Stock (Beringia Distinct Population Segment)

Species Description

Bearded seals are the largest of the true seals, or phocids. They are distinguished by their girth; small head in proportion to body size; unpatterned gray to brown pelage; long, mustache-like whiskers; and square-shaped front flippers. Some individuals have a rust-colored head and fore flippers (Lydersen et al. 2001). Adults are 2 to 2.5 m (6.5 to 8.2 ft) long, with an average weight of 250 to 300 kg (551.1 to 661.4 lbs). Sexes are generally indistinguishable, although females may be larger than males and weigh more than 425 kg (937.0 lbs) in the spring (Kovacs 2009).

Population Status and Trends

The two subspecies of bearded seals are *E. b. barbatus* in the Atlantic and *E. b. nauticus* in the Pacific. *E. b. nauticus* was further divided into an Okhotsk DPS and a Beringia DPS (Heptner et al. 1976c, Ognev 1935). The Beringia DPS was named for the land bridge—Beringia--that was exposed during the last glaciation and over which the range of bearded seals in the Bering, Chukchi, Beaufort, and East Siberian lies (Cameron et al. 2010).

Aerial surveys were flown along the Chukchi Sea coastal regions from Shishmaref to Barrow during May to June 1999 and 2000. The average density of bearded seals was 0.07 seals/km^2 in 1999 and 0.14 seals/km^2 in 2000. Highest densities were along the coast south of Kivalina (Bengtson et al. 2005). Accurate abundance estimates were not calculated due to lack of correction factors. A rough estimate, based on the densities, was 13,600 bearded seals for the U.S. coastal portion for the Chukchi Sea. If the Russian portion of the Chukchi Sea has similar numbers of bearded seals, a combined total would then be roughly 27,000 seals (Cameron et al. 2010).

Estimates for the Beaufort Sea, extrapolated from surveys in the eastern Beaufort in the 1970s and not corrected for seals in the water, was 3,150 seals (Stirling et el. 1982). This is likely a gross underestimate (Cameron et al. 2010).

On December 10, 2010, NMFS announced a 12-month finding on a petition to list the bearded seal as a threatened or endangered species in the *Federal Register* (75 FR 77496). In the *Federal Register* notice NMFS determined the Beringia DPS and the Okhotsk DPS are likely to become endangered throughout all or a significant portion of their ranges in the foreseeable future, but that such a determination is not warranted for *E. b. barbatus*. This announcement issued the proposed rule to list the Beringia DPS and the Okhotsk DPS of the bearded seal as threatened species; no listing action was proposed for *E. b. barbatus*. The basis for the determination was the likelihood of current and future sea-ice habitat modification due to climate change and marine habitat modification due to ocean acidification. On December 28, 2012, NMFS published the final rule in the *Federal Register* (77 FR 76740) listing the Beringia DPS and Okhotsk DPS of the bearded seal as threatened.

Distribution, Migration and Habitat Use

Bearded seal distribution is circumpolar (Burns 1967, Burns and Frost 1979, Kelly 1988) and extends from the Arctic Ocean (85°N) to Sakhalin Island (45°N) in the Pacific (Allen 1880, Ognev 1935). Distribution and seasonal movements are closely associated with seasonal changes in sea ice. Sea ice provides an important platform on which bearded seals haul out to give birth, nurse pups, rest, and molt. Bearded seals prefer ice in constant motion, with natural openings and areas of open water, such as leads, fractures, and polynyas (Heptner et al. 1976d). Bearded seals in the Beaufort Sea were most abundant where drifting pack ice interacts with fast ice, creating leads and other openings (Burns and Frost 1979).

Most adult bearded seals move north from the Bering Sea into the Bering Strait and Beaufort and Chukchi seas in spring as the ice retreats. From summer to early fall, they occur along the southern edge of the Beaufort and Chukchi Sea pack ice (Heptner et al. 1976d). Most bearded seals migrate south through the Bering Strait to the Bering Sea ahead of the advancing ice in the fall and winter. During late winter and early spring, bearded seals are widely distributed in the broken, drifting pack ice from the Chukchi Sea to the ice front in the Bering Sea (Figure 3.2-21) (Cameron et al. 2010).

Recent acoustic data indicate that bearded seals are present in the Chukchi Sea throughout the year. Acoustic detections of calls were highest off Wainwright and Barrow during the breeding season in May and June (Hannay et al. 2011). Bearded seals were visually detected during June to November COMIDA surveys in all years (2008 through 2010). Sightings were concentrated between Wainwright and Barrow during summer but otherwise spread throughout the survey area (Clarke et al. 2011a, 2012). Two female bearded seals tagged in Kotzebue Sound in 2011 travelled to and occupied the central Chukchi Sea prior to moving south to the Bering Sea with advancing sea ice in the fall (Native Village of Kotzebue 2012). Sub-adult males tagged in 2009 and 2011 remained nearer to shore between Point Hope and Wainwright, while the adult male tagged in 2009 traveled to an area near Prudhoe Bay, with occasional forays into deeper water to the north (Native Village of Kotzebue 2012).

Bearded seals were commonly observed during BWASP fall surveys. Distribution for 2006 through 2009 was consistently across the Beaufort Sea survey area and into the northeastern part of the Chukchi Sea (Clarke et al. 2011b, 2011c). Bearded seals were also sighted across the northeastern Chukchi and Alaskan Beaufort seas during 2011 ASAMM (formerly COMIDA and BWASP) surveys. Five were hauled out on ice; the rest were in open water (Clarke et al. 2012).

Pregnant females generally overwinter on drifting ice in the Bering Sea where they whelp and wean before migrating north. Wintering and whelping bearded seals are also found in coastal leads of the Bering and Chukchi Seas, including Bristol and Kuskokwim Bays, Norton and Kotzebue Sounds, the Gulf of Karaginskiy, the Gulf of Anadyr, and near Point Hope (Coffing et al. 1998, Georgette et al. 1998).

It is unusual for bearded seals in the Bering, Beaufort and Chukchi seas to haul out on land. Younger bearded seals have, however, been seen hauled out on land in lagoons and up rivers near Wainwright and on sandy islands near Barrow (Nelson 1981).

Since bearded seals feed benthically (on the ocean bottom), they generally associate with seasonal sea ice over shallow water of less than 200 m (656 ft). In the Beaufort Sea, bearded seals prefer areas of open ice cover and water depths of 25 to 75 m (82 to 246 ft) (Stirling et al. 1982). In the eastern Chukchi Sea, highest densities in May and June were in the offshore pack ice where benthic productivity is high (Bengtson et al. 2005). The shallow continental shelf area of the Bering and Chukchi Seas includes about half of the Bering Sea, the Bering Strait, and most of the Chukchi Sea. Bearded seals can dive to the bottom all along the shallow shelf, making it a favorable foraging habitat (Burns 1967).

Bearded seals primarily prey on benthic organisms, such as epifaunal and infaunal invertebrates and demersal fishes. Crabs, shrimp, and clams are major prey for bearded seals in the Bering, Beaufort, and Chukchi seas. Tanner crabs are important in the southern Bering Sea, and spider crabs are important in the northern Bering, Beaufort, and Chukchi seas. Sculpins, Arctic cod,, and saffron cod can also be important prey (Allen 1880, Antonelis et al. 1994, Dehn et al. 2007, Finley and Evans 1983, Heptner et al. 1976d, Kenyon 1962, Lowry et al. 1980, Ognev 1935, Quakenbush et al. 2011a, Wilke 1954). Prey preferences apparently changed over time. The consumption of fish and diversity of fish consumed increased while crustacean (primarily decapod) consumption decreased from the 1960s-1970s to the 2000s (Quakenbush et al. 2011a).

Reproduction and Growth

Female bearded seals reach sexual maturity at five to six years, and males become sexually mature at six to seven years. Most adult female bearded seals annually produce a single pup. Pupping takes place from mid-March to early-May in the central Bering Sea. The peak pupping in the Bering Strait and central Chukchi Sea occurs in late April (Heptner et al. 1976d).

Newborn bearded seals in the Bering and Chukchi Seas weigh an average of 33.6 kg (74.1 lbs) and are 131.6 cm (51.8 in) long. Pups grow rapidly and gain an estimated 2.8 to 3.6 kg (6.2 to 7.9 lbs) per day (Kovacs and Lavigne 1986, Lydersen and Kovacs 1999). Weight increases to about 85 kg (187.4 lbs) by the time of weaning at 12 to 18 days. The pups are able to enter the water within hours of birth and begin to forage while still nursing (Cameron et al. 2010).

Survival and Mortality

Bearded seals typically live 20 to 25 years (Kovacs 2009), with a maximum of around 30 years (Cameron et al. 2010).

Sources of mortality include subsistence hunting, fisheries interactions, and predation. Bearded seals have been an important subsistence species for Alaska Natives for thousands of years and continue to be so today. See Section 3.3.2, Subsistence Resources and Uses, for details on the subsistence harvest of bearded seals.

Mortality incidental to the Bering Sea/Aleutian Islands pollock trawl fisheries is rare but known to occur.

Between 2007 and 2009, there were incidental serious injuries and mortalities of bearded seals in the Bering Sea/Aleutian Islands pollock trawl and the Bering Sea/Aleutian Islands flatfish trawl fisheries, resulting in an estimated minimum annual mortality rate of 2.7 bearded seals (Allen and Angliss 2012a).

Mortalities incidental to permitted marine mammal research activities may occasionally occur. One mortality, resulting from research on the Alaska stock of bearded seals, was reported between 2003 to 2007 (Tammy Adams, Permits, Conservation, and Education Division, Office of Protected Resources, NMFS, cited in Allen and Angliss 2010).

Polar bears are the primary predators of bearded seals. Other predators include brown bears, killer whales, sharks, and walrus (Cameron et al. 2010).

Relatively little is known about diseases and causes of natural mortality in bearded seals, other than predation by polar bears. A variety of diseases and parasites, with which the seals likely co-evolved, have been documented in bearded seals. The observed prevalence is not unusual (Cameron et al. 2010). Symptoms characteristic of the disease outbreak described above for ringed seals were documented in low numbers of bearded seals in the Bering Strait/Chukchi Sea region in 2011.

Hearing and Other Senses

As with other pinnipeds, the estimated auditory bandwidth of bearded seals is 75 Hz to 75 kHz in water and 75 Hz to 30 kHz in air (Southall et al. 2007).

Male bearded seals vocalize during the breeding season. They produce four basic call types: trill; moan; sweep; and ascent. Trills, the predominant call during the breeding season, are one of the more distinctive calls of any marine mammals. The frequency modulated vocalizations with long downsweeps that begin between 3 and 6 kHz, can propagate up to 30 km (18.6 mi), and last up to 60 s (Cameron et al. 2010, Frankel 2009). The sounds of bearded seals during their breeding season (May) increases the ambient noise level by as much as 20 dB (Hannay et al. 2011).

Another sensory adaptation of bearded seals is that for which they were named—their well-developed facial whiskers. Theirs are among the most sensitive in the animal world with 1,300 nerve endings associated with each whisker. This extreme sensitivity is thought to be an adaptation to benthic feeding (Kovacs 2009). Additional information on hearing and other senses for seals in general can be found in the ringed seal description above.

Pacific Walrus

Species Description

The walrus is the only living member of the pinniped family Odobenidae. The species' Latin name *Odobenus rosmarus* means "tooth walking sea horse" (Kastelein 2009), in honor of one of their more distinguishing characteristics. The upper canine teeth are enlarged to form prominent tusks, which are longer and thicker in males than in females (Garlich-Miller et al. 2011).

The walrus is the largest pinniped species in the Arctic. Males are larger than females, with an average body length of 230 cm (90.5 in) and weight of 1,200 to 1,500 kg (2,646 to 3,307 lbs), compared to 270 cm (106.3 in) and 600 to 850 kg (1,323 to 1,874 lbs) for females (Kastlein 2009). Females attain maximum size by about 10 years old and males at about 15 to 16 years (Fay 1982).

Walrus are social and gregarious animals. They tend to travel and haul out on ice or land in densely packed groups. When hauled out, walrus tend to lie close together, with young animals often on top of adults. Group size can range from a few individuals, up to several thousand animals (Gilbert 1999, Kastelein 2002).

Population Status and Trends

The three modern subspecies of walrus are the Atlantic walrus (*O. r. rosmarus*), the Pacific walrus (*O. r. divergens*), and the Laptev walrus (*O. r. laptevi*) (ITIS 2010). The Pacific walrus is represented by a single population that inhabits continental shelf waters of the Bering and Chukchi Seas (Fay 1982), and is the only subspecies expected to occur in the EIS project area (Quakenbush 2010).

A portion of the spring range of Pacific walrus was surveyed in 2006 using a combination of thermal imaging and satellite transmitters. The number of walrus within the area of the Bering Sea pack ice that was surveyed was estimated at 129,000 individuals (Speckman et al. 2010). This represents only a partial population estimate, since only about half of the potential walrus habitat was surveyed (Speckman et al. 2010).

On February 10, 2011, the USFWS published a notice of a 12-month finding in the *Federal Register* (76 FR 7634 [2011a]) on a petition to list the Pacific walrus as threatened or endangered under the ESA. It was determined that listing the Pacific walrus was warranted but precluded by higher priority actions. The two factors considered primary threats to the Pacific walrus in the foreseeable future and the reason for the determination are the impacts of the loss of sea ice in summer and fall and subsistence harvest. Upon publication of the notice, the Pacific walrus was added to the USFWS list of candidate species.

Distribution, Migration and Habitat Use

Pacific walrus range across continental shelf waters of the northern Bering Sea and southern Chukchi Sea (Figure 3.2-22). Adult males remain in the Bering Sea to forage from coastal haul outs during the ice free season. The rest of the population migrates seasonally in conjunction with seasonal advance and retreat of sea ice (Garlich-Miller et al. 2011).

Walrus congregate in the Bering Sea pack-ice adjacent to areas with open water, such as leads and polynyas, during the breeding season from January to March (Fay et al. 1984b). Breeding aggregations are common southwest of St. Lawrence Island, south of Nunivak Island and south of the Chukotka Peninsula in the Gulf of Anadyr (Speckman et al. 2010).

Most of the population migrates north through the Bering Strait to summer feeding areas over the continental shelf in the Chukchi Sea when the ice in the Bering Sea breaks up in spring. Summer distribution in the Chukchi Sea depends on sea ice distribution and extent. Walrus form patchy aggregations across the continental shelf when loose pack ice is abundant. Aggregations range in size from less than 10 to more than 1,000 individuals (Gilbert 1999, Ray et al. 2006). Walrus concentrate in loose pack ice off the northwest coast of Alaska between Icy Cape and Point Barrow and along the coast of Chukotka, Russia, to Wrangel Island (Belikov et al. 1996, Gilbert et al. 1992). The return southbound migration to the Bering Sea wintering areas occurs in September and October in advance of sea ice formation in the Chukchi Sea. Large herds may gather to rest during migration at haul outs in the southern Chukchi Sea (Belikov et al. 1996).

Walrus were observed in June to October 2008 through 2011 during aerial surveys of the northeastern Chukchi Sea (Clarke et al. 2011a, 2012). Distribution was broad and associated with sea ice in June to early August. It then shifted to nearshore open water and coastal habitat in late August and September. Few were seen in the area in October 2008 to 2010 (Clarke et al. 2011a). Walrus were generally more common in the benthic-dominated ecosystem areas immediately southwest of Hanna Shoal (also referred to as the Burger and Statoil study areas) than in the pelagic-dominated Klondike prospect area further southwest during 2008 to 2010 CSESP surveys of the Lease Sale 193 area in the northeastern Chukchi Sea (Aerts et al. 2011). High biomass and numbers of bivalves, polychaetes, and sipunculid worms in these areas represent abundant prey for benthic feeding walrus (Blanchard et al. 2011). Walrus detected during fall BWASP surveys in 2006 and 2007 were north and east of Barrow (Clarke et al. 2011b, 2011c). No walrus were observed in the Alaskan Beaufort Sea in 2011 (Clarke et al. 2012).

Acoustic detections indicate that walrus are present in the Chukchi Sea from early June through December. Calls peaked in August and September, with the highest level of detections occurring off Wainwright (Hannay et al. 2011).

Walrus have been visually and acoustically detected in the vicinity of Hanna Shoal and between Hanna Shoal and Wainwright as late as December (Clarke et al. 2011a; Hannay et al. 2011). Walrus satellite-tagged in 2010, 2011, and 2012 regularly frequented Hanna Shoal during July through mid-September. This was particularly true in 2012 when tracking showed nearly all of the tagged walrus on or near Hanna Shoal from August into September (USGS 2011, 2012) where grounded ice remained later than in surrounding areas. Walrus observed offshore during August and September 2011 ASAMM aerial surveys showed a preference for Hanna Shoal, presumably using it as a feeding area (Clarke et al. 2012).

Sea ice serves as a platform for resting between feeding bouts, breeding, calving, and care of dependent young (Fay et al. 1984b, Kelly 2001). Walrus may haul out on land when sea ice is not available, which has occurred during several years since the mid-1990s. Females avoid using terrestrial haul outs, when possible, possibly because calves are more vulnerable to trampling (Fishbach et al. 2009).

Foraging trips last for a few hours to several days. Foraging trips from sea ice tend to be shorter than those from land. It is, presumably, more cost effective to haul out near the productive feeding areas and expend less energy traveling (Cooper et al. 2006).

Recent use of coastal haul outs along the northwestern Alaska coast is influenced by the availability of sea ice. In 2006 and 2008 walrus remained with the ice pack throughout the summer and fall, but in 2007, 2009, and 2010, the pack-ice retreated beyond the continental shelf and walrus hauled out on land at several locations between Point Barrow and Cape Lisburne (Clark et al. 2011a, Thomas et al. 2009). Between 2 and 13 September 2009, approximately 2,500 walrus were observed hauled out on Icy Cape. In 2010, walrus were distributed throughout the northeast Chukchi Sea in the water and on scattered ice floes in early August. In late August, most shifted nearshore between Point Lay and Barrow. On 30 August 2009, several large coastal haul outs with 2,500, 1,000, and 200 animals were documented east of Cape Lisburne. A coastal haul out near Point Lay had approximately 4,000 animals. The Point Lay haul out persisted through much of September, with counts ranging from <1,000 to >15,000 animals (Clarke et al. 2011a). In 2011, the haulout near Point Lay was observed earlier (mid-August) and persisted longer (to early October) than in previous years. Group sizes ranged from 1,000 to 20,000 walruses (Clarke et al. 2012).

Walrus are benthic feeders, specializing in invertebrates. Prevalent prey in both the Bering and Chukchi Seas includes bivalves, gastropods, and polychaete worms. Bivalves were more common in walrus stomachs from the Bering Sea and polychaete worms were more common in the Chukchi Sea (Sheffield and Grebmeier 2009). Sheffield and Grebmeier (2009) suggest that walrus exploit different benthic prey throughout their range depending on biomass availability and not just species.

Reproduction and Growth

Males reach sexual maturity at 6 to 7 years old, but are not likely to successfully compete for females until they are at least 15 years old (Fay 1982, Fay et al. 1984a). Females reach sexual maturity at 4 to 7 years old (Garlich-Miller et al. 2006). Mating takes place from January through March, and a single calf is born in May of the following year (Fay 1982). Newborn calves weigh 65 kg (143.3 lbs) and are 113 cm (44.5 in) long on average (Fay 1982).

Walrus have the lowest birth rate of any pinniped species. This is offset by a high level of maternal investment and the resulting high rates of calf survival. Females and newborn calves remain on ice floes until calves develop enough energy reserves to thermoregulate properly. The calf remains with its mother for at least two years. The prolonged nursing period of 1 to 2 years may suppress ovulation so that the birth interval is 3 or more years (Garlich-Miller and Stewart 1999). Young female walrus generally remain with groups of adult females after weaning, whereas young males associate with groups of other males (Fay 1982).

Survival and Mortality

Walrus may live to be 40 to 45 years old. Estimated survival rates for the first year of life are between 0.5 and 0.9. Survival rates may be as high as 0.96 to 0.99 for juveniles and adults (4 to 20 years old) (DeMaster 1984, Fay et al. 1997).

Walrus were historically harvested commercially. American whalers in the Bering Sea intensified hunts in the mid- to late-1880s. An estimated 15,000 to 20,000 were harvested annually between 1860 and 1880, with 60,000 reportedly taken between 1868 and 1872 (Fay 1957). The population decreased dramatically as a result, as did harvest levels. Annual harvests of 5,000 to 7,000 continued from 1910 to 1950 (Fay 1957). In 1960 and 1961, the State of Alaska imposed restrictions on subsistence takes in order to promote recovery of the population, which, by the 1980s appeared to be recovered to its pre-exploitation level (Fay et al. 1989).

The Pacific walrus is an important subsistence resource in many coastal communities along the Bering and Chukchi Sea coasts of Alaska (U.S.) and Chukotka (Russia). See Section 3.3.2, Subsistence Resources and Uses, for further details.

Incidental mortality of Pacific walrus in commercial fisheries is insignificant. Observed mortality in the Bering Sea/Aleutian Islands flatfish fishery averaged 1.8 walrus per year between 2002 and 2006 (Allen and Angliss 2010).

Disturbance-induced stampedes from haul outs can lead to injuries and mortalities. Calves and young animals are particularly vulnerable to trampling injuries (Garlich-Miller et al. 2011). A mortality event documented by USGS in September 2009 may have resulted from trampling of young walrus hauled out onshore near Icy Cape. One hundred thirty one (131) carcasses were counted on sandy beaches from Wainwright to Icy Cape. This is the first reported large mortality event for walrus hauling out on the Alaskan Chukchi Sea coast and may relate to the loss of sea ice over the Chukchi Sea continental shelf (Fischbach et al. 2009).

Pacific walrus are one of the largest animals of the Bering and Chukchi Seas. As such, they have relatively few natural predators. The principal natural predators of Pacific walrus are polar bears and killer whales.

Diseases and predation are not currently posing significant threats to the Pacific walrus population (Garlich-Miller et al. 2011).

In August and September 2011, approximately six percent of Pacific walrus hauled out at Point Lay had skin ulcers or sores similar to that characteristic of the disease outbreak reported for ringed seals. Most involved juveniles and subadults (NOAA 2012b). Although a similar disease condition has been observed in Chukotka, Russia, the only haulout where it was reported in Alaska was at Point Lay; other Alaskan walrus hunting communities report healthy animals (Stimmelmayr 2012a). In December, 2011, NOAA and the USFWS declared the walrus (and ringed seal) deaths an UME (NOAA 2011d). There have been no reports of widespread illness or mortality in harvested walrus as of June 2012 (NOAA 2012b).

The underlying cause is still unknown and it is not known if the seal and walrus diseases are related. Despite numerous tests for viral, bacterial pathogens, and biotoxins, no specific disease agent or process has been identified. The following have been ruled out, so far: Phocine distemper, influenza, Leptospirosis, Calicivirus, orthopoxvirus, and poxvirus, foot and mouth disease, VES, pan picornavirus, and Rickettsial agents (NOAA 2012a, 2012b). Tissue samples were also collected to analyze heavy metals, radionuclides (radiation), and persistent organic pollutant levels (NOAA 2012b). Results are pending, although preliminary screening showed radiation levels within the typical background range for Alaska and not of a level that would cause the observed symptoms (NOAA 2012c).

Hearing and Other Senses

As with other pinnipeds, the estimated auditory bandwidth of walrus is 75 Hz to 75 kHz in water and 75 Hz to 30 kHz in air (Southall et al. 2007).

Walrus produce a variety of sounds in and out of water. Acoustic threats when hauled out include roars, grunts, and guttural sounds, ranging in frequency from 13 Hz to 4 kHz. Males sing on the mating grounds and at summer seasonal haulouts. Songs include sequences of pulsed sounds and bell-like sounds. Pulsed sounds include intense “knocks” of 0.2 to 8 kHz and “taps” produced more rapidly at 0.2 to 4 kHz. Males also produce gong-like sounds (Frankel 2009).

3.2.4.4 Fissipeds

Polar Bear: Chukchi/Bering Seas Stock and Southern Beaufort Sea Stock

Species Description

Polar bears are the largest of the living bear species and have a longer neck and proportionately smaller head than other bears (DeMaster and Stirling 1981). Adult males are larger than adult females. Males can be 230 to 285 cm (90.5 to 112.2 in) long and weigh over 650 kg (1,433.0 lbs). Females range in size from 180 to 240 cm (70.8 to 94.5 in) in length and 181 to 317 kg (399.0 to 698.9 lbs) in weight (Amstrup 2003). The fur ranges in color from white, to yellow, to grey, to almost brown. The nose, lips, and skin are black (Amstrup 2003, DeMaster and Stirling 1981).

Adaptations to living on sea ice include white fur with water repellent guard hairs and a dense under-coat; a short snout; small ears; teeth specialized for eating meat; and hair on the soles of the feet. The large, paddle-like feet help disperse weight when walking on thin ice and aid in swimming (Stirling 1988).

Population Status and Trends

The two stocks of polar bears in Alaska are the Southern Beaufort Sea stock and the Chukchi/Bering Seas stock. Low population densities, inaccessible habitat, cross-boundary politics and budget constraints have made estimating abundance of the Chukchi/Bering Sea population difficult (Lentfer and Galster 1987).

There is currently no reliable population estimate for the Chukchi/Bering seas stock. The IUCN Polar Bear Specialist Group estimated a population of approximately 2,000 animals by extrapolating multiple years of aerial den survey data. However, the estimate is imprecise and not useful for evaluating status and trends for this population (Lunn et al. 2002). Sufficient information is available to support sound scientific judgments and reasoned managerial decisions. More accurate counts are not essential for a reasoned choice among alternatives. Furthermore, the missing information pertains to impacts that are common to all alternatives, limiting the utility of this information to the decision maker.

The southern Beaufort Sea population has been studied since 1967. The most current and valid population estimate (1,526 bears) was based on data collected from 2001 to 2006. The area to which this applies extends from Point Barrow east to the Baillie Islands in Canada (Regehr et al. 2006). The overall population growth rate declined by approximately 0.3 percent per year for the years 2001 to 2006 (Hunter et al. 2007).

A determination of threatened species status for the polar bear throughout its range was published by the USFWS in the *Federal Register* on May 15, 2008 (73 FR 28212). This determination was based on declining sea ice habitat throughout the species range and the anticipated continued decline in the foreseeable future. This loss of sea ice habitat was considered a sufficient threat that polar bears were considered likely to become an endangered species in the foreseeable future throughout all of its range.

Distribution, Migration and Habitat Use

Polar bears are distributed across ice-covered waters of the circumpolar Arctic. Sea ice is their primary habitat upon which they depend for most life functions, including hunting and feeding, breeding, travel, maternity denning areas, and resting (Stirling and Derocher 1993). Distribution and movements are intricately tied to seasonal sea ice dynamics and the polar bears range is limited to areas covered in sea ice for much of the year (Stirling et al. 1999, Quakenbush et al. 2009b).

Pack ice is the primary summer habitat for Alaska polar bears that use it for traveling, feeding, and denning in fall and winter. In the Beaufort Sea and to a lesser extent in the Chukchi Sea females may den and give birth to their young on the drifting pack ice (Amstrup and Gardner 1994). During the summer months when the sea-ice disappears from the Bering Sea and becomes reduced in the Chukchi Sea polar bears that occupy these areas can migrate as much as 1000 km (620 mi) to stay with the pack ice (Garner et al. 1990, 1994). During the summer months polar bears tend to concentrate along the edge or into the adjacent persistent pack ice. Distribution patterns for some populations during the open water and early fall seasons have changed over the last decade. Shorefast ice is important in the spring for preying on seal pups, traveling, and occasional denning. Leads that open and close between the active pack ice and shore-fast ice are important during winter and spring for feeding and travel (Schliebe et al. 2006a).

The Chukchi/Bering stock is widely distributed on pack ice in the Chukchi Sea, northern Bering Sea, and adjacent coastal areas in Alaska and Russia (Figure 3.2-23). The range extends to the northeast near the Colville Delta in the central Beaufort Sea and to the west near Chauniskaya Bay in the Eastern Siberian Sea. The southern boundary is determined by the annual extent of pack ice (Amstrup et al. 2005, Garner et al. 1990).

The Southern Beaufort Sea stock ranges east to south of Banks Island and east of the Baillie Islands, Canada (Amstrup et al. 2000). The western boundary is near Point Hope (Figure 3.2-23). Adult female polar bears from this stock occasionally move into an area that overlaps with the range of the Chukchi/Bering stock between Point Hope and Colville Delta, centered near Point Lay (Amstrup et al. 2000, Garner et al. 1990, Garner et al. 1994). Telemetry data showed that adult female polar bears from the Southern Beaufort Sea spend about 25 percent of their time in the northeastern Chukchi Sea, whereas females tagged in the Chukchi Sea spend only six percent of their time in the Southern Beaufort Sea (Amstrup 1995).

Polar bears do not disperse evenly throughout their range. Polar bears in the Southern Beaufort Sea concentrate in waters less that 300 m (984 ft) deep over the continental shelf and in areas with >50 percent ice cover in order to access ringed and bearded seals (Durner et al. 2004, Durner et al. 2006a, Durner et al. 2009, Stirling et al. 1999).

Polar bears from the Southern Beaufort Sea population historically denned on both the sea ice and in snow drifts on land. The number denning on sea ice declined from 62 percent (1985 to 1994) to 37 percent (1998 to 2004) in response to thinning of the sea ice (Fischbach et al. 2007). Additionally, a decline in hunting and more erosion may have made den sites on land more attractive. Barrier islands from Barrow to Kaktovik and coastal areas up to 25 miles inland, including the Arctic National Wildlife Refuge to Peard Bay, are the primary terrestrial denning areas for the Southern Beaufort Sea population in Alaska (Amstrup and Gardner 1994, Durner et al. 2001, Durner et al. 2006b, Durner et al. 2010). Polar bear denning occurs along the Chukchi Sea coast at Cape Lisburne, Cape Beaufort, the barrier islands between Point Lay and Peard Bay, the Kukpowruk, Kuk, and Sinaruruk rivers, Nokotlek Point, Point Belcher, Skull Cliff, and Wainright Inlet (Durner et al. 2010).

Distribution patterns have changed in recent years. In the Beaufort Sea more polar bears (up to 200) occurred on shore between 2000 and 2005 than at any previous time (Schliebe et al. 2006b). The reason for this is unclear, but a statistically significant relationship exists between the number of bears using the coast and the distance of the pack ice from shore. Telemetry data and habitat use data from the southern Beaufort Sea indicate shifting distribution during summer and fall, apparently in response to ice retreating farther offshore than in the past (Schliebe et al. 2006b). The number of bears on land increased when sea-ice retreated farthest from shore, but distribution was also related to the availability of subsistence harvested bowhead whale carcasses and the density of ringed seals offshore (Schliebe et al. 2008).

Polar bears were sighted in the northeastern Chukchi Sea all years of the COMIDA study (2008 to 2010). Most occurred west to northwest of Point Barrow during August 2008, including 10 bears observed swimming in open water. Of the ten bears, the southernmost bear was within 5 km (3.1 mi) of land and the northernmost was 90 km (60.0 mi) from the nearest land, but within 5 km (3.1 mi) of broken ice floes. Polar bears were also sighted in June of 2008, 2009, and 2010 (Clarke et al. 2011a). In 2011, only one polar bear was sighted during ASAMM surveys of the northeastern Chukchi Sea. The bear was swimming in open water approximately 65 km (40 mi) northwest of Icy Cape. Pack ice was estimated as 110 km (68 mi) offshore. No bears were sighted along the Alaskan coastline during ASAMM surveys (Clarke et al. 2012).

Polar bear sightings were also common during fall BWASP aerial surveys of the Beaufort Sea. During 2006 to 2009, all bears, except one, were on or near shore between Cape Halkett and Kaktovik. In 2009, one bear was seen swimming in open water 140 km (87.0 mi) north of the barrier islands (Clarke et al. 2011b, 2011c). In 2011, all polar bears sighted during ASAMM surveys were nearshore or onshore between Smith Bay and Kaktovik. No bears were sighted on ice; sea ice was not present near any of the sightings (Clarke et al. 2012).

Polar bears are apex predators in the Arctic marine ecosystem. Unlike other bear species that are generally omnivorous, polar bears are carnivores (Stirling 1988). Seals are their primary prey – particularly ringed seals and, in some areas, bearded seals or other ice seal species. Polar bears may occasionally prey on walrus, narwhals, and beluga whales (Calvert and Stirling 1990, Smith and Sjare 1990). Polar bears in the Beaufort Sea (e.g. at Barter Island, Cross Island, Barrow) gather to feed at the butchering sites of harvested bowhead whales. Bears observed feeding on these carcasses in the fall are generally large and healthy (Miller et al. 2006).

On December 7, 2010, the USFWS published a Final Rule in the *Federal Register* (75 FR 76086) designating critical habitat for U.S. populations of polar bears. This rule designated critical habitat in Alaska and adjacent territorial and U.S. waters and encompasses 484,734 km^2 (187,157 mi^2) (Figure 3.2-24). Excluded from designation were five U.S. Air Force Radar Sites, the Native communities of Barrow and Kaktovik, and all existing manmade structures (regardless of land ownership status).

Three habitat units designated were sea-ice habitat, terrestrial denning habitat, and barrier island habitat (Figure 3.2-24). The sea ice critical habitat area was located over the continental shelf in water 300 m (984 ft) or less in depth. The terrestrial denning habitat included lands within 32 km (19.8 mi) of the northern coast of Alaska between the U.S./Canadian border and the Kavik River and within 8 km (5.0 mi) between the Kavik River and Barrow. This area contained about 95 percent of known historical den sites from the southern Beaufort Sea population. Barrier island habitat included the coastal barrier islands and spits along Alaska's coast, along with the water, ice, and other terrestrial habitat within 1.6 km (0.99 mi) of the islands. On January 11, 2013, the U.S. District Court for the District of Alaska vacated the Final Rule, which designated critical habitat for the polar bear and remanded the matter back to the USFWS.

Reproduction and Growth

Polar bears have a low reproductive rate characterized by small litter sizes and extended parental investment (Angliss and Lodge 2004). Females come into estrus between March and June when breeding occurs. Mating induces ovulation (Ramsay and Dunbrack 1986).

In most areas, pregnant females come ashore in the fall (September to November) to excavate dens in snow drifts (Amstrup and Gardner 1994, Lentfer and Hensel 1980, Ramsay and Stirling 1990). Many pregnant females in the Beaufort Sea do not enter dens until late November or early December (Amstrup and Gardner 1994). In the Beaufort Sea and, to a lesser extent, the Chukchi Sea, females may den and give birth to their young on drifting pack ice (Schliebe et al. 2006a). As noted above, the use of pack ice for denning appears to be decreasing in recent years in the southern Beaufort Sea.

Females and cubs leave the dens in the spring (February through April) when their cubs are able to survive in the outside environment. They return to the sea ice soon thereafter (Amstrup 1995).

Newborn polar bears are helpless, blind, and weigh only 0.6 kg (1.3 lbs). Growth is rapid, and cubs may weigh 10 to 12 kg (22 to 26.5 lbs) when they emerge from the den. Weaning typically occurs in the spring when cubs are about 2 years old. Young bears remain with their mothers until then. Adult females can breed again once the cubs are weaned, resulting in a typical birth interval of 3 years (Schliebe et al. 2006a).

Survival and Mortality

Polar bears are long-lived. The oldest recorded age in the wild was 32 for a female and 28 for a male (Stirling 1990). The low reproductive rates of polar bears necessitate a high survival rate to maintain population levels (Schliebe et al. 2006a).

Polar bears have been harvested both commercially and for subsistence. Russia prohibited all hunting of polar bears in 1956 as populations declined (Uspenski 1986). Illegal hunting of polar bears in the Russian Arctic began to increase in 1992. As many as 150 to 250 bears may be illegally harvested from the Chukchi/Bering stock each year (Kochnev 2006). Subsistence hunting by Alaska Natives is discussed in Section 3.3.2, Subsistence Resources and Uses.

Polar bear stocks in Alaska have no direct interaction with commercial fisheries activities (Allen and Angliss 2012b).

Mortality related to industrial activities has occurred in the Southern Beaufort Sea. One incident was at an offshore drilling site in the Canadian Beaufort Sea in 1968. One bear died at the Stinson site in the Alaska Beaufort Sea in 1990, and another died after ingesting ethylene glycol stored at an offshore island in the Alaska Beaufort Sea in 1988. A polar bear was killed in self-defense at a remote radar defense site in 1993 after it severely mauled a worker (Allen and Angliss 2010). More recently (August 2011), a female polar bear was shot and killed by a security guard near employee housing at the Endicott oil field (Reuters 2011).

Polar bears are not known to be particularly susceptible to disease, parasites, or injury. *Trichinella* is commonly observed in polar bears throughout their range, but infections are not normally fatal (Rogers and Rogers 1976).

Hearing and Other Senses

There is limited information on the hearing of polar bears. Polar bears are not known to communicate underwater. Nachtigall et al. (2007) measured the in-air hearing of three polar bears using evoked auditory potentials. Measurements were not obtainable at 1 kHz, and best sensitivity was found in the 11.2 to 22.5 kHz range. Preliminary behavioral testing of hearing indicates that they can hear down to at least 14 Hz and up to 25 kHz (Bowles personal communication 2008 cited in URS 2009). Information on the hearing of polar bears is not relevant to reasonably foreseeable adverse effects, as the under water seismic activity would not interfere with their communication.

3.2.4.5 Influence of Climate Change on Marine Mammals

Climate change impacts on the Arctic are of growing concern. Changes to the physical environment in the Arctic are described in more detail in Sections 3.1.2.6 and 3.1.4.4. Increased temperatures, longer periods of open water with an earlier onset of melting and later onset of freeze-up, increased rain-on-snow events, warm water intrusion into the Arctic, and changing atmospheric wind patterns, are contributing to overall reduction and changes in sea ice and polar ecosystems (Allen and Angliss 2010). Loss of sea-ice is one of the most pronounced changes currently occurring and projected to continue into the future. Arctic sea ice is changing in extent, thickness, distribution, age, and timing of melt. Analysis of long-term data sets show substantial decreases in both extent (area of ocean covered by ice) and thickness of sea ice cover during the past 30 years (Perovich et al. 2010).

The impacts of climate change on marine mammals in the Arctic will likely be profound, but exactly what form these impacts will take is not easy to determine (ACIA 2005). Direct loss of habitat for feeding, breeding, pupping, and resting is likely, as are changes in prey composition and availability. Ice-obligate species, such as walrus, ringed seals, ribbon seals, bearded seals, spotted seals, and polar bears, are intricately tied to and heavily dependent upon sea ice and particularly vulnerable to changes. Concern over habitat degradation and loss due to climate change prompted petitions to list all of these species as either threatened or endangered under the ESA. Polar bears, ringed seals, and the Beringia Distinct Population Segment of bearded seals are now listed as threatened and walrus are a candidate species for listing (73 FR 79822; 73 FR 28212; 74 FR 53683;; 75 FR 65239;; 76 FR 7634; 77 FR 76706; 77 FR 76740). Detailed analyses of potential impacts of climate change on these species are available in the respective *Federal Register* notices and status reviews (see Boveng et al. 2008, Boveng et al. 2009, Cameron et al. 2010, Garlich-Miller et al. 2011, and Kelly et al. 2010a).

Recent shifts in distribution and habitat use by polar bears and walrus in the Beaufort and Chukchi seas are likely attributable to loss of sea ice habitat. Durner et al. (2009) predict that the greatest declines in twenty-first century optimal polar bear habitat will occur in these areas and, although the exact relationship between habitat loss and polar bear demographics is not known, reduced total optimal habitat will likely reduce polar bear populations. The increased frequency with which female polar bears in the southern Beaufort Sea now den on land rather than on pack ice was attributed to reductions in stable old ice, increases in unconsolidated ice, and lengthening of the melt season (Fischbach et al. 2007). Fischbach et al. (2007) anticipate this trend will continue as long as ice remains near enough to the coast in the fall to provide land access for pregnant females. Although population-level effects of sea-ice loss have only been observed in polar bears at the southern edge of their range in western Hudson Bay, models predict decreased survival (including breeding rates and cub litter survival) of polar bears in the southern Beaufort Sea with reduced sea-ice coverage (Hunter et al. 2011, Regehr et al. 2009). Reduced body size and cub recruitment in polar bears has been documented in years when sea ice availability was reduced (Rode et al. 2010). Over the past decade, the number of walrus coming to shore along the coastline of the Chukchi Sea in Russia has increased, and recent use of coastal haul outs along the northwestern Alaska coast was influenced by the loss of sea ice over the Chukchi Sea continental shelf (Clarke et al. 2011a, Clarke et al. 2012, Allen and Angliss 2010, Fischbach et al. 2009). Use of shore-based haul outs may leave walrus, particularly calves and juveniles, vulnerable to disturbance related stampedes and trampling mortalities (Fischbach et al. 2009).

Loss of sea ice habitat and associated ecosystems will impact access to prey, prey availability, and species composition. Predictions for biotic change include increased primary and secondary production, particularly in the central Arctic, during summer open-water conditions; reduced benthic and pelagic biomass in coastal/shelf areas (due to increased river runoff and changes in salinity and turbidity); and increased pelagic grazing and recycling in open-water as opposed to the current tight benthic–pelagic coupling in ice-covered shelf areas (Bluhm and Gradinger 2008). If this holds true, the feeding range for ice dependent, benthic shelf–feeding Arctic marine mammals, such as walrus and bearded seals, would decrease and nearshore areas may become less productive. This could prove advantageous to pelagic-feeding or generalist marine mammals species (Bluhm and Gradinger 2008).

Bowhead whales may be sensitive to changes in Arctic weather, sea-surface temperatures, or ice extent, and resulting impacts on prey availability. It is not, however, currently possible to make reliable predictions of the effects of climate change on the species. Research by George et al. (2006, cited in Allen and Angliss 2010) showed that the body condition of bowheads harvested by Iñupiat Eskimos was better during years of light ice cover. Thus far, it appears that the Western stock of bowhead whales is tolerating the recent ice loss in the Arctic (Allen and Angliss 2010).

Range expansion of sub-Arctic and temperate species into the Beaufort and Chukchi seas has been observed in recent years and could continue with changing Arctic conditions. Humpback whales and fin whales in the northeastern Chukchi Sea appears a relatively recent phenomenon (Clarke et al. 2011a). Thus far, potential range expansion into the Beaufort Sea is limited to one humpback whale sighting just east of Barrow in 2007. This was, incidentally, a low ice year (Hashagen et al. 2009). Along with range expansion of the more temperate species comes the possibility for competition for resources with Arctic species (ACIA 2005).

Other risks to Arctic marine mammals induced by climate change include increased risk of infection and disease with improved growing conditions for disease vectors and from contact with non-native species, increased pollution through increased precipitation transporting river borne pollution northward, and increased human activity through shipping and offshore development (ACIA 2005, Huntington 2009).

3.2.5 Terrestrial Mammals

There are approximately 30 species of terrestrial mammals within the vicinity of the EIS project area (Table 3.2-6). Among these species, it is expected that only barrenground caribou (*Rangifer tarandus granti*) may experience interactions with oil and gas exploration activities during critical periods of their life cycle; therefore, this section focuses only on caribou. Descriptions of distribution, life cycle, and habitat characteristics of other terrestrial mammal species are not included in this EIS.

Table 3.2-6 Terrestrial Mammals of the North Slope of Alaska

Terrestrial Mammals of the North Slope of Alaska		
Common Name	**Scientific Name**[2]	**Inupiaq Name**[3,3]
Arctic Ground Squirrel	*Spermophilus parryii*	Siksrik
Alaska Marmot	*Marmota broweri*	Siksrikpak
Collared lemming	*Dicrostonyx groenlandicus*	Qixafmiutauraq
Brown lemming	*Lemmus trimucronatus*	Aviffaq
Singing vole	*Microtus miurus*	Avieeaq
Root (Tundra) vole	*Microtus oeconomus*	Avieeaq
Northern red-backed vole	*Myodes rutilus*	
North American porcupine	*Erethizon dorsatum*	Qifabluk
Snowshoe hare	*Lepus americanus*	Ukalliq
Cinereus shrew	*Sorex cinereus*	Ugrufnaq
Dusky shrew	*Sorex monticolus*	
Tundra shrew	*Sorex tundrensis*	Ugrufnaq
Barren ground shrew	*Sorex ugyunak*	
Alaska tiny shrew	*Sorex yukonicus*	
Canadian lynx	*Lynx canadensis*	Niutuiyiq
Wolf	*Canis lupus*	Amabuq
Arctic fox	*Vulpes lagopus*	Tibiganniaq
Red fox	*Vulpes vulpes*	Kayuqtuq
Cross fox	*Vulpes vulpes*	Quanbaq
Brown bear	*Ursus arctos*	Akjaq
Wolverine	*Gulo gulo*	Qavvik
Ermine (short tailed weasel)	*Mustela erminea*	Itibiaq
Least weasel	*Mustela nivalis*	Itibiaq
Moose	*Alces americanus*	Tuttuvak
Barrenground caribou	*Rangifer tarandus granti*	Tuttu
Muskox	*Ovibos moschatus*	Umifmak
Dall's sheep	*Ovis dalli*	Imnaiq

3.2.5.1 Caribou

Four caribou (also known as "*Tuttu*" to local Iñupiat residents) herds utilize habitats along Alaska's North Slope: the Western Arctic, the Porcupine, the Central Arctic, and the Teshekpuk herds (MMS 2008, ADFG 2010a). Of those, the Western Arctic and Porcupine herds make up approximately half of the total caribou population in Alaska (ADFG 2008). Barrenground caribou generally have large home ranges throughout this treeless tundra region often migrating long distances between winter ranges, calving grounds, and summer feeding areas. Calving areas are usually located in mountain foothills or on open

[2] Nomenclature according to MacDonald and Cook 2009
[3] Bacon and Akpik 2010
[3] Interactive Inupiaq Dictionary 2011

coastal tundra (ADFG 2008). North Slope caribou tend to calve in the same general areas year after year followed by movements to insect relief areas in the Brooks Range foothills and along certain stretches of the Arctic coast, which is further explained below. Sport hunters from across Alaska, other states, and other countries hunt caribou along the Arctic coast, and local residents depend on North Slope caribou populations for subsistence food (See Section 3.3.2, Subsistence Resources and Uses).

Population Status and Trends

The Western Arctic Caribou Herd

The geographic range of the Western Arctic Caribou Herd (WAH) is over 140,000 square miles in northwestern Alaska from the Colville River to the eastern Chukchi coast and from the Kobuk River to the southern Beaufort coast (Figure 3.2-2) (Dau 2005, ADFG 2009). During spring, the caribou travel north from the Seward Peninsula and Nulato Hills to their calving grounds toward the Lisburne Hills before the herd moves eastward through the Brooks Range. Typically, most pregnant cows reach the calving grounds by late May, calving in the Utukok uplands from May through early June. By mid-June, large post calving aggregations form, as cows with neonates move west (Dau 2005, MMS 2008). The WAH are dispersed in the fall as they move southwest toward their wintering grounds. In winter, the range extends south as far as the Seward Peninsula and Nulato Hills, and east as far as the Sagavanirktok River north of the Brooks Range and the Koyukuk River south of the Brooks Range. Since 1996, much of the WAH has shifted its winter range from the Nulato Hills to the eastern half of the Seward Peninsula and has generally been more dispersed than prior to that time (Dau 2005).

The WAH is the largest caribou herd in Alaska. In 1970, the WAH numbered approximately 242,000, and, by 1976, it had declined to approximately 75,000 animals. From 1976 to 1990, the WAH grew 13 percent annually, and from 1990 to 2003, it grew 1 to 3 percent annually. In 2003 the WAH numbered more than 490,000. As of July 2011, the population is reported to be about 325,000, which represents an estimated four to six percent annual decline since its peak in 2003 (Woodford 2012). The WAH calving area is inland on the NPR-A.

The Central Arctic Caribou Herd

As their name suggests, the Central Arctic Caribou Herd (CAH) roam the central region of northern Alaska (USFWS 2009b). The CAH range extends from the Itkillik River east to the Canning River and south from the Beaufort coast into the south slopes of the Brooks Range (Figure 3.2-3). CAH's summer range extends from Fish Creek, just west of the Colville River, eastward along the coast, and slightly inland, to the Katakturuk River. The CAH winters in the foothills and mountains of the Brooks Range; often overlapping with the Porcupine Caribou Herd (PCH) during the summer and winter and overlapping with the WAH and Teshekpuk Caribou Herd (TCH) in the summer and winter (Lenart 2005, MMS 2007a). The CAH has grown from an estimated 5,000 animals in 1975 to approximately 31,857 animals in 2002 (Lenart 2005, Cameron and Whitten 1979, ADFG 2009). Once thought to be part of the WAH, the CAH is now recognized as a distinct herd, an identification based on where females within the herd give birth to their calves (USFWS 2009b). The female caribou of the CAH calve across a broad swath of the Arctic coastal plain from the Canning River drainage of ANWR west to the Colville River. Most calves are born in areas on either side of the Prudhoe Bay oil complex (USFWS 2009b). Soon after calving season, CAH move outward both east and west to summer ranges, which extend from the ANWR coastal plain west, beyond Prudhoe Bay. In the fall, many of these caribou migrate south through the Brooks Range mountains, overwintering along south slope river drainages deep within ANWR. Some members of the herd, however, remain on their summer range north of the mountains throughout the year, foraging in wind-blown valleys and tundra benches for lichens necessary to survive during long, cold winters (USFWS 2009b).

Although the CAH traditionally calved between the Colville and Kuparuk rivers on the west side of the Sagavanirktok River and between the Sagavanirktok and the Canning rivers on the east side, the greatest concentration of caribou calving has shifted southwest. (Lawhead and Prichard 2002, Lenart 2007).

The Porcupine Caribou Herd

The Porcupine Caribou Herd (PCH) ranges through eastern portions of the Arctic Slope, the Brooks Range, northeastern Interior Alaska, and Canada's Northwest Territories (Figure 3.2-4). Named for the major river within its range, the Porcupine herd uses an area roughly the size of Wyoming in the Refuge, Yukon, and Northwest Territories. A July 2010 photographic census shows the PCH has grown to an estimated 169,000 animals. The herd peaked in size in 1989 at 178,000 caribou, and the four surveys that followed over the period of 1992–2001 documented a decline in the herd to 123,000 caribou. The 2010 effort is the first successful photographic census on the PCH since 2001, due to factors such as weather, poor aggregation, and herd movements (ADFG 2010a).

The calving grounds of the PCH include the northern foothills of the Brooks Range and the Arctic coastal plain from the Tamayariak River in Alaska to the Babbage River in Canada. The most often used calving area, however, is the Refuge coastal plain between the Katakturuk and Kongakut Rivers. Commonly, one-half to three quarters or more of the calves are born within this area (USFWS 2009b, ADFG 2010a). The PCH winters in the southern portion of its range, including the Refuge, where they are an important resource for the Gwich'in people (USFWS 2009b).

The Teshekpuk Caribou Herd

The Teshekpuk Caribou Herd (TCH) is distributed primarily within the NPR-A, with its summer range extending between Barrow and the Colville River (see Figure 3.2-5). In certain years, most of the TCH remains in the Teshekpuk Lake area all winter. In other years, some, or all, of the herd winters in the Brooks Range or within the range of the WAH. The TCH numbered about 45,000 animals in 2002, and the 2008 photographic census indicates the herd had grown to 64,000; up from a little more than 28,000 in 1999 (MMS 2007a, ADFG 2010a). In 1984, the herd only numbered 11,800 animals but has grown rapidly since then (ADFG 2010a). The TCH calve on the east side of Teshekpuk Lake (this herd is also sometimes called the Teshekpuk Lake Herd based on their calving area) and near Cape Halkett, adjacent to Harrison Bay (MMS 2007a).

Management

Alaska has a dual system for the management of fish and wildlife resources, as both state and federal harvest regulations apply to much of the state. The federal land management agencies regulate subsistence harvest on federal public lands, while the State of Alaska provides harvest opportunities for both recreational and subsistence purposes through the Alaska Board of Game's authorities. Subsistence harvest of caribou is discussed in more detail in Section 3.3.2, Subsistence Resources and Uses, but the foundation for the state's ungulate harvest regulations are described below.

The Alaska Legislature passed the Intensive Management Law in 1994 [Alaska Statute 16.05.255(e)-(g)]. This law requires the Alaska Board of Game to identify moose, caribou, and deer populations that are especially important food sources for Alaskan residents and to insure that these populations remain large enough to allow for adequate and sustained harvest (ADFG 2010a). Intensive management is a process that starts with investigating the causes of low ungulate numbers and then identifying steps to increase those numbers. This can include restricting hunting seasons and bag limits, evaluating and improving habitat, liberalizing the harvest of predators, and predator control. For purposes of implementing the Intensive Management Law, the Board of Game has determined that the Central Arctic, Teshekpuk, Western Arctic, and Porcupine caribou herds are important for providing high levels of harvest for human consumptive use and has established the following population and harvest objectives (AAC 2011) (Table 3.2-7).

Table 3.2-7 Population and Harvest Objectives

Caribou Herd	Population Objectives	Harvest Objectives
Western Arctic Caribou Herd	at least 200,000	12,000 - 20,000
Porcupine Caribou Herd	100,000 - 150,000	1,500 - 2,000
Central Arctic Caribou Herd	28,000 - 32,000	1,400 - 1,600
Teshekpuk Caribou Herd	15,000 - 28,000	900 - 2,800

Source: AAC 2011

Migration

Caribou migrate seasonally between their calving areas, summer range, and winter range to take advantage of seasonally available food resources. If movements are greatly restricted, caribou are likely to overgraze their habitat, potentially leading to drastic, long-term population declines. The caribou diet shifts from season to season and depends on the availability of forage. Generally, the winter diet of caribou consists of lichens, with a shift to vascular plants, such as *Eriophorum spp.*, sedges, and grasses, during the spring (Thompson and McCourt 1981). However, when TCH caribou winter near Teshekpuk Lake, where relatively few lichens are present, they typically consume more sedges and vascular plants (MMS 2007a).

Calving Grounds

Calving takes place in the spring, generally from late May to late June (Hemming 1971). Spring migration of parturient female caribou from the overwintering areas to the calving grounds starts in late March (Hemming 1971). Often the most direct routes are used; however, certain drainages and routes are theorized to be used during calving migrations because they tend to be corridors free of or with shallow snow (Lent 1980). Bulls and nonparturient females generally migrate later. Severe weather and deep snow can delay spring migration, with some calving occurring en route (Carroll et al. 2005). Cows calving en route usually proceed to their traditional calving grounds after giving birth (Hemming 1971, MMS 2007a).

The evolutionary significance of the establishment of the calving grounds may relate directly to the avoidance of predation on the caribou calves, particularly predation by wolves (Bergerud, 1974, 1987). Caribou calves are very vulnerable to wolf predation, as indicated by the documented account of surplus predation by wolves on newborn calves (Miller et al. 1985). By migrating north of the tree line, caribou leave the range of the wolf packs, which generally remain on the caribou winter range or in the mountain foothills or along the tree line during the wolf-pupping season (Heard and Williams 1991, Bergerud 1987). By calving on the open tundra, the cow caribou also avoid ambush by predators. The selection of snow-free patches of tundra on the calving grounds also helps to camouflage the newborn calf from other predators such as golden eagles (Bergerud 1987). It is also believed that the sequential spring migration, first by cows and later by bulls and the rest of the herd, is a strategy for optimizing the quality of forage as it becomes available with snowmelt on the Arctic tundra (Whitten and Cameron 1980, Griffith et al. 2002).

The timing of snow melt and plant “green up” on the coastal plain coincides with the caribou calving period. Traditional calving grounds consistently provide high nutritional forage to lactating females during calving and nursing periods, which is critical for the health of the cow and the growth and survival of newborn calves (USFWS 2009b). The ANWR coastal plain provides an abundance of plant species preferred by caribou, *Eriophorum*-tussock sedge buds (tussock cotton grass) appear to be very important in the diet of lactating caribou cows during the calving season (Lent 1966, Thompson and McCourt 1981, Eastland et al. 1989), while orthophyll shrubs (especially willows) are the predominant forage during the postcalving period (Thompson and McCourt 1981). The availability of sedges during spring, which is thought to be dependent on temperature and snow cover, probably affects specific calving locations and calving success. Finally, the earlier migration of parturient cow caribou to the calving grounds could also serve to reduce forage competition with the rest of the herd during the calving season (MMS 2007a).

The WAH calving area is inland on the NPR-A, outside of the EIS project area (Figures 3.2-2 and 3.2-6). Typically, most pregnant cows reach the calving grounds by late May. Most give birth in the Utukok uplands during late May through early June. By mid-June large post calving aggregations begin forming as cows with neonates move west toward the Lisburne Hills (Dau 2005). The TCH's central calving area is generally located on the east side of Teshekpuk Lake and near Cape Halkett, adjacent to Harrison Bay. The CAH generally calves within 30 km (18.6 mi) of the Beaufort coast between the Itkillik and Canning rivers. The herd separates into two segments based on the locations of the calving concentration areas, one on each side of the Sagavanirktok River (MMS 2007a). The PCH calves along the northern foothills of the Brooks Range and the Arctic coastal plain from the Tamayariak River in Alaska to the Babbage River in Canada. The most often used calving area, however, is the ANWR coastal plain between the Katakturuk and Kongakut Rivers (USFWS 2009b).

During the postcalving period in July through August, caribou generally attain their highest degree of aggregation with continuous masses of animals in herds, sometimes in excess of tens of thousands. Cow/calf groups are most sensitive to human disturbance during this period. However, during this time, most of the PCH has moved or is relocating to the Brooks Range foothills; therefore, most of this herd is no longer near the coast.

Summer Distribution/Insect Relief Areas

After calving, caribou collect in large "postcalving aggregations" to avoid predators and seek relief from mosquitoes and warble flies. These large groups of caribou stay together in the high mountains and along seacoasts where wind and cool temperatures protect them from summer heat and insects. After insect numbers decline in August, caribou scatter out and feed heavily on willow leaves and mushrooms to regain body weight.

Members of the WAH may be found in continuous herds numbering in excess of tens of thousands of individuals, and portions of the WAH may be found throughout their summer range. Insect-relief areas continue to be important during late June to mid-August during the insect season (Lawhead 1997). Insect harassment reduces foraging efficiency and increases physiological stress (Reimers 1980). For insect relief, caribou use various coastal and upland habitats such as sandbars, spits, river deltas, some barrier islands, mountain foothills, snow patches, and sand dunes, where stiff breezes prevent insects from concentrating and alighting on the caribou. In the EIS project area, members of the TCH generally aggregate close to the coast for insect relief. Some small groups, however, gather in other cool, windy areas such as the Pik Dunes located about 30 km south of Teshekpuk Lake (Hemming 1971, Philo et al. 1993). Caribou aggregations move frequently from insect-relief areas along the Arctic coast (the CAH, WAH, and especially the TCH) and in the mountain foothills (PCH and some aggregations of the WAH) to and from green foraging areas (MMS 2007a).

Winter range use and distribution

The WAH caribou generally reach their winter ranges in early to late November and remain on the range through March (Hemming 1971, Henshaw 1968). The primary winter range of the WAH is located south of the Brooks Range along the northern fringe of the boreal forest (Figure 3.2-2). Since 1996, much of the WAH has shifted its winter range from the Nulato Hills to the eastern half of the Seward Peninsula and has generally been more dispersed than prior to that time (Dau 2005). However, in recent winters, >30,000 WAH caribou have wintered in the northwest portion of their range. During two of these winters (1994 to 1995 and 1999 to 2000), caribou wintering along the Chukchi Sea coast between Cape Lisburne and Cape Krusenstern experienced high, localized mortality; the investigation indicated that caribou in this area were malnourished (Dau 2005). During winters of heavy snowfall or severe ice crusting, caribou may overwinter within the mountains or on the Arctic Slope (Hemming 1971). Even during normal winters, some caribou of the WAH overwinter on the Arctic Coastal Plain. The majority of the PCH often winter on the south side of the Arctic National Wildlife Refuge or in Canada (Figure 3.2-4). The CAH overwinters primarily in the northern foothills of the Brooks Range (Figure 3.2-3) (Roby 1980) (MMS 2007a). The TCH was presumed to reside in the Teshekpuk Lake area year-round (Davis et al. 1982); however, satellite-collar data from Teshekpuk caribou indicate that some animals travel great distances to the south, as far as the Seward Peninsula (Carroll 1992).

The movement and distribution of caribou over the winter ranges reflect their need to avoid predators and their response to wind (storm) and snow conditions (depth and snow density), which greatly influence the availability of winter forage (Henshaw 1968, Bergerud 1974, Bergerud and Elliot 1986). The numbers of caribou using a particular portion of the winter range are highly variable from year to year (Davis et al. 1982; Fancy et al. 1990, as cited in Whitten 1990). Range condition, distribution of preferred winter forage (particularly lichens), and predation pressure all affect winter distribution and movements (Roby 1980, Bergerud 1974, MMS 2007a).

3.3 Social and Economic Environment

3.3.1 Socioeconomics

Economic activity, broadly defined, is a basic determinant of socioeconomic change and therefore the starting point in assessing change for the affected communities. BOEM NEPA documents define a sociocultural system as encompassing social organization, cultural values, and institutional organization of communities (MMS 2007a, MMS 2007c, Impact Assessment Inc. 2011). The discussion of subsistence and cultural values associated with this economic activity can be found in Section 3.3.2. This description will be limited to baseline economic and demographic conditions, as well as social organizations and institutions of communities that would be directly affected by proposed offshore oil and gas exploration and seismic activities. These communities, adjacent to the Beaufort and Chukchi seas, from east to west are: Kaktovik; Nuiqsut; Barrow; Wainwright; Point Lay; Point Hope; Kivalina; Kotzebue; and Nome. Prudhoe Bay/Deadhorse, located between Kaktovik and Nuiqsut on the Beaufort Sea coast is an industrial site and oil field, not a community.

3.3.1.1 Economy

This section provides an overview of the region's (non-subsistence) economic drivers. It first describes the major economic sectors (oil and gas, government spending/administration, transportation/logistics) and activity that occurs within the project area, followed by a description of the source and relative amounts of public revenue and expenditures budgeted by these communities.

<u>**Economic Sectors and Activity**</u>

Oil and Gas Exploration and Production History

Exploration, development, production, and transportation of oil and gas are major contributors to the economy of Alaska and the NSB. These activities have created employment, generate contracts for service providers within the NSB and the state, and provide royalty and tax revenue to local, state and federal government. Extensive oil and gas exploration activities have occurred on Alaska's North Slope since 1940, with large-scale development and production beginning at the Prudhoe Bay field in the 1970s Also in the late 1970s and early 1980s, exploration for oil and gas was initiated offshore into the Beaufort and Chukchi seas. Nearshore Beaufort Sea development and production began in the 1980s (MMS 2008); no development and production has occurred to date in the Chukchi Sea. Offshore lease sale environmental documents by BOEM and ADNR Division of Oil and Gas provide a more detailed description of the history of oil and gas development and production. These studies are available on the BOEM and ADNR websites: http://www.gomr.boemre.gov/homepg/lsesale/lsesale.html and http://www.dog.dnr.state.ak.us/oil/. The State of Alaska has held oil and gas lease sales on the North Slope and Beaufort Sea since 1964. The state leases offshore acreage for exploration (up to three miles offshore, including off of barrier islands). The State of Alaska Beaufort Sea Areawide oil and gas lease sales for 2009 to 2018 contain approximately two million acres in 573 tracts from Barrow to the Canadian border. This represents 19 percent of the state's total acreage for oil and gas leasing; however, 89 percent of this sale is onshore (ADNR 2009). In August 2011, BOEM approved Shell's proposal to conduct exploration drilling on three leased tracts near Camden Bay in the Beaufort Sea. In 2012, Shell commenced preliminary drilling activity at one well site on the Sivulliq prospect.

The federal government has held oil and gas lease sales since 1976 in areas three or more miles offshore. MMS held 10 lease sales in the Beaufort Sea OCS between 1979 and 2006 (see Figure 1.2) (ADNR 2009). As of February 1, 2013, there were 183 active leases in the Beaufort Sea OCS where exploration activity could occur (BOEM 2013). Thirty exploratory wells have been drilled, and there is production from a joint federal/state unit of over 23 million barrels of oil since 2001 (MMS 2009a).

Federal OCS lease sales in the Chukchi Sea have only been offered since 1988. Two-dimensional seismic data collected starting in 1969 and five large prospects drilled between 1989 and 1991 resulted in no commercial development of oil or gas on the 483 leased tracts (MMS 2009a). All 483 leases have now expired. The potential for significant Arctic oil and gas resources remains high (Bird et al. 2008). The USGS estimated 90 billion barrels of oil and 1,669 trillion cubic feet of natural gas may exist in areas north of the Arctic Circle, of which approximately 84 percent is expected to occur in offshore areas. In February 2008, the federal government issued 487 leases for more than 2.66 billion dollars in the Chukchi Sea Planning Area (see Figure 1.3). Several companies have conducted seismic and scientific surveys, and exploratory drilling in 2012 on two lease tracts. In December 2012, BOEM approved Shell's proposal to conduct exploration drilling on leases in the Chukchi Sea. In 2012, Shell commenced preliminary drilling activity at one well site on the Burger prospect.

The baseline economic conditions reflect highly variable, complex, and dynamic socioeconomic impacts of some 40 years of oil and gas development on adjacent communities (MMS 2009, Galginaitis 2009).

Government

Alaska's largest employment sector is the government, which is comprised of federal (16,604 employees), state (25,121 employees or 8 percent), and local (45,608 employees or 15 percent) government employees (ADCCED 2011a). Government bodies are also the largest employer with 1,973 employees in the NSB (58.1 percent) and Northwest Arctic Borough (NAB) employs 1,245 workers (39.2 percent) (ADLWD 2005, NSB 2005; ADCCED 2011a). Major local government employers include borough and other municipal government and school districts. Government funding also influences construction employment for capital projects in the NSB and NAB.

Transportation

Trade, transportation, and utilities are the largest non-government sector employers in the State of Alaska (ADCCED 2011a). Nome, Kotzebue, Barrow, and Prudhoe/Deadhorse are regional transportation and utility hubs for surrounding villages and for oil and gas and mining support activities. Transportation services are a key economic sector and source of employment for the region.

Mining

Mining is a major economic sector in the NAB, and has occasionally resulted in economic activity in the NSB. The Red Dog Mine creates local and statewide employment, generates contracts for service providers within the borough and the state, and provides payment in lieu of tax (PILT) revenue to local and state government.

Public Revenue and Expenditures

The state and local governments levy taxes on the oil and gas industry for onshore and offshore exploration and production on state and private lands and in state waters. Lease sales and production on state lands and waters also generates state royalty payment. Production on federal lands and waters generates federal royalty and tax revenue; however, revenue sharing is limited from activities in the federal OCS. Though federal revenue sharing is limited, any offshore development would require billions of dollars of onshore facilities that would likely be subject to borough and state taxes (NEI and ISER 2011). Offshore oil production would also add to the thru put of the Trans-Alaska Pipeline System, paying tariff, extending the life of the pipeline, and supporting the value of onshore property owned or leased by the oil industry, the major source of NSB revenue.

Borough and Municipal Revenue

North Slope Borough - The predominant source of NSB revenue comes from property owned or leased by the oil industry in the Prudhoe Bay area (MMS 2008). The fiscal year (FY) 2010 budget was $306.7 million, and the FY 2009 actual revenues from property taxes were $243.6 million (NSB 2011, NSB 2010). Communities within the NSB are allowed to set sales tax and other special taxes, but the Borough property tax mill rate is set at a ceiling of 18.5 (Table 3.3-1).

Northwest Arctic Borough – NAB generates revenue from activities related to government, mining, health care, transportation, services, and construction. The NAB FY 2011 budget is $11.6 million (NAB 2011). The Red Dog Mine, 90 miles north of Kotzebue, is the world's largest zinc and lead mine. Owned by NANA Regional Corporation and operated by Teck, Red Dog provides 370 direct year-round jobs and over a quarter of the borough's wage and salary payroll (ADCCED 2011b). NAB received $972,000 in PILT and $6.73 million from Teck in 2010 (NAB 2010). The Red Dog Mine Extension (Aqqaluk Project) EIS explains that without PILT funds from the Red Dog Mine, the NAB would be much more reliant on state and federal funds. These funds are not only important logistically but give the region a degree of self-reliance and self-determination (EPA 2009).

City of Nome – The Nome FY 2011 budget is $10.8 million (City of Nome 2011a). Government services provide the majority of employment, and the largest revenue source in 2010 was capital grants and contributions ($6.71 million). Property taxes generated $1.69 million, and general sales tax generated $4.43 million (City of Nome 2010). Retail services, transportation, mining, medical, and other businesses provide year-round income. Several small gold mines continue to provide some employment, and NovaGold Resources, Inc., a large gold mining operation, is developing a mine eight miles north of Nome. In 2009, 42 residents held commercial fishing permits.

State of Alaska Revenue and Expenditures

The main source of Alaska's revenue comes from tax and royalty revenue from oil and gas production. Depending on the tax structure and price and volume of oil produced, state revenue can vary significantly. Tax revenue totaled $4.2 billion in FY 2009 (a decline from FY 2008 when $8.5 billion was collected). Approximately 90 percent of all state tax revenue is paid by the oil and gas industry ($3.8 billion, see Figure 3.3-1). Investments held by the Alaska Permanent Fund and other investment accounts, were $2.5 billion in FY 2009. Oil and gas contributed $6.1 billion through tax and royalty payments (ADCCED 2011a). State revenue peaked in FY 2008 at $13.1 billion as a result of record oil prices and changes in the state oil and gas tax structure.

For future oil and gas activities in the NSB, the state would collect $20 million in property tax and return $18.5 million to the NSB (see Table 3.3-1 for the local tax structure).

Table 3.3-1 Local Government Classification and Tax Regime

Community	Classification[a]	Sales Tax	Property Tax	Special Tax
Kaktovik	2nd Class City	None	See NSB	None
Prudhoe Bay (includes Deadhorse)	Unincorporated	None		None
Nuiqsut	2nd Class City	None		None
Barrow	1st Class City	None		Room 5% Tobacco $1 Alcohol 3%
Wainwright	2nd Class City	None		None
Point Lay	Unincorporated	None		None
Point Hope	2nd Class City	3%		None
North Slope Borough (NSB)	Home Rule Borough	Deferred to cities	18.5 mills	Deferred to cities
Kivalina	2nd Class City	2%	None	None
Kotzebue	2nd Class City	6%	None	Bed 6% Alcohol 6% Gaming 6%
Northwest Arctic Borough (NAB)	Home Rule Borough	Deferred to cities	None	Payment in lieu of taxes (PILT)
Nome	First Class City	5%	7.0 mills	Bed 6%
Unalaska/Dutch Harbor[b]	First Class City	3%	10.5 mils	Raw Fish 2% Cap Sales 1% Bed 5%

Note:

a) Definitions of city and borough powers and responsibilities are defined in the AK Constitution, Article X, Section 3, 5 and 7 and AS 29.04.020

b) Unalaska/Dutch Harbor is not part of the EIS project area, but it is discussed in Section 4.5.3.1

Source: Alaska Department of Community and Economic Development Community Database Online Available from: http://www.commerce.state.ak.us/dca/commdb/CF_BLOCK.htm

Federal Revenue and Expenditures

Overall, federal revenue from personal income tax, corporate tax, and other types was $2.11 trillion in 2009 (OMB 2011). Oil and gas lease sales and production in federal lands and waters generate federal royalty revenue. For example, the recent Chukchi Seas lease sale has generated $2.66 billion in bonus bids (NEI and ISER 2011).

Federal spending for the State of Alaska totaled $14.2 billion, ranking Alaska first in the U.S., based on per capita federal spending (ADCCED 2011a). Federal spending has a significant impact on Alaska's economy through annual contributions to retirement and disability ($1.5 billion), other direct payments ($875 million), grants ($3.7 billion), procurement ($4.97 billion), and salaries and wages (military and government employment; $3.1 billion) (Census 2010). In many cases, state dollars are able to match federal funds for in-state community programs and projects.

3.3.1.2 Employment and Personal Income

Employment and income statistics for the State of Alaska mirror important economic sectors to some degree in the NSB and NAB. The government sector is a major employer, particularly in the NSB and NAB. The oil and mining industry generate high income jobs and service contracts for local businesses and the construction industry. Transportation and utilities also provide substantial levels of employment.

Employment

About 63.8 percent of Alaska's potential workforce is employed (American Community Survey 2010). The most recent statewide employment figures show that statewide, the government is the largest employer (27 percent), followed by "trade, transportation, utilities" (19 percent), and "educational and health services" (14 percent) (Figure 3.3-2). Oil and gas and construction accounted for four percent each (ADLWD 2011b).

The extraction of natural resources from remote rural Alaska produces only modest direct economic benefit in the form of jobs, household income, business purchases, and public revenue for most residents (Goldsmith 2007). At the scale of Figure 3.3-3, the value of local wages generated from these industries cannot be seen on the bar chart.

Oil Industry Employment and Residency

North Slope oil field operations provide employment to over 5,000 people who are not residents of the NSB. These employees arrive from Anchorage, other areas of the state, and the lower 48 (ADCCED 2011b) and rotate in and out of work sites. This transient population is not reflected in the Census numbers until 2010 as shown in Table 3.3-4.

The 2010 average unemployment rate for the State of Alaska is 9.6 percent with 28 percent of the potential workforce not seeking work (not in the labor force) (Table 3.3-2). The average unemployment rate for the entire U.S. in 2010 was 7.9 percent with 35 percent of the potential work force not seeking work. NSB and NAB generally experience much higher rates of unemployment than the state or nation. Unemployment rates in 2010 that appear higher than in 2000 are shown in ***bold/italics*** below.

Table 3.3-2 Employment, Unemployment and Underemployment in the Project Area

	2000[a]		2010[b]

Notes:

a) 2000 Census Data
b) 2006-2010 American Community Survey, 5-Year Estimates
c) Population aged 16+
d) Unemployed and seeking work

Alaska Economic Trends special issue on the northern region of Alaska explains that Alaska has naturally higher unemployment rates because of the nature of the state's economy rather than relative economic health (ADLWD 2005). The state's economists theorize that more jobs are temporary or seasonal, and there are greater rates of geographic mismatches between employment opportunities and available/skilled workers.

Rural communities in general have a large number of discouraged workers who are involuntarily unemployed because they have stopped attempting to find work and/or they have exhausted their employment security benefits. In addition, underemployment is a common condition where an individual involuntarily worked less than 40 weeks in the previous year and/or did not make full use of their education, skill, or abilities (NSB 2005). Employment and race data in Section 3.3.10, Environmental Justice, show that unemployment and poverty disproportionately affects Alaska Native people.

North Slope Borough Employment

Oil and gas exploration and development on Alaska's North Slope is the principal industry in the NSB; however, the oil and gas industry provides a limited amount of direct employment to NSB residents. Residents with vocational or college degrees may be hired for professional and technical work in Prudhoe Bay and Anchorage. Temporary employment opportunities include subsistence and protected species observers or village liaisons. Previous MMS lease sale EIS documents include descriptions of a historic lack of Alaska Native employment in and near Prudhoe Bay (MMS 2008, MMS 2007a). Indirect employment is provided through service contracts with Alaska Native corporations and other providers. However, while a limited percentage of the direct oil and gas jobs are taken by local residents, a much larger share of the indirect jobs in other sectors of the economy that provide goods and services to support OCS exploration, development, and production are obtained by local residents from support contracts for North Slope and OCS projects (Northern Economics Inc. and ISER 2010). It is estimated that for each direct job created by future OCS activity in the oil and gas sector (and the revenues associated with production) an additional 4.8 indirect jobs are created in the Alaskan economy in the form of infrastructure, support, and state and local government employment (Northern Economics and ISER 2010).

The major employers are the NSB, North Slope School District, and the Alaska Native corporations and tribal organizations. Although dated, Figure 3.3-4a, Top Employers in the NSB, was produced from supplemental surveys to the U.S. Census. Figures 3.3-4a and 3.3-4b demonstrate that the majority of residents employed in the NSB work for the NSB and other local governments in an administrative, educational, or social service capacity. In 2009, approximately 60 percent of resident workers by industry worked for local government (ADLWD 2011a). The third largest employers (after the NSB and NSB School district) are the village corporations that provide support services to the communities and the oil and gas and mining industries. It should be noted that employment data can be difficult to interpret because of aggregation; different organizations categorize their data into different categories. For example, residents employed by the government may fall under several categories like "Education, Health and Social Services" as well as "Public Administration." The oil and gas industry may employ residents in numerous sectors including: "Transportation, Warehousing and Utilities;" "Construction;" or "Professional, Scientific, Management, Administrative."

Northwest Arctic Borough Employment

The largest employers in the NAB are Teck (Red Dog Mine), Maniilaq Association (regional non-profit Alaska Native corporation), the NAB School District, Kikiktagruk Iñupiat Corporation (KIC) (Kotzebue ANCSA village corporation), and NANA Corporation (ADCCED 2011b). With the exception of KIC, all of NANA Region's ANCSA village corporations have merged with NANA Corporation, which makes it the area's largest corporation in the private sector (ADLWD 2005). Figure 3.3-4c demonstrates that the "education, health and social services" are the largest employment sector, similar to the NSB. However, the "transportation, warehousing and utilities" is a larger employment sector for the NAB than it is for the NSB, as well as a large "agriculture, forestry, fishing & hunting, mining" sector that does not rank as high for NSB. In 2009, local government accounted for 39 percent of resident employment (ADLWD 2011a).

City of Nome

The City of Nome is the supply, service, and transportation center of the Bering Strait region. Government services provide the majority of employment. Retail services, transportation, mining, medical, and other businesses provide year-round income. Several small gold mines continue to provide some employment, and NovaGold Resources is developing a mine 8 miles north of Nome. In 2009, 42 residents held commercial fishing permits (ADCCED 2011b). The top employers in Nome include Bering Strait School District, Kawerak (the regional Native non-profit corporation), and Norton Sound Health Corporation (ADLWD 2011a).

Personal Income

Wage Income

Average monthly wages in Alaska total $3,886 per month per household, but the oil and gas extraction industry has the highest monthly wages at $13,924. Mining support was second at $8,164 per month (ADCCED 2011a). The most common employer is the government, where the average monthly wages were $4,293 in 2010. All industries combined produced $4.05 billion in total wages (including commission, bonuses, and other gratuities) in the state in the third quarter of 2010 (ADLWD 2011c). Table 3.3-3 shows 2010 per capita income and 2010 average annual earnings for the NSB at $22,109 and $64,532 respectively. The respective per capita income and average annual earnings for the same reporting period were $21,278 and $55,387 for the NAB, $20,549 and $60,096 for the Nome Census Area, and $30,726 and $76,891 for the State of Alaska (US Census Bureau 2010).

Figure 3.3-5 demonstrates the proportion of workers making under $20,000 per year. This is likely due to a lack of opportunities with local governments, school districts, construction camps, and support facilities for both the oil and gas and mining industries.

Transfers and Dividends

Transfer payments and dividends can provide a substantial contribution to household income in rural Alaska. Transfer payments can represent the value of services to individuals in government programs like Medicaid/Medicare, food stamps, housing assistance, and Social Security payments (a more detailed description of the distribution of transfer payments in Alaska can be found in Goldsmith 2007). Dividends come in the form of Alaska Permanent Dividend Fund and shareholder dividends from Alaska Native Corporations. In 2010, the Alaska Permanent Dividend Fund was $1,281 per qualified Alaska resident. Depending on financial performance, dividends to shareholders may be paid by regional and village Alaska Native Corporations. Table 3.3-5 provides 2009 dividend per share for each of the three regional corporations in the project area: Arctic Slope Regional Corporation (ASRC); NANA Regional Corporation (NANA); and Bering Straits Regional Corporation. As an example of the higher end of dividend payments, ASRC has distributed over $423.8 million in dividends to shareholders since its incorporation (ADCCED 2011a, Stricker 2010).

Contribution of Subsistence

Subsistence is the customary and traditional uses of wild, renewable resources for direct personal or family consumption as food, shelter, fuel, clothing, tools, or transportation. It is a critical component of the project area's economy. Under NMFS' MMPA implementing regulations, subsistence is defined as "the use of marine mammals taken by Alaskan Natives for food, clothing, shelter, heating, transportation, and other uses necessary to maintain the life of the taker or those who depend upon the taker to provide them with such subsistence" (50 CFR Part 216.3). Subsistence activity is inseparable from the Alaska Native cultures, including the Iñupiat Eskimo of the Beaufort and Chukchi seas and the Siberian Yupiit of the Bering Strait and points south, and encompasses vital economic, social, cultural and spiritual dimensions. Ronald H. Brower of Barrow was quoted, "it is a way of life that requires learning special skills, knowledge, and using one's resourcefulness" (ADLWD 2005). For the purposes of this EIS, subsistence activities are part of the non-monetized economy and a complete discussion can be found in Section 3.3.2.

Table 3.3-3 Regional Demographic Summary

	North Slope Borough	Northwest Arctic Borough	Nome Census Area	Alaska
Area in sq. miles	87,860	35,862	23,012	570,373

Source: ADLWD 2005; US Census (2010), US Census Bureau (2010) American Community Survey 5 Year Estimates

Craft Income

Sale of Alaska Native crafts is an important source of income in many areas of the North Slope and Northwest Arctic regions of Alaska. Many of these crafts depend on the harvest of marine mammals. For example, detailed surveys conducted in the NSB in 2003 indicated that about 20 percent of households supplement household income by making and selling arts and crafts such as ivory and whalebone carvings, baleen baskets and boats, and clothing (mukluks, parkas, slippers). The communities vary in how much supplemental income the crafts produce. Usually, individual income is less than $500 per year, but it can represent a substantial portion of income for some households in thousands of dollars (Shepro et al. 2003).

3.3.1.3 Demographic Characteristics

State of Alaska Demographics

Alaska's population in 2010 was 710,231 (US Census 2011a). Population growth is a result of natural increases (births minus deaths) and positive net migration as a result of assignment of military personnel (ADCCED 2011a). The State of Alaska's Alaska Native population was 13 percent statewide, but the rural Arctic communities are predominantly Alaska Native. The Institute of Social and Economic Research conducted a study on the special socioeconomic features of remote rural Alaska and found that this region has more children and fewer middle-aged adults. The non-Native population is composed primarily of working age adults. Men outnumber women, particularly among young adults (Goldsmith 2007). Complete race and poverty tables can be found in Section 3.3.10, Environmental Justice.

Regional Demographics

Table 3.3-3 provides a snapshot of regional demographics showing numerous similarities across the northern regions in terms of populations, racial composition and educational attainment.

North Slope Borough Demographics

There are eight communities within the NSB, all of which occur in the EIS project area. The population of the NSB is estimated at 9,430 (ADLWD 2005, U.S. Census Bureau American Community Survey). The vast majority the borough's population is Alaska Native. There have been short-term population spikes in the last thirty years which have been attributed to the construction of major infrastructure and resource development projects (Shepro et al. 2003). The median age of the borough is estimated at 26 years, which is substantially younger than the state median age (32.9 years) (Table 3.3-3). An estimated 60 percent of NSB residents have educational attainment of a high school diploma or less; 40 percent of the borough residents have attended some college, or attained a college diploma (Table 3.3-3).

Northwest Arctic Borough Demographics

There are 11 communities within the NAB (of these Kivalina and Kotzebue occur in the EIS project area). The population of the NAB is estimated at 35,862 (ADLWD 2005, US Census Bureau 2006-2010 5-Year American Community Survey). The vast majority of the NAB population is Alaska Native (Table 3.3-3). The median age of the borough is estimated at 24.5 years, which is substantially younger than the state median age (33.8 years) (Table 3.3-3). An estimated 62.8 percent of borough residents have educational attainment of a high school diploma or less; 37.2 percent of the borough residents have attended some college, or attained a college diploma (Table 3.3-3).

Nome Demographics

There are 16 communities in Nome Census Area. However, Nome is the only community in the census area that occurs in the EIS project area. The majority of the Nome Census Area is Alaska Native (75.8 percent), although slightly lower than the NAB. The median age of the borough is estimated at 26.7 years, which is notably younger than the state median age (33.8 years) (Table 3.3-3). An estimated 58.6 percent of borough residents have educational attainment of a high school diploma or less; 41.4 percent of the borough residents have attended some college, or attained a college diploma (Table 3.3-3).

Communities' Demographics

A summary of population trends since 1990 are shown in Table 3.3-4. Communities are organized by region, and decreases in population between 2000 and 2010 are shown in ***bold/italics***. The communities described below are generally coastal communities with the potential to be affected by proposed seismic exploration and exploratory drilling.

Historically, workers in Prudhoe Bay and other industrial-enclaves commuted to the workplace and were counted as residents elsewhere. In the 2010 U.S. Census, workers that spend a majority of their time at Prudhoe Bay were counted as residents of the North Slope.

Table 3.3-4 Population Growth Rates 1990-2010[a]

Community	1990	2000	2010 [a]
Kaktovik	224	293	***239***
Prudhoe Bay	47	5	2,174
Nuiqsut	354	433	***402***
Barrow	3,469	4,581	***4,212***
Wainwright	492	546	556

North Slope Borough Communities

Kaktovik is located on the northern shore of Barter Island in the eastern Beaufort Sea and has a long history as an Iñupiat meeting and trading place (Shepro et al. 2003). The City of Kaktovik was established in 1923 as a fur trading post and was moved three times, partly in response to Department of Defense Distant Early Warning (DEW) facilities. It was incorporated as a city in 1971. Kaktovik has a population of 239 residents (2010 Census), and like other North Slope communities is a highly active subsistence community for marine and terrestrial mammals. The borough provides electricity, water and sewer, and a health clinic, as well as a school that serves students from kindergarten through grade 12.

Prudhoe Bay is an industrial site and oil field, not a community. As described in Section 3.3.1.1, exploration activities began in the 1940s. An industry-support community and airfield was developed at Deadhorse in the 1970s. Prudhoe Bay's inter-connected, industrial infrastructure includes roadways, pipelines, production and processing facilities, gravel mines, and docks (MMS 2008).

The ***Nuiqsut*** area on the Colville River was used for centuries for subsistence activities, but the Iñupiat village of Nuiqsut was abandoned until it was resettled in 1973 by 27 Barrow families (NSB 2005). The current population is 402 (2010 Census), and the residents participate in a high level of subsistence activity and subsistence resource use (NSB 2005). The borough provides electricity, water and sewer, and a health clinic, as well as a school that serves students from kindergarten through grade 12. The Alpine oil field and satellite infrastructure are nearby.

Barrow is located at a point that is the dividing line between the Beaufort and Chukchi seas. The area was historically a hunting and fishing area for Iñupiat Eskimos with archaeological sites indicating habitation from 500-900 A.D (ADCCED 2011b). Commercial whaling and trading was established officially at the turn of the nineteenth century (NSB 2005). The City of Barrow was incorporated in 1958. It is the largest community within the NSB with 4,212 residents and only about 55 percent identified as Alaska Native (2010 Census). The population increases through the 1980s to today were stimulated by a boom in Barrow's economy and an influx of non-Alaska Natives into the community (MMS 2008). Like Kaktovik, the military had a large influence on the community before it was incorporated into a city due to the construction and operation of military installations, including the Naval Arctic Research Laboratory and DEW Line Station. Barrow's unemployment rate (21.4 percent estimated in 2010) is still high despite having a more diverse economy than smaller NSB communities. The borough provides electricity, water and sewer, as well as a school that serves students from kindergarten through grade 12. Advanced education is available as well through Ilisagvik College. The primary healthcare facility for the North Slope region is the Samuel Simmonds Memorial Hospital, operated by Arctic Slope Native Association, the regional Native non-profit corporation.

Wainwright is located on the Chukchi Sea within the region that has become the NPR-A. It is a community with 556 residents (2010 Census) that is growing slowly and steadily. The City of Wainwright was incorporated in 1962, but the construction of a school and health clinic dates back to 1904. Numerous historic and contemporary hunting and fishing camps are in the area; indigenous residents refer to themselves as the Tagiumiut or "people of the sea." Reindeer herding, oil and gas exploration, and military activities in recent history have greatly influenced the community (NSB 2005). The borough provides electricity, water and sewer, and a health clinic, as well as a school that serves students from kindergarten through grade 12.

Point Lay is located on the Chukchi Sea and was established as a trading post in the 1920s after small hunting and fishing groups from the area congregated south of the Kokolik River mouth. The village has been moved a few times before its current location on the Chukchi Sea coast (NSB 2005). Point Lay has not been incorporated as a city, but the Native Village of Point Lay is a federally recognized tribe, and Cully Corporation is the ANCSA village corporation. A DEW line site just southwest of the community was removed in 2005 (ADCCED 2011b). The borough provides electricity, water and sewer, and a health clinic, as well as a school that serves students from kindergarten through grade 12. Water from a lake is treated for residents to haul to tanks at their homes. The 2010 Census estimated the population to be 189, a loss of about 58 people since the 2000 Census. This 31 percent population loss is the largest relative population loss for all the NSB communities since 2000. About 783 percent of residents over the age of 16 worked in 2010. Local government is the main industry, employing 74.8 percent of the area's workers. Maintenance and repair workers are the largest occupational category (ADLWD 2011).

Point Hope is located on the Chukchi Sea and is the second largest NSB community (after Barrow) with 674 residents in 2010 (Census). The Point Hope peninsula is one of the oldest continuously occupied "Tikeraqmuit" Iñupiat Eskimo areas in Alaska with different settlement names over the past 2,500 years. Commercial whalers brought an influx of Westerners by 1848 who disappeared by the early 1900s. Strong influences included commercial whaling, trading, reindeer herding, the introduction of alcohol and diseases, missionaries, and federal agencies. The City of Point Hope was incorporated in 1966 and moved to its present location after a storm surge in 1978 (NSB 2005). The borough provides electricity, water and sewer, and a health clinic, as well as a school that serves students from kindergarten through grade 12.

Northwest Arctic Borough Communities

Kivalina is located on the northern tip of a barrier reef between the Chukchi Sea and Kivalina River. Kivalina is the only village in the NAB region that hunts bowhead whale, and it is a member of the Alaska Eskimo Whaling Commission. Historically, it was a stopping-off place for seasoned travelers between Arctic coastal areas and Kotzebue Sound communities (ADCCED 2011b). The community has been subject to severe erosion and wind-driven ice damage to the current site. Storm surges and erosion have been a concern since the community was first established (City of Kivalina 2010). The City of Kivalina was incorporated in 1969. The economy is dependent on subsistence activities, and the infrastructure is modest; water is treated and stored in a community water tank where the public hauls it to their homes. Most residents haul their own honey buckets (sewage containers) to an open disposal site and a washeteria (public laundromat) provides showers (NSB 2005). The NAB provides kindergarten through grade 12 education.

Kotzebue, originally named Kikiktagruk or "place that is almost an island" has been occupied by Iñupiat Eskimos for at least 600 years (City of Kotzebue 2000). The city was formed in 1958 as a service and transportation center for all villages in the northwest region. Kotzebue has a healthy cash economy, a growing private sector, and a stable public sector. Due to its location at the confluence of three river drainages, Kotzebue is the transfer point between ocean and inland shipping. It is also the air transport center for the region. Activities related to oil and minerals exploration and development have contributed to the economy. The majority of income is directly or indirectly related to government employment, such as the school district, Maniilaq Association, the city, and the borough. The Teck Alaska Red Dog Mine is a significant regional employer. Commercial fishing for chum salmon provides some seasonal employment. In 2009, 115 residents held commercial fishing permits. Most residents rely on a combination of subsistence activities and cash income (ADLWD 2011b).

Nome Census Area Unorganized Borough

Nome was established as a gold mining town in 1901, but Malemiut, Kauweramiut, and Unalikmuiut Eskimos occupied the Seward Peninsula historically. All former villagers from King Island were moved to Nome by 1970. The town site was built along the Bering Sea and acts as the supply, service, and transportation center of the Bering Strait region. . It has provided support for offshore activities in the Chukchi Sea. The Nome 2010 population was 3,598, which was a modest increase from 3,505 in 2000 (U.S. Census). Nome has the largest white population in the project area (estimated at 30.4 percent in 2010) communities. Individual poverty rates are low in Nome (3.9 percent) compared to other communities in the project areas (see Table 3.3-51 in Section 3.3.10, Environmental Justice), however nearly all of the individuals living in poverty are Alaska Natives by ethnicity.

Complete community profiles can be found in other publications (e.g. 2005 NSB Comprehensive Plan, individual community comprehensive plans), and updated online profiles at the Alaska Department of Commerce, Community, and Economic Development (ADCCED) Division of Community and Regional Affairs (DCRA) *Alaska Community Database* website: http://www.commerce.state.ak.us/dca/commdb/CIS.cfm.

3.3.1.4 Social Organizations and Institutions

The following represents a brief overview of social and governmental organizations in the project area and their roles among communities. Cultural values are incorporated into governmental and tribal (governmental) bodies in the project area (see Table 3.3-6) to ensure that economic development and social services address the needs of local communities appropriately.

Village/Tribal Governments

All communities described in this section, except for Prudhoe Bay, have established tribal governments recognized by the Bureau of Indian Affairs that are eligible for funding and services and receive special status as a government (75 *Federal Register* 60810, October 1, 2010). As a federally-recognized tribal government, these tribes are accorded the right of federal government-to-government consultations per federal policies that affect them and executive orders that pertain to this federal tribal relationship. Tribal governments are of two types: those with formal constitutions established under the Indian Reorganization Act (IRA) of 1934 (as amended in 1936 by the Alaska Reoganizations Act), and those recognized as traditional councils, formed through custom and necessaity according to the traditions of the particular tribe.

The tribal governments formed under the Indian Reorganization Act of 1934 are known as IRA councils. IRA councils in the project area include: Nome Eskimo Community, Native Village of Kivalina, Native Village of Kotzebue, Native Village of Point Hope, Native Village of Point Lay, and the Iñupiat Community of the Arctic Slope (ICAS). ICAS is comprised of all the Tribal entities/membership of the Native Villages of Barrow, Atqasuk, Naqsragmuit, and Point Lay (ICAS 2011). Communities represented by traditional councils include: Kaktovik Village, Native Village of Nuiqsut, Native Village of Barrow, and Native Village of Wainwright(see Table 3.3-6).

Municipal Government

The state recognizes municipal governments as representing all residents, while tribal governments represent the interests of the tribal membership. Cities within the NSB and NAB receive public education from the boroughs and can exercise their power to enforce special taxes, but they do not set property taxes. The classification of project area cities can be found in Table 3.3-1.

North Slope Borough is Alaska's largest borough, encompassing 88,000 square miles of land and 5,900 square miles of water. It was incorporated in 1972 and adopted its Home Rule Charter in 1974 allowing it to exercise any legal governmental power in addition to its mandatory powers of taxation, property assessment, education, and planning and zoning services. The borough provides a full range of services, including police and fire protection, search and rescue, construction and maintenance of roads and other infrastructure, water and wastewater treatment, light, power and heat, health and clinic services, fuel storage, solid waste collection and disposal (FY2009 Report). NSB is also financially accountable for a legally separate school district. In addition, there are seven incorporated municipal governments within the NSB. The borough's administrative center, Barrow, has operated as a city since 1958. Barrow is the largest community which acts as the hub of government, transportation, communications, education, and economic development (ADCCED 2011b).

Northwest Arctic Borough is the second largest borough in Alaska, encompassing 35,800 square miles. It was incorporated in 1986 and adopted its Home Rule Charter in 1987, allowing it to exercise any legal governmental power in addition to its mandatory powers of taxation, property assessment, education, and planning and zoning services. NAB does not levy taxes on its residents, although Kivalina and Kotzebue do. Many local services are provided by the cities, but education is the responsibility of the borough (ADCCED 2011b). In addition, there are 11 incorporated communities with municipal governments within the NAB (of these Kivalina and Kotzebue occur in the EIS project area). Kotzebue is the largest community in the borough and serves as the hub of government, transportation, communications, education, and economic development. Kotzebue is also the gateway to four major National Park units.

The ***City of Nome*** was formed in 1901 after gold was found in the area. The region in which Nome is situated is does not have an incorporated borough; statistics are gathered for the Nome Census Area. Nome is a first class city that manages a school district, contains the offices of Bering Straits Native Corporation, Kawerak, and hosts the Norton Sound Regional Hospital. Nome is the supply, service, and transportation center of the Bering Straits region (ADCCED 2011b).

Alaska Native Regional and Village Corporations

Alaska Native Corporations were created as a result of the 1971 Alaska Native Claims Settlement Act that conveyed 44 million acres and $962.5 million in compensation funds to 12 regions and their associated villages. The 13th Regional Corporation received a share of the compensation funds, but not land, on behalf of eligible Alaska Natives who no longer resided in Alaska. The three Native Regional Corporations in the EIS project area are the Arctic Slope Regional Corporation (ASRC), NANA, and Bering Straits Regional Corporation (listed in Table 3.3-5). These ANCSA corporations reflect a mix of traditional and Western values (Braund and Kruse 2009).

The 2009 dividend per shareholder is shown in Table 3.3-5. ASRC generated 1.94 billion in revenue in 2009, the highest for the 12 Alaska regional corporations, but down from its record $2.3 billion in 2008. Since its incorporation, ASRC has distributed over $423.8 million in dividends to shareholders (ADCCED 2011a, Stricker 2010).

Table 3.3-5 ANCSA Corporations in Project Area and Shareholder Dividends

ANCSA Corporation	Region	Money from ANCSA (mil)	2009 Revenue (mil)	Net Income (mil)	Shareholders	Dividend Per Share (2009)
Arctic Slope Regional Corporation	North Slope	$22.5	$1,945	$169.3	9,616	$57.12
NANA Regional Corporation	Northwest Alaska	$44.0	$1,259	$17.1	12,044	$12.00
Bering Straits Regional Corporation	Nome and Seward Peninsula	$38.2	$162	$8.1	6,334	$1.00

Source: 2009 Alaska Economic Performance Report (ADCCED 2011a)

Alaska Native corporations have established subsidiaries to provide contract services for a variety of activities, including oil field services, ice road construction, and oil spill response. This provides a small amount of employment opportunities for North Slope and NANA regional and village corporation shareholders because many of these jobs are in Anchorage, the lower 48, or require travel to Prudhoe Bay. (Data on the numbers of shareholders that find employment with Native Corporations and their subsidiaries are unavailable.)

Along with ASRC and NANA, many North Slope Village Corporations have subsidiaries that provide oil field services (a list of village corporations can be found in Table 3.3-6). Like regional corporations, village corporations also provide services throughout the state and the world. Administrative offices are not always in their respective villages.

Regional Non-Governmental Organizations

Native regional non-profits (or tribal associations) often function as service providers for Alaska Native members within the ANCSA regions, with authorizing resolution from the member tribes. Maniilaq is the regional Alaska Native non-profit corporation for the NAB area; Kawerak for the Nome area; and Arctic Slope Native Association for the NSB area.

There are several important non-governmental organizations in the region, including the membership-based AEWC, and Eskimo Walrus Commission, Alaska and Inuvialuit Beluga Whale Committee, Alaska Nanuuq Commission, and Ice Seal Committee. These groups are consulted by state and federal agencies when making decisions about actions that could affect these resources (MMS 2007a).

AEWC was established in 1977 to protect the subsistence practice of bowhead whaling that the International Whaling Commission attempted to ban. AEWC has helped contribute to the management of the bowhead whale and provided traditional knowledge to the oil and gas industry regarding potential impacts and mitigation. More can be found on the website at: http://www.alaska-aewc.com/aboutus.asp

The Eskimo Walrus Commission was organized by Kawerak, Inc. of Nome in 1978 to represent coastal walrus hunting communities in issues of co-management. The member communities are listed at: http://www.kawerak.org/servicedivisions/nrd/ewc/.

The Alaska and Inuvialuit Beluga Whale Committee was established in 1988. Committee membership includes representatives from communities and regions that hunt beluga whales, including western and northern Alaska and the Mackenzie River Delta in Canada. Scientists, researchers, and technical advisors are also part of the committee, including federal, state and local government representatives (Adams et al. 1993). Within the project area, member entities include North Slope Borough, Kawerak, and NANA Regional Corporation.

The Alaska Nanuuq Commission was established in 1994 to "represent the villages in North and Northwest Alaska on matters concerning the conservation and sustainable subsistence use of polar bear" (Alaska Nanuuq Commission 2011). Committee membership includes representatives from fifteen tribal councils; communities within the project area that participate include: Kaktovik; Nuiqsut; Barrow; Wainwright; Point Lay; Point Hope; Kivalina; and Kotzebue. Additional information is available on the commission website, http://www.nanuuq.info/index.html.

Understanding that ice seals are important food sources for polar bears and coastal subsistence communities, the Alaska Nanuuq Commission established the Ice Seal Committee. The purpose of the committee is to "preserve and enhance the marine resources of ice seals including the habitat; to protect and enhance Alaska Native culture, traditions, and especially activities associated with subsistence uses of ice seals; to undertake education and research related to ice seals" (Ice Seal Committee 2005). Committee membership includes representatives from five entities located within the Alaska coastal regions with polar sea ice, including: NSB; Maniilaq; Kawerak; Association of Village Council Presidents; and Bristol Bay Native Association. Additional information may be found on the Nanuuq Commission website, http://www.nanuuq.info/iceseal.html.

Table 3.3-6 Institutions in the EIS Project Area

Municipality	Regional Govt.	ANSCA Regional Corp.	Regional Native Non-Profit	Tribal Govt	ANSCA Village Corp	Other Non-profit Orgs*	Housing Authority	Econ Dev. or CDQ Group	Utilities

3.3.2 Subsistence Resources and Uses

3.3.2.1 Introduction

This section describes the subsistence harvest patterns of the Iñupiat communities in the EIS project area: Kaktovik; Nuiqsut; Barrow; Wainwright; Point Lay; Point Hope; Kivalina; and Kotzebue. This community-by-community description provides general information on harvest information by resource, seasonal subsistence harvest patterns, including community, timing of the subsistence harvest cycles, and harvest-area participation rates by community.

3.3.2.2 Definition of Subsistence and Cultural Importance

<u>Definition of Subsistence for this EIS</u>

Subsistence is central to the livelihood of many Alaskan Native communities and other rural residents. The patterns of subsistence harvests are shaped by local and regional factors of ecology, community history, culture, and economy. What is termed "subsistence" in law is in fact, on the ground, a myriad of distinct, localized traditions established by communities (Wolfe 2004). The subsistence patterns of local communities can include extensive ecological knowledge, effective harvest techniques, traditions for cooperation and sharing, and cultural ceremonial activities.

Subsistence harvest activities involve hunting, fishing, trapping, and gathering. A wide array of natural resources is harvested throughout the year in a regular cycle of seasonal efforts timed for availability, access, and condition of the resources. The composition of subsistence harvests includes many species of fish, land mammals, marine mammals and invertebrates, terrestrial invertebrates, waterfowl, berries, roots, and plants and fuel gathering. Many of these resources are migratory in nature so are only seasonally available. People rely on these locally available resources for food, clothing, fuel, transportation, construction materials, art, crafts, exchange, and customary trade (Wolfe 2000).

The MMPA and the ESA are relevant to subsistence uses. Under the MMPA (1994 amendment) and ESA, Alaska Natives are allowed to harvest marine mammals as subsistence resources. The MMPA defines subsistence as:

> *…the use of marine mammals taken by Alaskan Natives for food, clothing, shelter, heating, transportation, and other uses necessary to maintain the life of the taker or those who depend upon the taker to provide them with such subsistence (50 CFR § 216.3).*

The NSB defines subsistence as:

> *… an activity performed in support of the basic beliefs and nutritional needs of the residents of the borough and includes hunting, whaling, fishing, trapping, camping, food gathering, and other traditional and cultural activities (NSBMC 19.20.020 (67)).*

<u>The Cultural Importance of Subsistence</u>

The Iñupiat consider subsistence to be more than just a "way of life," and for the people who live along the Beaufort Sea and Chukchi Sea coasts, subsistence is their life (NSB 2007, Maclean 1998). Subsistence defines the essence of who they are, and it provides a connection between their history, culture, and spiritual beliefs. An essential component of Iñupiat values is the sharing of subsistence resources among families, friends, elders, and those in need. *"[V]irtually all Iñupiat households depend upon subsistence resource to some degree"* (NSB 2004).

Subsistence is a term that can be interpreted in many different ways. Some people consider subsistence as an indicator of economic deprivation; a way of life that is necessary due to the high costs of food and absence of jobs in rural areas. As Wheeler and Thornton (2005) stated, Euro-American conceptions [of subsistence] tend to be static, restrictive and minimalist, often defining subsistence as 'the minimum resources necessary to support life'. However, to the Iñupiat and Siberian Yupiit residents of the EIS project area, subsistence is none of these things. As described by the people of Kaktovik,

> *"[S]ubsistence" is certainly not an adequate or meaningful word here either, or at least not as it is normally defined and used outside the context of aboriginal resource use. In fact, the more we look at it, think about it, the more insult we feel by its application to our lives. We are not peasants. We do not subsist; we thrive here, live our lives with great relish.* (Kaktovik undated in NSB 2007)

Subsistence activities are assigned the highest cultural value by the Iñupiat and provide a sense of identity in addition to the substantial economic and nutritional contributions. The importance of subsistence activities was summarized by the NSB (2007):

> *The foundation of the Iñupiat sociocultural system is their utilization of the natural environment and its biotic resources. This deep attachment provides the basis of the value of subsistence (Worl 1980). Subsistence activities have provided the cohesive threads around which the Iñupiat have held their culture together during times of economic and social change. It constitutes far more than just "food on the table."*

Many species are important for the role they play in the annual cycle of subsistence resource harvests, and each subsistence food resource plays an important role. Loss of access to any subsistence food resource could have serious effects. When a subsistence resource is unavailable for any reason, families will adapt and redirect harvest effort towards other species, but the contribution of some resources to the annual food budget would be very difficult to replace. Besides their dietary benefits, subsistence resources provide materials for family use and for the sharing patterns that help maintain traditional Iñupiat family organization. Relationships between generations, among families, and within and between communities are honored and renewed through sharing, trading, and bartering subsistence foods. The bonds of reciprocity extend widely beyond the EIS project area and help to maintain ties with family members elsewhere in Alaska. Subsistence resources provide special foods for religious and ceremonial occasions; the most important ceremony, Nalukataq, celebrates the bowhead whale harvest (NMFS 2008b).

The use of traditional food in the subsistence lifestyle provides important benefits to users. Subsistence foods are often preferable as they are rich in many nutrients, lower in fat, and healthier than purchased foods. Subsistence foods consist of a wide range of fish and wildlife and vegetable products that have substantial nutritional benefits. Community studies in the 1980s and 1990s found that rural Alaskans statewide harvest more than 44 million pounds (lb) of wild foodstuffs every year. On average, food produced through hunting, fishing, and gathering amounts to just over 1 lb of wild edible products per person per day. According to 1990 estimates (Wolfe 1996), the annual wild food harvest in rural Alaska was 375 lb per person, compared to 22 lb per person in urban Alaska. Subsistence harvesting of traditional foods, including preparation, eating, and sharing of resources contributes to the social, cultural, and spiritual well-being of users and their communities (ISER 2010).

Subsistence production is also linked to the market economy. Subsistence harvest byproducts are used by many households to earn cash from crafting whale baleen and walrus ivory and from harvesting furbearing mammals. Also, market economy wages contribute to acquisition of more efficient harvest tools, better firearms, snow machines, boats, and all-terrain vehicles.

Subsistence harvest practices have been documented in many studies over the last several decades including Worl (1980) and Nelson (1979) who describe subsistence as a central focus of North Slope personal and group cultural identity. Hopson (1976, 1978) establishes the political and ideological power of subsistence as an organizing concept for the NSB (See also Davidson 1974, Arnold 1978, Lewis 1978, Lonner 1980, Langdon and Worl 1981, Kelso 1981, 1982, Case 1984, 1989, Ellanna and Sherrod 1984, Berger 1985, Caulfield and Brelsford 1991, Bryner 1995, Naiman 1996, ADNR 1997). Communities express and reproduce their unique identities based on the enduring connections between current residents, those who used harvest areas in the past, and the wild resources of the land. Elder's conferences, spirit camps, and other information exchange and gathering events serve to solidify these cultural connections between generations and between the people and the land and its resources.

Subsistence activities and wage economic opportunities are highly developed and highly interdependent (Kruse et al. 1981, Kruse 1981 and 1982). Subsistence activities are dependent upon cash for equipment and operating costs, but at the same time these activities are very cash efficient, in that relatively modest investments of cash produce large quantities of fresh, nutritious food. Moreover, households that are most active in subsistence activities tend also to be those highly involved in the wage economy. Monetary resources are necessary to assist in the harvest of subsistence resources, both as they affect individual harvesters (such as to purchase a boat, snow machine, all-terrain vehicle, fuel, and guns and ammunition) and as they affect the head of a whaling crew. The heads of the whaling crews traditionally occupy positions of authority and respect within their communities (EDAW-AECOM 2007). Whaling captains' are responsible for the readying of supplies, weapons, boats and gear for the hunt, distribution and storage of the meat and decisions on when and where to locate hunting camps. Full-time employment is also limiting as it affects the time a subsistence hunter can spend harvesting. In summer, extensive hunting and fishing can be pursued after work and without any daylight limitations, but, during midwinter and winter, daylight is a limiting factor (MMS 2008).

As one North Slope hunter observed:

> *The best mix is half and half. If it was all subsistence, then we would have no money for snowmachines and ammunition. If it was all work, we would have no Native foods. Both work well together.* (ACI et al. 1984 in MMS 2008)

Cultural Importance of Subsistence Hunt of Bowhead Whales and Other Marine Mammals

Iñupiat and Siberian Yupik Eskimos have hunted bowhead whales continuously for over 2,000 years (Stoker and Krupnik 1993). Hunting bowhead whales in Arctic Alaskan waters remains a communal activity that supplies important meat and maktak (the skin and a layer of blubber used for food) for entire communities, as well as for feasts and during annual celebrations. Formalized patterns of hunting, sharing, and consumption characterize the modern bowhead harvest. In addition, whaling captains are highly respected and carry the burden of the hunts within their communities for their traditional knowledge of ice, weather, and whale behavior, which is necessary to hunt successfully, for their generosity in supporting their whaling crews, and for their stewardship of traditions of sharing and distributing maktak throughout the community (NMFS 2008b). As one whaling captain expressed:

> *We have to go 93 miles from here to go hunt, do our subsistence fall hunt and be out there until we meet our -- until we meet our quota. That's taking away from our families and very costly. It's a burden to the captain just to try and provide the needs of what we depend on; a subsistence lifestyle.* (Nuiqsut Public Scoping Meeting, March 11, 2010)

The bowhead whale hunt represents one of the greatest concentrations of community-wide effort and time. It is highly productive, accounting for a substantial percentage of the food consumed in the Beaufort communities and to a lesser extent in several of the Chukchi Sea communities. As the principal activity through which traditional skills for survival in the Arctic are passed from elders to younger generations, the bowhead hunt provides ongoing reinforcement of the traditional social structure. Thus, the bowhead subsistence hunt is a large part of the cultural tradition and modern cultural identity (Worl 1980, Braund et al. 1997). Spiritual and moral values, beliefs, and cultural identity are expressed and recreated through subsistence harvest activities. The great gifts of food from bowheads are recognized in the ceremonies of the Nalukataq festival at the conclusion of spring whaling (NMFS 2008b).

In addition to this high reliance on bowhead whales, Iñupiat and Siberian Yupik communities harvest many species throughout an intricate annual cycle of subsistence activities (NMFS 2008). The species composition of subsistence harvests provides an indication of the flexible adaptation of subsistence patterns to ecological patterns of abundance and access to various resources. For example, while bowhead, caribou, and fish make up the majority of subsistence foods in most of the Iñupiat communities, the Chukchi Sea communities rely more heavily on beluga whales, walrus, and seal than do the Beaufort Sea communities. The Beaufort Sea communities of Kaktovik, Nuiqsut, and Barrow have high proportions of total subsistence food derived from the bowhead harvest and lower proportions from other marine mammals. The communities of Wainwright, Point Lay, Point Hope, Kivalina, and Kotzebue harvest greater numbers of marine mammals and fish (NMFS 2008b).

Additional comprehensive descriptions of subsistence harvest patterns and uses are found in BOEM, BLM, and U.S. Army Corps of Engineers (USACE) EIS and EA documents and are incorporated by reference: the Liberty Development and Production Plan final EIS (MMS 2002); the Beaufort Sea Multiple Sale Final EIS (MMS 2003); the Northwest NPR-A Final IAP/EIS (BLM and MMS 2003); the Beaufort Sea Sale 195 EA (MMS 2004); the Alpine Satellite Development Plan Final EIS for potential expansion of Alpine field production near Nuiqsut (BLM 2004); the Northeast NPR-A Amendment IAP/EIS (BLM 2005) and the final supplemental IAP/EIS (BLM 2008a); the USACE Delong Mountain Terminal Project Draft EIS (USACE 2005); the Kobuk-Seward Peninsula Resource Management Plan (BLM 2006); the MMS seismic-survey PEA (MMS 2006b);; the Beaufort Sea Sale 202 EA (MMS 2006c); the Chukchi Sea Lease Sale 193 Final EIS (MMS 2007a); Chukchi Sea Planning Area Oil and Gas Lease Sale 193 Final Supplemental EIS (BOEM 2011b); the 2012-2017 Five Year Oil and Gas Leasing Program Final EIS (BOEM 2012); and USGS (2011).

3.3.2.3 Subsistence Resources

This section describes the primary subsistence resources harvested by the Beaufort Sea and Chukchi Sea communities of Kaktovik, Nuiqsut, Barrow, Wainwright, Point Lay, Point Hope, Kivalina, and Kotzebue. A general description of the resource in relation to subsistence harvests is included in this section. Marine mammal species are discussed first, followed by fish, waterfowl, and caribou. More detailed ecological accounts of the species, including population abundance and distribution are found in Section 3.2.4, Marine Mammals.

Important subsistence resources in the EIS project area include the bowhead whale, beluga whale, seal (ringed and bearded), walrus, polar bear, fish, migratory waterfowl (including their eggs), and caribou. It is important to note that the species composition of community subsistence harvests vary from one region to another, depending largely on the ecological setting. While residents of the NSB and NAB tend to concentrate harvests on the highest value species and those species groups it should be noted that subsistence harvests are diverse (USGS 2011). For instance, walrus and belugas are harvested less in Kaktovik where their occurrence and distribution is lower in comparison to Point Lay where these two species are more prevalent in seasonal abundance. Communities which have higher rates of harvest for bowhead whales are less likely to harvest seals. Table 3.3-7 provides an overview of Community Subsistence Harvest by Species Group (percent total harvest by species, total harvest and pounds per capita). Specific harvest patterns by seasonal round and areas of use by community are described in

Section 3.3.2.4. Maps of subsistence harvest areas for subsistence resources are presented as Figure 3.3-18 through Figure3.3-27.

Table 3.3-7 Community Subsistence Harvest by Species Group
(percent total harvest by species, total harvest and pounds per capita)

Species	Kaktovik (1992 – 1993)	Nuiqsut (1993)	Barrow (1987 – 1989)	Wainwright (1988 - 1989)	Point Lay (1987)	Point Hope (1992)	Kivalina (2007)	Kotzebue (1986)

Bowhead whale (Agviq)

The Western Arctic bowhead whales (*Balaena mysticetus*) migrate annually from wintering areas in the northern Bering Sea, through the Chukchi Sea in the spring, and into the Beaufort Sea where they spend the summer (Figure 3.3-19). In the autumn they return to the Bering Sea to overwinter. Eleven Alaskan coastal communities along this migratory route participate in traditional subsistence hunts of these whales: Gambell, Savoonga, Little Diomede, and Wales (on the Bering Sea coast); Kivalina, Point Lay, Point Hope, Wainwright, and Barrow (on the coast of the Chukchi Sea); and Nuiqsut and Kaktovik (on the coast of the Beaufort Sea). The eight communities which are the focus of this EIS and harvest areas are shown on Figure 3.3-19. As noted, the bowhead whale hunt constitutes an important subsistence activity for these communities, providing substantial quantities of food, as well as reinforcing the traditional skills and social structure of Iñupiat culture. Partly as a result of concerns about sustainability, such hunts have been regulated by a quota system under the authority of the IWC since 1977, with Alaska Native subsistence hunters from northern Alaskan communities taking less than one percent of the stock of bowhead whales per year (NMFS 2008b). The stock has reported to continue to grow at a rate of 3.4 percent per year since 1978 (NMFS 2008b). A total of 832 whales were landed by subsistence hunters between 1974 and 2003, with Barrow landing the most whales during this time period (418 whales) (Suydam and George 2004).

The IWC is the authority which sets the quota for bowhead subsistence hunts and the Alaska Eskimo Whaling Commission allocates that quota among the whaling communities in multi-year periods. At present there are 280 strikes allocated over the current five year period (2008 through 2012) with no more than 67 whales struck in any year (up to 15 unused strikes may be carried over each year). The term strike is defined as penetration with a whaling weapon. The term "strike limit" is used to refer to this limitation on the number of whales that may be struck, and the term "unused strike" refers to an unused portion of the limit on the number of whales that may be struck. The strike limit is larger than the landed limit, to take into account whales that may be struck but not successfully landed. The term "landed" refers to the number of whales that are actually harvested. As the strikes may be carried over and at the end of the 2010 harvest 15 strikes that were not used were available for carry-forward. The combined strike quota for 2011 is 82 (67 plus the 15) (Federal Register 2011b). An agreement between the U.S. and the Russian Federation gives the Russian natives no more than 7 of these strikes and Alaskan Natives may use no more than 75 strikes (Federal Register 2011b). In 2012, the IWC adopted catch limits allowing Alaska and Russia hunters to land up to 336 bowhead whales during the next five year period, 2013 to 2018 (AEWC 2012). The IWC catch limits are implemented by NMFS, which released a Draft EIS in June 2012, with a Final EIS anticipated in early 2013. The preferred alternative in the Draft EIS corresponds to the catch limits adopted by the IWC. The AEWC noted that annual limits adopted are the same as they have been for the past 15 years and anticipates that the same allocations will be agreed for 2013 (AEWC 2012).

Under a Cooperative Agreement between NOAA and the AEWC, the AEWC allocates the strikes and catch limit for landed whales among 11 Alaska Eskimo communities that harvest bowhead whales. These communities include: Kaktovik, Nuiqsut, Barrow, Wainwright, Point Hope, Kivalina, Gambell, Savoonga, Wales, and Little Diomede. Point Lay became the eleventh AEWC member in 2008 (Suydam et al. 2008). Figure 3.3-6 describes the efficiency of the bowhead subsistence harvest in Alaska from 1973 to 2010. Figure 3.3-7 describes the number of bowheads landed, and struck by subsistence hunters in the U.S., Canada, and Russia from 1974 to 2010.

Data from four communities on the Chukchi Sea from 1982 through 2011 was compiled by BOEM from various sources for Lease Sale 193 and depicts the annual bowhead whale subsistence harvest of Barrow, Wainwright, Point Hope and Kivalina (BOEM 2011b) and is described in Table 3.3-8.

Table 3.3-8 Bowhead Subsistence Harvest for Barrow, Wainwright, Point Hope and Kivalina from 1982 to 2011.

Year	Barrow	Wainwright	Point Hope	Kivalina
1982	0	2	1	0
1983	2	2	1	0
1984	4	2	2	1
1985	5	2	1	0

Note: Summarized in these references by the authors from data provided by AECW to NSB.
.

Note: Suydam et al. (2005) indicates that four whales were landed at Wainwright during the 2005 subsistence harvest which would result in the total harvest of 38 whales for the years 1997 through 2006.

Summary information for the number of bowhead whales landed between 2001 and 2010 complied from NMFS (2012) is described in Table 3.3-9. Additional harvest data is provided in Table 3.3-10 for the years 2005 to 2011. The IWC reports that in 2011, 51 bowhead whales were struck during the Alaskan subsistence hunt, with 38 whales landed with 20 landed during the spring hunt and 18 landed in the fall by Kaktovik, Nuiqsut, Barrow and Wainwright (IWC 2012, Suydam et al. 2011b). In the fall of 2010 the community of Wainwright landed a whale for the first time since 1974 and possible 50 years (Suydam and George 2004 in Suydam et al. 2010, Brower 2010). The fall harvest in Wainwright continued in 2011 with one bowhead whale being landed (IWC 2012). More recently in order to meet allotted quotas whaling crews from Wainwright, Point Hope and Point Lay have all been conducting fall hunts as changing sea ice conditions have been more dangerous in the spring (Comstock 2011).

Table 3.3-9 Number of Bowhead whales landed 2001 to 2010.

Note: Summarized in these references by the authors from data provided by AECW to NSB.

Barrow, Wainwright and Point Lay are the only communities within the EIS project area that hunt bowhead whales in the spring and fall. Kivalina, Wainwright, Point Hope, and (beginning recently in 2009) Point Lay hunt bowhead whales during the spring season. Kivalina and Kotzebue residents join bowhead whaling crews out of Point Hope. The communities of Kaktovik and Nuiqsut bowhead whale only during the fall season, although some Nuiqsut hunters join Barrow whaling crews during the spring whaling season (NSB 1998, Alaska Consultants Inc. and S.R. Braund and Assocs. 1984). Bowhead whale harvest areas for Kaktovik, Nuiqsut and Barrow have been extensively mapped by S.R. Braund and Associates (2010). Bowhead whale subsistence harvest areas for the Beaufort and Chukchi seas are provided on Figures 3.3-20 and 3.3-21. Harvest areas for the recently resumed bowhead whale hunt near Point Lay are unavailable and are not depicted on Figure 3.3-21. Descriptions of the bowhead whale hunts and their management are provided in NMFS (2008b) and are incorporated by reference. There are also many reports on subsistence patterns available from BOEM through the BOEM Environmental Studies Program Information System at http://www.data.boem.gov/homepg/data_center/other/espis/espismaster.asp?appid=1.

Beluga Whale (Quilalugaq)

Beluga whales (*Delphinapterus leucas*) are distributed throughout seasonally ice-covered Arctic and subarctic waters of the Northern Hemisphere (Gurevich 1980), and some stocks are closely associated with open leads and polynyas (nonlinear openings in the sea ice) in ice-covered regions of the Beaufort and Chukchi seas. Depending on season and region, beluga whales may occur in both offshore and coastal Alaskan waters. Mapping data is limited regarding harvest areas of the Beaufort Sea for beluga whales. Harvest areas where mapping data is available in the Chukchi Sea are described on Figure 3.3-23.

The Alaska Beluga Whale Committee (ABWC) monitors the subsistence harvest of beluga whales by Alaska Native hunters. There are five stocks of beluga whales recognized in U.S. waters: Cook Inlet; Bristol Bay; eastern Bering Sea; eastern Chukchi Sea; and Beaufort Sea (Allen and Angliss 2010) (see also Section 3.2.4.2). The harvest by all Alaska Native communities is approximately 300 to 350 belugas a year. According to the ABWC, the eastern Chukchi Sea stock (Kotzebue, Point Lay and Wainwright harvest from this stock) averaged 99 per year during 2007-2011, but it should be noted according to Suydam (in NMFS 2012) that if numbers harvested in the Kotzebue Sound area are separated from the Chukchi Sea stock, that number would go down. The Eastern Bering Sea (Norton Sound, Yukon and the Kuskokwim Delta) is the stock that is harvested the most heavily in Alaska and averaged 166.8 per year in 2007-2011 (Suydam in NMFS 2012). In Bristol Bay, about 20 beluga whales are harvested per year, with a total of approximately 350 beluga whales then taken annually in western and northern Alaska although this number does not include struck and lost beluga whales (Suydam in NMFS 2012). For 2011, the reported beluga whales harvest were: Kotzebue 30 whales landed; Kivalina 3; Point Hope 32; Point Lay 23; Wainwright 9; Barrow 6; and Kaktovik 0 (unconfirmed as there may have been 2 -3 harvested) (Suydam in NMFS 2012).

Ice Seals

Harvest areas for seals are described on Figures 3.3-24 and 3.3-25

Spotted Seal (Qasigiaq)

Spotted seals (*Phoca largha*) are distributed along the continental shelf of the Beaufort, Chukchi, Bering, and Okhotsk Seas south to the northern Yellow Sea and western Sea of Japan (Shaughnessy and Fay 1977). As of August 2000, the subsistence harvest database indicated that the estimated number of spotted seals harvested for subsistence use per year was 5,265 animals (Allen and Angliss 2010).

Bearded Seal (Ugruk)

Bearded seals (*Erignathus barbatus*) are circumpolar in their distribution, extending from the Arctic Ocean south to Hokkaido in the western Pacific. In Alaskan waters, bearded seals occur on the continental shelves of the Bering, Beaufort, and Chukchi seas (Burns 1981, Johnson et al. 1966, Ognev 1935 in NMFS 2008b). Bearded seals are an important species for Alaskan subsistence hunters, with estimated annual harvests of 6,788 (Allen and Angliss 2010).

Ringed Seal (Natchiq)

In the Beaufort and Chukchi seas, ringed seals (*Phoca hispida*) haul out in highest densities in shorefast ice during the May-June molting season, immediately following the March-April pupping season (Johnson et al. 1966; Burns and Harbo 1972; Frost et al. 1988, 1997, 1998, 1999 in NMFS 2008b). Ringed seals are an important species for Alaska Native subsistence hunters. The most recent annual subsistence harvest in Alaska is estimated to be 9,567 (Allen and Angliss 2010).

Ribbon Seal (Qaigulik)

Ribbon seals (*Histriophoca fasciata*) may migrate north to the Chukchi Sea during the summer (Kelly 1988). Ribbon seals are taken by Alaska Native subsistence hunters, primarily from communities in the vicinity of the Bering Strait and to a lesser extent at communities along the Chukchi Sea coast (Kelly 1988). The more recent annual subsistence harvest in Alaska is estimated to be 193 (Allen and Angliss 2010).

Walrus *(Aiviq)*

Walrus (*Odobenus rosmarus*) are harvested at higher levels in the Chukchi Sea communities than in the Beaufort Sea communities. Subsistence harvest mortality levels are estimated at 5,789 animals per year (Allen and Angliss 2010). When harvested walrus meat may be eaten and its ivory used in the manufacture of traditional arts and crafts. Harvest areas are described on Figures 3.3-22 and 3.3-23.

Polar Bear *(Nanuq)*

Polar bears (*Ursus maritimus*) are harvested primarily during the winter months on ocean ice and along ocean leads. The 1995-2000 mean U.S. harvest from the Beaufort Sea stock was 32.2 animals per year (NMFS 2008b). The Alaska Nanuuq Commission was formed in 1994 and represents 15 coastal villages from Kaktovik to the villages of Gambell and Savoonga on St. Lawrence Island (Alaska Nanuuq Commission 2012). This commission is recognized in federal legislation as the co-management authority, along with the U.S. Fish and Wildlife Service, in the management of the U.S.' shared polar bear populations. The Alaska Nanuuq Commission is directed by commissioners that are appointed by each village and is active in most polar bear matters both national and international (Alaska Nanuuq Commission 2012). In 2012 the U.S. – Russian Polar Bear Commission approved a multi-year quota system that intends to ensure that levels of polar bear harvest are sustainable (Alaska Nanuuq Commission 2012). The Alaska Nanuuq Commission noted that the quota harvest will be phased in during 2013 and then is expected to be officially implemented beginning in 2014 with 58 bears to be taken each year – 29 per country (Smith 2012). Polar bear fur is used to manufacture cold-weather gear such as boots, mitts, and coats. These sewn items are bartered, sold, and given as gifts to relatives and friends. Harvest areas for the Chukchi Sea are described on Figure 3.3-25.

Fish

Both marine and anadromous fish inhabit coastal Arctic waters. Marine fish include Arctic cod (Iqalugaq), saffron cod (Uugaq), two-horn and four-horn sculpins, Canadian eelpout, Arctic flounder (Nataagnaq), capelin, Pacific herring, Pacific sand lance, and snailfish. Migratory (anadromous) fish common to the Arctic environment include Arctic and Bering cisco (Qaaktaq), least cisco (Iqalusaaq), rainbow smelt (Ilhuagniq), humpback whitefish (Pikuktuuq), broad whitefish (Aanaakliq), Dolly Varden char, and sheefish. Although uncommon in the North Slope region, salmon are present in Arctic waters and used for subsistence. Subsistence fisheries for pink (Amaqtuuq) and chum salmon (Iqalugruaq) occur in the Colville and Itillik rivers and at Elson Lagoon near Barrow (Carothers 2010). In general, fish species include Pacific salmon (chum and pink), whitefish, Arctic char (Iqalukpik), Arctic grayling (Sulukpaugaq), burbot (Tittaaliq), lake trout (Iqaluaqpak), northern pike (Siulik), capelin, rainbow smelt, Arctic cod, tomcod (Uugaq), and flounder. Harvest areas are described on Figures 3.3-26 and 3.3-27.

Waterfowl

Migratory birds and their eggs (Mannik) are an important food source. Species harvested vary be region but generally include black brants (Niglingaq), long-tailed ducks (oldsquaw) (Aaqhaaliq), eiders, snow geese (Kanuq), Canada geese (Iqsragutilik), and pintail ducks (Kurugaq), although other birds, such as loons, may be occasionally harvested. Eider and long-tailed ducks are the most hunted ducks, while brant and Canada geese are the primary goose species. Ptarmigan (Aqargiq) can be taken all year in some communities. Since waterfowl is a highly preferred food, it is shared extensively within the community. Birds are often given to relatives, friends, and community elders. While most birds are eaten fresh, usually in soup, some are stored for the winter. Birds are often served for special occasions and holiday feasts such as Nalukataq and Thanksgiving. Harvest areas are described on Figures 3.3-26 and 3.3-27.

Caribou (Tuttu)

Caribou *(Rangifer tarandus)* are the main land mammals hunted for subsistence harvest by the Beaufort Sea and Chukchi Sea coastal communities. In some of the communities, caribou are the primary source of protein and are available year round. Other terrestrial mammals used for subsistence include moose, brown bear, Dall sheep, musk ox, Arctic fox, red fox, porcupine, ground squirrel, wolverine, weasel, wolf, and marmot. Harvest areas are described on Figures 3.3-26 and 3.3-27.

3.3.2.4 Community Subsistence Harvest Patterns – Seasons and Use Areas

This section describes annual subsistence cycles and harvest use areas by community. The timing of subsistence harvests is depicted in Tables 3.3-11 through 3.3-18 for the communities of Kaktovik, Nuiqsut, Barrow, Wainwright, Point Lay, Point Hope, Kivalina, and Kotzebue.

Subsistence harvest patterns are seasonal, responding to biological cycles, the proximity of resources, environmental conditions, and ease of travel. These patterns have a long historical basis and have been modified with the establishment of permanent settlements. It is important to note that the seasonal movement of subsistence resources to hunting sites and camps involves travel over and use of the extensive areas around each of the communities. Each community relies on specific subsistence resources to varying degrees, depending on their abundance, seasonal distribution, and proximity to the community. Many studies have been conducted to identify traditional subsistence use areas and are incorporated by reference throughout this section. They include studies by: NSB 1979; Pederson 1979; MMS 2007a, 2007b, 2007c; MMS 2008; Galginaitis 2009; Braund and Kruse 2009; EDAW-AECOM 2007; and Braund 2010. Seasonal descriptions of harvest are reported from the NSB's Coastal Management Plan (2007) and the NAB's Coastal Management Plan (2006). Extensive marine and terrestrial subsistence map efforts were conducted by Stephen R. Braund & Associates (2010) for the communities of Kaktovik, Nuiqsut, and Barrow in an effort to develop a GIS system that depicts regional subsistence patterns and measuring changes in these patterns over time.

Subsistence harvests tend to occur within traditional use areas, for which hunters have accumulated detailed knowledge of the physical geography of landscape and waters, the social geography of place names and the associated stories, and the wildlife ecology of likely animal distributions by seasons and under varying weather conditions. Hunters have a repertoire of effective harvest strategies to draw upon as they hunt throughout these traditional harvest areas. For example, bowhead subsistence whaling occurs in U.S. waters primarily during the spring and autumn migrations as the bowhead whales move north and east through near shore leads in the spring, and then west and south as ice forms in the autumn (Figures 3.3-19 through 3.3-21). The bowhead migration patterns are conducive to spring harvests for the Chukchi Sea communities, while Barrow's (and now Wainwright's) location provides for successful spring and fall hunts, the communities of Nuiqsut and Kaktovik on the Beaufort Sea participate in the fall hunt (NMFS 2008b).

<u>Beaufort Sea Communities</u>

Kaktovik

The subsistence patterns of Kaktovik are influenced not only by the seasonality of the resources but by the community's geographical position and periodic access limitations. Along this portion of the Beaufort Sea coast there is shorefast ice for at least 10 months of the year due to the currents. During the winter, marine mammals such as seals and walrus are not as numerous in the Beaufort Sea as in the Chukchi Sea, and they are not present as long in the summer. Some species such as walrus rarely occur near Kaktovik. Belugas are harvested opportunistically during the bowhead hunt. The majority of summer activities are coastal oriented, as Kaktovik lacks direct access to a navigable river because the waters are too shallow for boating. Hunters will go out along the coast for seals throughout the year.

Kaktovik has winter access to resources such as Dall sheep in the Brooks Range and to the Porcupine and Central Arctic caribou herds. Caribou hunting also occurs along the coast from June through September. These two resources make up for the lessened availability of marine mammals. Kaktovik's primary subsistence resources are caribou, sheep, bowhead whale, fish, and waterfowl, with seal, polar bear, and furbearers also being important. Main subsistence areas include a summer coastal zone extending from Foggy Island to Demarcation Bay and inland areas, such as along the Hula Hula River and into the Brooks Range, used when snow cover permits access by snowmachine (NSB 2007)

Winter: Sheep and caribou hunting declines during December due to the lack of daylight. Some limited trapping occurs and wolves and wolverines are taken in the mountains. Foxes are trapped along the coast, and polar bears are hunted near the community. During late January hunters begin returning to the mountains with trips becoming more frequent in March with increasing daylight. Winter fishing reported at the Hula Hula camps occurs during late February to April. Some caribou remain on the coast and are taken in late winter; and moose may be taken if they are needed and available (NSB 2007). Some sheep hunting may also be done in late winter. Lake trout are taken at places in the mountains, and ling cod can be obtained along inland portions of rivers (Wentworth 1979).

Spring: The long daylight hours of April and May and sufficient snow cover are good conditions for snow machine travel. Fishing at favored locations on the Hula Hula and other rivers continues until early April. Sheep might be taken until May (NSB 2007). Furbearer hunting continues until then also. Ground squirrels and marmots are hunted from early April when they come out of their holes. Often, the last trips to the mountains for the season are used to hunt them. Ptarmigan, though hunted all year, are most easily taken when they congregate in large flocks in the spring. Upon returning from the mountains, the first migratory waterfowl are taken along the coast in late spring/early summer, especially at traditional sites like Nuvuaq where seals, caribou, fox, and fish can be taken in various seasons (Wentworth 1979).

Summer: Waterfowl arrive as soon as there is open water. Tent camps are then set up in the Camden Bay area. As the season progresses and snow machine travel diminishes, hunting is done closer to the community, such as on the mainland or the historic area of Arey Island. Eggs are gathered on several of the barrier islands. Seals may also be taken, particularly for the oil and hides, but are hunted less than they were previously when they were needed for dog food. Towards the end of June, subsistence activities can come to a standstill as there is no snow for snow machine travel, and the frozen waters prohibit boat travel. Later, summer use areas are confined mainly to coastal and river delta regions due to shallow water. Griffin Point is a primary summer subsistence area; caribou, seals, and fish are taken there by people who may stay there for up to two months (Wentworth 1979).

In early July, boat travel is possible, and nets are set in Kaktovik Lagoon and other sites from Camden Bay to Jago Spit for Arctic char, which are harvested until August. Cisco and pink salmon are caught in the nets later in the summer; and, occasionally, beluga whales are taken. Beluga whales usually are harvested in August through November, incidental to the bowhead harvest. Caribou season occurs in about July, and they are taken along the coast and especially along the lower seven miles of the Canning River, where boating is possible (NSB 2007). A particularly good caribou hunting area has been identified at Konganevik Point. Grayling and whitefish are taken in the Canning Delta, which is one of the most important fishing areas for Kaktovik.

Fall: In late August, bowhead migration begins as the whales move westward, and crews may travel 20 miles out to sea at the beginning of the season, though later in the season, the whales migrate closer to shore and can be taken nearer the community during early September(Huntington and Quakenbush 2009). Kaktovik whalers have noticed patterns in the size of the whales during their migration and speculate that the larger whales are further offshore (more than 20 miles [32.2 km]) than they usually hunt (Huntington and Quakenbush 2009). Whaling may continue for several weeks, and butchering and transporting the whale can take another week. Peak sealing occurs during the whaling season. After whaling and freeze-up, inland travel is possible, and trips are frequently made along the Hula Hula River and into the mountains. Various camps along the Hula Hula are good spots for ice fishing for grayling and Dolly Varden/ char and provide a base of operations for caribou and sheep hunting in late October/early November. Kongakut River fishing sites produce Dolly Varden/char. Grayling fishing is done in nearly all the major rivers and especially along the Canning, where whitefish and ling cod are also taken, and along the Kuparuk (Jacobson 1979).

Many studies document the customary and traditional use of subsistence resources by Kaktovik residents. These studies are herein incorporated by reference: Brower and Hepa 2000; Caufield and Pedersen 1981;

Chance 1966; Chance 1997; Coffing and Pedersen 1985; Craig 1987; George and Fuller 1997; ADFG 2000; Haynes and Pedersen 1989; Impact Assessment, Inc. 1990; Jacobson and Wentworth 1982; MMS 2003; MMS 2001; MMS 1998; MMS 1996b; MMS 1990; MMS 1986; MMS 1983; MMS 1998; MMS 1996;; MMS 1986;; Nielson 1977; NSB 1979; Oldham n.d.; Patterson 1974; Pedersen 1995; Pedersen 1990; Pedersen 1984; Pedersen 1979; Pedersen and Linn 2005; Pedersen and Coffing 1984; Pedersen and Coffing 1985; Pedersen et al. 1991; Pedersen et al. 2000; Huntington and Quakenbush 2009; Wentworth 1979.

Nuiqsut

Marine mammals harvested by Nuiqsut hunters include bowhead whales, beluga whales, bearded seals, ringed seals, spotted seals, and polar bears. Bowhead whales are hunted from Cross Island.. The barrier island and Thetis Island are also reported as important seal hunting areas:

> *Thetis Island is one of the most important areas for seal hunt during -- when you have access to go out to the ocean or you have access closer to the shore. Once that ice goes out, it goes out, it doesn't come back. And we depend on these islands for subsistence.* – Nuiqsut Public Scoping Meeting March 11, 2010.

Nuiqsut hunters report caribou and moose as their most important subsistence land mammals, but also harvest wolf, wolverine, and fox. Fish harvests include Arctic cisco, whitefish, least cisco, grayling, humpback whitefish, burbot, northern pike, pink salmon, and Arctic char. The general area of terrestrial subsistence activities extends from the community east to the Sagavanirktok River, south to the middle Colville, west to Teshekpuk Lake, and along the coast to Pitt Point to the mouth of the Canning River. Hunters also join Barrow hunts for sea mammals and occasionally go to Kaktovik and Wainwright (NSB 2007).

Winter: Activities slow down during the coldest and darkest part of winter. Trapping for foxes and hunting of wolves and wolverines are accomplished during this season. Caribou and moose have traditionally been taken during winter. Seals are hunted on sea ice when open leads appear. As weather and light improve, trapping, caribou hunting, and fishing for cod, grayling, and lake trout increase (NSB 2007).

Spring: Spring whaling on the coast draws some men to Barrow to participate as crew members or whaling captains. No spring whaling occurs from Nuiqsut or Cross Island. Seals are taken on the sea ice during April and May. Furbearer hunting in the foothills and on the coastal plain is an important activity as the daylight and weather improves and continues until the snow is gone in May. Grayling, cod, and lake trout are taken with hook and line during the warmer weather. Long snow machine trips may be taken to Barrow or Kaktovik or even farther to visit friends and relatives before the snow melts and some caribou may be taken in conjunction with these trips (NSB 2007).

Summer: In the summer, ringed and spotted seals are hunted near the Colville River as far south as Ocean Point (EDAW-AECOM 2009). Following breakup in early summer, whitefish are taken in nets in the Colville River when the water clears in June. As this season progresses, fishing is conducted farther up river and on Fish Creek. Waterfowl begin to appear and are taken periodically until their fall migration. In late summer, char and salmon begin running up the Colville River, followed by spotted seals. Some coastal fishing occurs for whitefish and cisco. Children set traps for ground squirrels and fish for grayling with nets and rod/reel. Caribou hunting then becomes the primary activity in late summer (NSB 2007).

Fall: Caribou hunting, fishing, and bowhead whaling are the most important subsistence activities that occur in the fall. Bowhead whaling begins in mid-September along the coast as far east as the Canning River. The base for fall whaling is Cross Island which is 90 to 100 miles from the community by boat (EDAW-AECOM 2009). As indicated by Nuiqsut whalers:

> *Thetis Island, on to Cross Island and beyond Cross Island to Camden Bay. Those are our very important areas for feeding, resting for the bowhead whales while they're migrating west during fall time.* – March 11, 2010 Nuiqsut Scoping Meeting.

Seals are also hunted near the Colville Delta and along the coast from Cape Halkett to Foggy Island (EDAW-AECOM 2009). Caribou migrate south from their respective calving grounds, though some remain in the area throughout the winter near Fish Creek. Moose are a newer species to the region and are becoming an important resource, especially during times of restricted hunting of caribou and are taken along the middle Colville River. Fishing for cisco and whitefish is done with nets before freeze-up in the rivers and continues after freeze-up at fish camps on the Colville and Fish Creek. Grayling and ling cod are taken through the ice in later fall. Berries are picked during fishing and hunting trips, and sometimes driftwood and coal are collected. Seals, ducks, caribou, and sometimes polar bear are taken concurrent with bowhead whaling activites (NSB 2007).

Whaling activities of Nuiqsut have been extensively studied in cooperation with participating whaling captains for more than a decade. BOEM (and previously MMS) has conducted long-term environmental monitoring around the Northstar development, which is near the Nuiqsut subsistence-whaling area at Cross Island. As part of this monitoring effort, BOEM conducted a multiple-year collaborative project with Nuiqsut whalers that describes present-day subsistence whaling practices at Cross Island to verify any changes to whaling due to weather, ice conditions, or oil and gas activities. The project findings were summarized during the 2005 MMS Information Transfer Meeting (MMS 2005) and specifically through Galginaitis (various studies through 2009). These observations and narrative annual reports were performed in participation with whaling captains from Nuiqsut that depict geospatial information from the sharing of GPS data. This data reflects the extensive use of the area for bowhead hunts from whaling camps at Cross Island (specifically see Galginaitis 2009).

The customary and traditional use of subsistence resources by Nuiqsut residents and the effects of oil development is documented in many studies, which are herein incorporated by reference: ADFG 2000; ADF&G 2003; Brower and Opie 1998; Brown 1979; Burns 1990; Craig 1987; Galginaitis and Funk 2005; Galginaitis et al. 1984; George and Fuller 1997; George and Nageak 1986; George and Kovalsky 1986; Hall 1983; Hoffman et al. 1978; Impact Assessment, Inc. 1990; Kruse 1982; Kruse et al. 1982; Kruse et al. 1981; Moulton and Field 1988; MMS 2003; MMS 2001; MMS 1998; MMS 1996a and 1996b; MMS 1990; MMS 1986; MMS 1983; Nielson 1977; NSB 2003; NSB 1979; NSB 1978; NSB 1975; Patterson 1974; Pedersen 2001; Pedersen 1995; Pedersen 1988; Pedersen 1986; Pedersen 1979; Pedersen et al. 2000; USACE 1997; U.S. Department of the Interior 1998.

Barrow

Barrow is one of two communities, the other being Wainwright, in the EIS project area that hunts bowhead whales in the spring and fall. Hunters in Barrow harvest bowhead whale, ringed and bearded seal, and walrus as they migrate north along the Chukchi Sea towards the Beaufort Sea. In the fall, Barrow whalers hunt bowhead whales as they migrate south. Birds, such as eider ducks and geese, are also present in great numbers during their migrations to key nesting grounds on the North Slope (Braund 2010). Caribou migrate across the tundra throughout the year and are available to hunters primarily during the summer and fall while they migrate to the coastal areas and along rivers to escape the heat and insects. Barrow residents harvest fish including: broad whitefish; Arctic grayling; tomcod; and burbot in local rivers and lakes and in Elson Lagoon. Other subsistence resources include moose, ptarmigan, and furbearing animals, such as wolf and wolverine (Braund 2010).

Boats are used for travel in the open water season and in open water leads. Outboard motors and all-terrain vehicles now enable hunters to travel much farther in a day than in the past. Aircraft are used by some to access fish camps or special hunting areas far from the community. Barrow hunters use the sea-ice/ocean environment at all times of the year, in the areas ranging from Peard Bay to Pitt Point for marine mammals, waterfowl, and fox. Spring whaling is based from camps on the ice shelf northwest of the community. The coastal zone is used for hunting ducks, seals, and walrus, fishing (spring/summer), and, in the fall, for whaling (especially at Pigniq). The coast is also used for collecting eggs, driftwood, and occasionally plants and invertebrates, also for picnics and camping. Inland areas are used in pursuit of caribou, fish, and fur-bearers (Schneider et al. 1980).

Winter: During the coldest and darkest of the winter months, subsistence activities progressively decrease. Sealing occurs on the west side of Barrow, and polar bears are harvested if they are encountered along the coast. Polar bear are hunted during the fall and winter – October to June – in the same areas where walrus are hunted from west of Barrow southwestward to Peard Bay. Inland travel is lessened with river and lake fishing ceasing by midwinter. Light trapping occurs, but the hunting of furbearers is conducted by use of snow machine. Trap lines are set on nearshore pack ice off Barrow and inland about one hour from the community. Trap lines are extended much farther in all directions from Barrow when the weather warms beginning in late winter (March). The historic site of Pulayaaq on the Meade River is used for trapping in late winter and for taking waterfowl in the spring, as well as for summer fishing and hunting. Nearby, Pulayatchiaq is also noted as a current and historical area for trapping and spring waterfowl. Some trap lines extend for a hundred miles with many loops and follow the rivers, ridges, or other easily traversed features. Furbearer hunting by snow machine is also done when people are out hunting caribou or trapping. Foxes are trapped or shot incidental to other hunting trips. The local demand for wolf and wolverine far exceeds the supply (NSB 2007).

Midwinter is also a time for socializing and celebrations at which subsistence foods, particularly bowhead whale, play an important role. As winter progresses and daylight hours lengthen, subsistence activities and travel increases. Trap lines are extended, and caribou hunting becomes of increased importance as food supplies become generally low. Sealing and polar bear hunting continue along the coast in each direction from Barrow. In late winter, preparations begin throughout the community for spring whaling (NPR-A Task Force 1978, Schneider et al. 1980).

Spring: The spring bowhead hunt occurs west and east of Point Barrow (Braund 2010). Barrow residents have reported hunting bowhead whales almost as far as Smith Bay to the east and as far as Skull Cliff to the west where there is an area of overlap with Wainwright whaling areas (Braund 2010). The location of Barrow allows access for whalers from April to June in offshore leads from historic areas such as Nuvuk. Spring whaling areas depend on the location of the open lead. Huntington and Quakenbush (2009) reported that whalers have noticed an increase in the numbers of bowheads over the last few decades and that changes in ice in conditions and have influenced the spring migration pattern near Barrow with fewer whales migrating next to the edge of the shorefast ice and fewer seen southwest of Barrow.

The spring hunt for beluga whale occurs from April to June in the spring leads between Point Barrow and Skull Cliff. Later in the spring, whalers in Barrow hunt belugas in open water around the barrier islands off Elson Lagoon.

With the increase of daylight hours, other subsistence activities increase, and migratory animals return to the coast. Ducks, some walrus, and bearded seals may become available offshore west and north of Point Barrow in April. Trapping ends at about this time, though furbearer hunting continues at places, such as Qaviarat on the Meade River (where geese can be taken later on), and Kalayauk, which is also noted for its geese and ducks. While caribou may be hunted, whaling takes precedence unless the quota is met early, in which case all of the above resources are then pursued (NSB 2007). Ptarmigan are available year round but are taken in greater numbers in the spring when they flock. By June, when spring whaling is over, seal and duck hunting camps are set up along the coast southwest to Peard Bay. One especially popular camp is at the historic site of Pigniq, north of Barrow (NSB 2007).

Summer: In late spring/early summer, gathering of coastal and inland birds including eggs commences. When the rivers become free of ice, nets are set at fish camps for harvest of whitefish, char, and salmon. When the shore ice retreats in about early July, boat travel becomes more frequent, and trips are taken to Wainwright, Nuiqsut, Beechey Point, and inland fish camps, such as Qaviarat, where other year round activities take place as well. As the ice recedes, ringed sealing decreases though bearded and harbor seals become more common in abundance. Bearded seal hunting is a communal effort, and hunts are conducted west of Barrow or from Pigniq (NSB 2007).

After the shore ice breaks up, walrus are also hunted cooperatively. Barrow residents harvest walrus for their meat, hides, and ivory tusks. The walrus supplies food and material for clothing and arts and crafts. Residents hunt walrus in early summer to early fall, June to September, from west of Barrow southwestward to Peard Bay. Barrow residents hunt seals for their meat, oil, and skins. The meat and oil serve as dietary supplements. Seal skin is used in clothing, as wells as for boats.

Coastal fishing with nets for salmon, and char occurs at traditional sites along Elson Lagoon and west of Point Barrow, where tending nets may be combined with duck and marine mammal hunting. Whitefish and grayling are taken with gill nets during mid to late summer. Inland fishing becomes intensified. Payugvik, on the Meade River, is a noted traditional site used for more than a hundred years as a summer and winter fishing spot. The area is a common rest stop for people traveling the trail between Barrow and the community of Atqasuk further inland.

In conjunction with other activities on the coast and at inland lakes and rivers, berries and plants are collected when in season. The major fish effort for the Barrow area takes place at inland sites. Sealing and walrus hunting begins to decrease in late summer. Caribou skins are considered to be in prime condition in late summer when the main hunting effort begins. The majority of caribou hunting occurs by boat during the summer and fall months along the coast and inland along various rivers; whereas caribou are taken as needed throughout the winter months (Braund 2010). A few grizzly bears are taken if the opportunity presents, usually while conducting other subsistence activities along rivers. Duck hunting can continue into September as the southward migration begins, especially at Pigniq where some fishing is also done (Schneider et al. 1980).

Fall: Intensive caribou hunting, fishing, and whaling occur during the fall. Barrow residents have reported that fall hunting areas depend on the location of the migrating whales, weather, and ice conditions, and hunters generally indicated that the primary fall hunting area is east or northeast of Cape Simpson on Smith Bay (Braund 2010). Fall bowhead whaling occurs from August to October in an area that extends 16 km (10 mi) west of Barrow to 48 km (30 mi) north of Barrow, and southeast 48 km (30 mi) off Cooper Island with an eastern boundary on the east side of Dease Inlet. Occasionally, bowhead whale hunting may extend east as far as Smith Bay and Cape Halkett or Harrison Bay. In a 2009 study (Braund 2010), respondents noted that the whaling captains set the timing of the fall hunt with some hunters preferring to hunt in October after the larger whales have migrated through.

Caribou are still numerous near Barrow in September. Inland fishing is considered to be most productive in the fall, and this activity increases especially at such historic places as Iviksuk on the Inaru River and Nauyalik on the Meade, where a landing strip provides easy access for the community. As during the summer months, fishing is often combined with caribou hunting and berry picking and later with furbearer hunting. Permanent (cabins) and temporary camps are set up at favorite spots to conduct these subsistence activities for extended periods of time. Food storage is another function of these camps, as ice cellars store excess food which can be transported to the community later. They are not, however, as commonly used today as in the past. The camps are like small tent cities, especially after freeze-up, and are heavily used on weekends. Distant camps as far away as Teshekpuk Lake are used by Barrow residents, either because their past history includes personal familiarity or because nearer camps may be overcrowded (NSB 2007).

During the fall, coastal areas such as Pigniq continue to produce ducks while they are available, and seals and walrus may also still be available. When the ice begins to form on inland waters, fishing continues for whitefish, grayling, and burbot with nets and by jigging (NSB 2007). Ringed seals will begin to appear on the coast. Moose, which have recently extended their range northward, can sometimes be available in the Colville drainage, but the number taken by Barrow residents is considered low.

Chukchi Sea Communities

Wainwright

Wainwright is situated close to several different environments, each of which provides the community with diverse wildlife resources for subsistence harvest. Bowheads, belugas, walrus, and seals are taken from the ocean/sea ice environments. The lagoon system inside of the barrier islands provides habitat for waterfowl, seals, and other marine mammals. Subsistence hunts for bowhead whales occur in the spring and fall. Beluga whales comprise a main portion of the subsistence economy of Wainwright (NSB 2007). Beluga subsistence hunters conduct annual hunts for cultural and nutritional reasons, and, in Wainwright, up to forty belugas per year are harvested (Willie Goodwin - ABWC 2007). Seals are also harvested, with bearded seal being the most sought after species, and ringed seal is not considered as important. Bearded seals are considered a mainstay subsistence resource and are prized for their fat and meat. Bearded seals are harvested from spring through fall. Smaller bearded seals are preferred for their meat, and the larger ones are considered best for rendering oil (MMS 2008). The Kuk River is an area where fish and other predators attracted to them are taken. The Kuk River estuary provides habitat for fish, especially smelt. Terrestrial resources such as caribou, furbearers, plants/berries, bear, and ptarmigan are also harvested. Subsistence activities are concentrated along coastal areas from Point Franklin to Icy Cape and inland along the Kuk and Utukok river drainages. The sea and sea/ice environments are used for many miles out from the shore. Avid hunters may extend their operations to the Meade and Colville rivers or along the coast to Point Lay and Peard Bay (Ivie and Schneider 1979) overlapping with subsistence user areas of other communities.

Winter: Wainwright residents hunt polar bear for their meat and pelts. Polar bear subsistence hunts occur in the fall and winter around Icy Cape, at the headland from Point Belcher to Point Franklin, and at Seahorse Island. In the winter, furbearers are taken during late winter when there is increased daylight and weather improves. Fox are harvested along major rivers and at coastal sites, while wolf and wolverine are trapped or shot on the coast or at inland locations. Throughout the winter, ringed seals are taken along leads in the ice. Caribou and polar bear may occasionally also be taken. Wainwright is noted throughout the North Slope for its smelt, and much fishing is done in January through March in the Kuk Lagoon.

Spring: Whaling is the most important subsistence activity in spring. Bowhead whaling occurs beginning in April, and these whales are taken in open leads in the offshore ice as they pass close to shore near Point Belcher and Icy Cape. More recently is has been reported that bowheads are appearing in early April and sometimes even in March, with movements being determined by ice conditions (Quakenbush and Huntington 2010). Wainwright residents will travel up the coast as far as Peard Bay to hunt bowheads in the spring. Whaling camps are sometimes located 10 to 15 mi (16 to 24 km) from shore (MMS 2009b). Hunters report that the bowhead whales reach the Wainwright area approximately a week after passing Point Hope (Quakenbush and Huntington, 2010). The beluga whale hunt takes place in the spring lead system from April to June. The beluga whales arrive about the same time as bowheads. Belugas are hunted from the ice along leads or driven into inlets in summer and harvested. Belugas are hunted from late June through mid-July and sometimes later into the summer. Walrus and harbor and bearded seals also may be taken but are more commonly hunted in summer; ringed seals, however, are taken during the spring. Migratory waterfowl harvest occurs along the coast and along rivers beginning in May. Squirrels and marmots are sometimes harvested in conjunction with furbearer hunting trips inland toward the mountains.

Summer: Bearded seals are hunted in early summer southwest of the community, and spotted seals, which migrate south in fall, are harvested in late summer when they will float after being shot. Walrus become prevalent during July and August and are taken from drifting ice floes near Wainwright and along the coast to Peard Bay. From August to September, Wainwright residents may hunt walrus at local haulouts, with the main area being from Milliktagvik north to Point Franklin. Icy Cape is a known walrus haulout location (NSB 2007).

Subsistence activities occur on the coast and at rivers as overland tundra travel becomes more difficult in summer. Families occupy traditional camping sites along the coastline for sealing, waterfowl hunting, and other activities up until the midsummer, and then fishing activities intensify. Waterfowl are harvested in early summer until nesting and some egg collecting occurs along Kasegaluk Lagoon or Seahorse Island (NSB 2007).

Caribou migrate to the coast during summer and are harvested from Icy Cape to Peard Bay beginning in late August and into the fall. Berries are collected during the late summer near the community and along the Kuk River. Fishing is a major subsistence activity that occurs all year, and, during midsummer, nets are set up in front of the community for salmon, trout, and whitefish. Fishing activities then move to streams and rivers as the migratory fish work their way upstream (NSB 2007).

Fall: Fishing and caribou hunting are the main subsistence harvest activities in the fall. Caribou skins are considered the best at this time of year, and they are hunted on the coast from Icy Cape to Peard Bay and along major rivers (NSB 2007). Migratory waterfowl are also harvested at areas including Icy Cape and Point Belcher. While caribou is not a coastal resource, access is closely tied to the waterways as they travel along the drainages and beaches, and the waterways provide an avenue for transportation for locating the caribou and hauling the harvest home. Wainwright residents recently resumed a fall bowhead hunt and landed a whale in the fall of 2010 for the first time since 1974 and possible 50 years (Suydam et al. 2010, Brower 2010) and landed another whale in 2011 as well.

Fall fishing occurs at camps for up to two months along the Kuk, Ivisaruk, and Avalik rivers, often in combination with other hunting and berry-picking expeditions (Nelson 1981). After freeze-up in the fall, travel becomes easier overland, and additional fishing trips are made to Utukok River camps. Sometimes people use charter airplanes to reach these camps. Sites on the Kuk River are used after freeze-up with access by snow machines. When the shorefast ice begins to form in the late fall, polar bears are taken when they come to the coast to feed on sea mammal carcasses. The meat is popular for winter holiday feasts. Coal is collected in late summer and fall along the Kuk River and coastal beaches after heavy storms (NSB 2007).

The customary and traditional use of subsistence resources is documented in many studies that are herein incorporated by reference, including: Bane 1966; Braund 2003; Braund 2003; Braund 1993; Braund 1989; Burns 1990; Chance 1966; Craig 1987; George and Fuller 1997; ADFG 2000; Ivie and Schneider 1988; Jorgensen 1990; Kassam and Wainwright Traditional Council 2001; Lutton 1985; Nelson 1981; Nelson 1969; NSB 2002; NSB 1979; Patterson 1974; Pedersen 1979. A particularly important collaborative effort to document traditional use areas and potential impacts of oil and gas development is found in Wainwright Traditional Council and the Nature Conservancy, n.d. [est 2007].

Point Lay

Beluga whales comprise a main portion of the subsistence economy of Point Lay. The beluga subsistence hunters of this community conduct annual hunts for cultural and nutritional reasons, and, in Point Lay, hunters will harvest approximately 30 to 50 belugas each year (Willie Goodwin – in MMS 2008). Frost and Suydam (2010) estimated that up to sixty percent of the eastern Chukchi Sea harvest occurred at Point Lay and noted that the hunt usually occurs in very shallow water, less than two meters near the town. Point Lay hunts belugas from late June through mid-July. It is estimated that up to two-thirds of the annual subsistence production by weight is beluga whale (ADFG 2011) with the majority of the harvest being taken in one or two cooperative hunts in the early summer. Point Lay hunters take belugas near the community, usually herding them from the south to the shallows inside Kasegaluk Lagoon. Hunters are most familiar with belugas in the area between Omalik Lagoon and Point Lay, although they also have hunted belugas as far north of the community as Icy Cape (Huntington et al. 1999).

There are several overlapping areas of subsistence usage between the communities of Point Lay and Wainwright such as in the Beaufort and Raven basins up the Kukpowruk River where hunters from both communities harvest furbearers. Icy Cape is another area that each community uses for hunting waterfowl. Caribou hunting areas in the western Brooks Range in the southeast corner of the NPR-A are used by Point Lay and Wainwright hunters (NSB 2007). In March and April, both communities may hunt for wolf and wolverine in the Amatusuk Hills. A seasonal description of current subsistence activities of Point Lay follows.

Winter: Some ice fishing continues in early winter, and occasional caribou hunting trips are taken. Trapping occurs throughout the winter primarily at coastal areas, though winter storms may prevent the checking of traps at regular intervals. Wolf, wolverine, and caribou hunting may be combined in areas towards the mountains. Coastal traps are often set next to washed up marine mammal carcasses which attract fox and wolverine. Polar bears are also taken at these trapping sites as they are attracted because of the bait or foxes. Polar bears are not as actively hunted as in former years. Some sealing is attempted. In late winter, some people travel to other communities to participate in the bowhead whaling activities (NPR-A Task Force 1978, Schneider and Bennett 1979 in NSB 2007).

Spring: During the spring, Point Lay residents gather eggs and hunt terrestrial mammals and marine mammals. Migratory waterfowl and eggs are harvested during May and June at coastal sites and along inland rivers. Large quantities of eggs are harvested at specific areas, such as the islands in Kasegaluk Lagoon north of the community and along the barrier islands. Ground squirrels are harvested by the community and hoary marmots are hunted in the Amatusuk Hills. Ringed and bearded seals are available year-round. Ringed and bearded seals are hunted 20 mi (32 km) and 30 mi (48 km) north of Point Lay, respectively, with bearded seals concentrated in the Solivik Island area and up to three miles north off the island (NSB 2007, MMS 2009b). Bearded seals are also hunted from south of Point Lay to the southern end of Kasegaluk Lagoon. Snow machines are used to hunt caribou as they move toward the coast for the summer or in the Amatusuk and Kiklupiklak hills (Schneider and Bennett 1979 in NSB, 2007). While Point Lay hunts mostly beluga whales, in the spring of 2009, a bowhead whale was landed for the first time since 1937 and in May 2011 a whaling crew again landed a bowhead whale (Arctic Sounder 2011).

Summer: Many different subsistence activities occur during the summer, and boats are used for access to subsistence resources. In early June, the open lead allows for sealing, and later the annual walrus hunt occurs near Icy Cape. As the sea ice retreats in June, the walrus migrate north past Point Lay, and the community conducts their annual hunt. Walrus are hunted from June to August – depending on favorable ice conditions – along the entire length of Kasegaluk Lagoon, south of Icy Cape, and as far as 20 mi (32 km) offshore (NSB 2007, MMS 2009b).

Beluga whales are harvested from the middle of June to the middle of July. The hunting area is concentrated in Naokak and Kukpowruk Passes south of Point Lay. Hunters use boats to herd the whales into the shallow waters of Kasegaluk Lagoon where the belugas are harvested. If the July beluga hunt is unsuccessful, Point Lay hunters may travel as far north as Utukok Pass and as far south as Cape Beaufort in search of beluga whales. Like the walrus hunt, all available hunters participate. Boats are used to herd whales into shallow water where they can easily be retrieved after being stuck. Occasionally, belugas can be taken in August as well. Data from satellite tagging and aerial surveys in the eastern Chukchi Sea indicate that belugas make extensive use of the coastal waters within 50 miles of the coast in June and July, and more than 1,000 belugas have been observed at Kukpowruk, Akunik, and Utukok passes along Kasegaluk Lagoon during these months (Willie Goodwin – ABWC in MMS 2008; Suydam et al. 2000).

Caribou are taken along the coast and around Icy Cape, and waterfowl and eggs continue to be taken in early summer. Fishing using gill nets occurs near river mouths (except Kokolik), at ocean passes, in Kasegaluk Lagoon, and at Sitkik Point. The season lasts from early July to late September. The nets are moved about 15 miles up the Kukpowruk River in September for grayling fishing. A variety of salmon, whitefish, flounder, smelt, herring, bullhead, and an occasional char are taken. A majority of residents of the community are engaged in fishing during the summer months (NSB 2007). Berries and other edible plants are collected along the coast, inland along rivers and near the historic site of Cully. As fall approaches, preparations are made for ice fishing. Snow machines are taken by boat up the Kukpowruk River and left to be used after freeze-up (Schneider and Bennett 1979 in NSB 2007).

Fall: Point Lay residents hunt for polar bears from September to April along the coast with the hunting area rarely extending more than two miles offshore. The fall migration of waterfowl attracts hunters to the area near Icy Cape. Caribou hunting is actively pursued from late August to October at inland locations. Whole families will engage in fall grayling fishing up the Kukpowruk River, even after the school year has begun. Nets are used until freeze-up, when hook and line methods are then used for ice fishing at traditional ice fishing sites. Berry picking is combined with fishing trips, and coal is sometimes brought back to the community after freeze-up by snow machine from the mine on the Kukpowruk. Residents hunt moose, which is considered a new species to the area. Spotted seals are hunted in early fall when they are fat and do not sink (Schneider and Bennett 1979 in NSB 2007). Point Lay has been recently conducting fall hunts as changing sea ice conditions have been more dangerous in the spring (Comstock 2011).

Point Hope

During much of the year, certain species, including seals and caribou, are present, as well as smaller mammals and ptarmigan. A discussion follows of the seasonal description of subsistence use and harvest areas for Point Hope.

Winter: Winter lasts in this area from approximately November to March and April. During this time, inland travel is most accessible. Trips are taken to Cape Lisburne and Kivalina in conjunction with caribou and furbearer hunting. Sealing and caribou hunting are the major resources for subsistence foods during winter, and sea ice fishing for cod contributes to the diet of residents in January (NSB 2007). Cod fishing is done with hook and line through the ice. Trapping sites are set up along the coast north and south of the community, especially around sea mammal carcasses to attract Arctic fox and wolverine.

Sealing sites along the south coast are used most frequently, but north coast sites are used if ice and wind conditions permit (Lowenstein 1980). Polar bears are more abundant in late winter. Point Hope residents hunt polar bear for their meat and their fur. Primary polar bear hunting takes place from January to April and occasionally from October to January (MMS 2007c). Residents hunt these mammals in the area south of the point, as far out as 16 km (10 mi) from shore. The winter area of subsistence usage is more extensive than at any other season, ranging from Cape Lisburne to the ice pack well beyond Cape Thompson to inland regions encompassing nearly all the Kukpuk and Ipewik river drainage (Foote and Williamson 1966).

Spring: Migration patterns of subsistence resources (mainly the bowhead whale migration) influence the harvest, which occurs in the spring. Whaling occurs from the time the offshore leads form in the ice in late March or early April until June. Bowhead whales are hunted from March to June from whaling camps along the ice edge south and southeast of Point Hope. The pack-ice lead is rarely more than 10 to 11 km (6 to 7 mi) offshore (MMS 2007c). Seals, some walrus, beluga whales, and polar bears are taken if the bowhead whales are not present. The main sealing season begins along the south shores of the peninsula after whaling has concluded. Belugas are usually taken from late March through June. Seals and walrus follow the receding ice pack and are not commonly available at Point Hope during the summer months. Walrus are also hunted in south shore leads and by boat as the old ice breaks up (NSB 1979). Hunters harvest walrus from May to July along the southern shore from Point Hope to Akoviknak Lagoon.

Early migratory birds passing through the area are also harvested. The area of subsistence activities includes extensive sea ice usage along the north coast and around Point Hope north toward Cape Thompson. Inland areas along the Kukpuk and Ipewik rivers also are utilized (Foote and Williamson 1966).

Summer: Open water by late June allows for boat travel. Some bearded and harbor sealing may occur in late spring/early summer (Pedersen 1971). Beluga whaling also occurs again in July, and some may be taken with nets from the beach (Burch 1981). The second beluga hunt occurs later in the summer from July to August. During this second hunt, Point Hope residents hunt beluga whales in the open water near the southern shore of Point Hope close to the beaches, as well as north of Point Hope as far as Cape Dyer (MMS 2007c).

Bird nesting sites at Cape Thompson and Cape Lisburne are visited by boat to collect eggs and harvest birds (Maclean 1971 in NSB 2007). Marine fishing for char and salmon is conducted with beach seines and nets along the north and south shores, and lagoons yield whitefish. Caribou are also harvested at several places inland along the coast, including the Kukpuk River area or towards the Pitmegea River (Lowenstein 1980). Salmon and grayling are caught at the mouth of the Kukpuk River and at other fishing areas along the river. Berries and edible plants are collected and, if not used immediately, are stored in oil or frozen.

Fall: Subsistence activities in the fall are conducted from about mid-September to early November and are characterized by intensive fishing along the Kukpuk River. About three fourths of the total fish harvest is obtained in the fall (Pedersen 1971). Fishing is combined with caribou and moose hunting up to the mouth of the Ipewik River. Gill nets and hook and line are used for fishing before freeze up and afterwards through holes in the ice. Grayling, char, whitefish, and Dolly Varden are harvested. Cod are harvested in the fall when storms throw them up on the beaches (Lowenstein 1980). Caribou are hunted along the Kukpuk River and at coastal and inland areas around Cape Thompson. Migratory waterfowl are harvested again in the fall. As the sea ice forms, seals begin to reappear, and some are hunted by boat while residents collect driftwood. Sealing becomes more intense as the ice thickens. In early November, the trapping season begins. The area of greatest fall subsistence usage extends from the south shore inland to an area beyond the Kukpuk River and part of the north coast. Point Hope has recently been conducting fall hunts to meet their allocated quota and provide for their community as changing sea ice conditions have been more dangerous in the spring hunt (Comstock 2011).

Kivalina

Kivalina residents use a continuous offshore area that extends from Cape Krusenstern to Cape Thompson with use areas also extending to Point Hope and then inland to the DeLong Mountains and Noatak River (Braund 2008, Magdanz et al. 2010). Some use areas also occur near Kotzebue, Cape Lisburne, Point Lay and Selawik. Areas with the highest overlapping use were located directly west of the community in the Chukchi Sea for marine mammal harvests and also in the lowland areas to the east of the community, including the Kivalina and Wulik rivers for caribou, furbearers, fish, berries, and other resources (NAB 2006). In 2007, residents reported subsistence use areas extending along the coast from Cape Thompson towards Cape Krusenstern and inland from Rabbit Creek into the Delong Mountains (Braund 2008). Surveys conducted in 2007 reported that subsistence activities of Kivalina residents (and the nearby inland community of Noatak) occur over more than a 25,000 sq km area and can range more than 150 km (93 mi) from home (Magdanz et al. 2010).

Marine mammals are hunted by residents between Cape Thompson and Sheshalik Spit (NAB 2006). Seal and walrus use areas extend farther out into the Chukchi Sea, while beluga and polar bear subsistence use areas are located closer along the coastline. Areas where land mammals are harvested, including caribou, bear, and furbearers, occur over an expansive inland area from Cape Thompson in the north to Cape Krusenstern in the south and inland into the Noatak National Preserve and DeLong Mountains (EPA 2009). Moose hunting is focused along the coast and nearby rivers, and sheep hunting was reported around several inland mountains. Use areas for fishing occur along the Kivalina and Wulik rivers, in lagoons south of the community, in the waters near Sheshalik, and in Selawik Lake. Bird hunting and egg gathering occurs along the coast and along the Wulik and Kivalina rivers. Harvests of vegetation, including berries, plants, and wood, are reported as located along the Kivalina and Wulik rivers and on the coast from south of Chariot (an area between Cape Thompson and Cape Seppings) to Sheshalik (EPA 2009).

Winter: Kivalina Lagoon is a subsistence use area that provides overwintering habitat for fish and serves as a migration pathway for anadromous fish bound for the Wulik and Kivalina Rivers (NAB 2006). The occurrence of marine mammals within the Kivalina Lagoon area is closely associated with the presence of shorefast ice along the coast during the winter and the recurring polynyas between Kivalina and Point Hope (NAB 2006). During the winter, ringed seals and bearded seals are harvested. Beluga whales may occur in the open leads along the coast as early as January and February due to the presence of a persistent polynya. Caribou winter use areas where subsistence harvest occurs are along the north Kivalina coast and the Upper Kivalina River and its tributary streams.

Spring: During the spring and summer, Cape Krusenstern is an important use area for residents of Kivalina, Noatak, and Kotzebue when spring sealing takes place in the open leads (NAB 2006). The north Kivalina coast is an important resource use area where waterfowl hunting occurs during the spring and later in the fall. The north Kivalina coastline is used for hunting ringed seal and bearded seal during the spring, for beluga whales during spring and summer, bowhead whales during the spring, and walrus during spring and summer (NAB 2006). Spotted seals may haul out here as well. Polar bears are hunted in the spring during years of abundance along the north Kivalina coast.

Summer: During the summer, the camps are established near Cape Krusenstern to harvest berries and plants. Whitefish (least cisco, Bering cisco and humpback whitefish) are harvested in Cape Krusenstern Lagoon (NAB 2006). Herring have also been reported to spawn in the lagoon and are harvested. The north Kivalina coast is another important resource use area where berry picking occurs in the summer. Dolly Varden, salmon, and whitefish are harvested in this area as well during this season. During the summer, spotted seals are present on barrier island beaches, and harvest occurs along the north Kivalina coastline. The Upper Kivalina River and its tributary streams are used for fishing and hunting. During the summer months, Dolly Varden, chum salmon, and whitefish are harvested.

Fall: The Cape Krusenstern area is used by waterfowl during fall migration. Species present may include brant, Canada geese, northern pintail, tundra swan, and oldsquaw. Waterfowl hunting also occurs during the fall along the North Kivalina coast. The Upper Kivalina River and its tributary streams are use areas for moose hunting during the fall (NAB 2006).

Subsistence use seasonal patterns and cycles have been extensively studied as a result of its location to Red Dog Mine and Red Dog's associated DeLong Mountain Terminal. These studies include work by: Braund and Burnham (1983), and Schroeder et al. (1987) which described and documented Kivalina's pre-mine subsistence use areas for varying time periods. Extensive pre and post mine subsistence map efforts were conducted by Stephen R. Braund & Associates (2008) and are found in Appendix D of the Red Dog Supplemental EIS prepared for the EPA in 2009 (Braund and Associates 2009).

Kotzebue

Seasonal and subsistence use areas for Kotzebue overlap with the use areas of neighboring communities of Kivalina, Noatak, Kiana, Noorvik, and Buckland (Magdanz et al. 2010). A discussion of the seasonal harvest activities of Kotzebue and specific harvest areas follows as described most recently in Whiting et al (2011).

Winter: Most harvest in December consists of land resources including caribou, furbearers and wood gathering. The inner areas of Kotzebue Sound are frozen with only occasional open water areas near the tip of Sisualik Spit and along the northern coast. Saffron cod and smelt fishing can occur in front of Kotzebue itself. Sheefish fishing with nets takes place in Kobuk Lake. During January caribou can be found over the ice from Sisualik toward Kobuk Lake and sometimes directly away from the coast toward the southern shore of Kotzebue Sound (Whiting et al. 2011). Arctic foxes have been observed offshore with the forming pack ice and red foxes are hunted along the shorefast ice. At Kobuk Lake fishing for sheefish with nets occurs under the ice. Leads and open water near Sisualik or Cape Blossom provide opportunities for ringed seals to be hunted (Whiting et al. 2011). By February the ice becomes thick enough to allow for red king crab pots to be placed up to a mile or two off the northern. Around the mouth of the Noatak River ice fishing with hooks for sheefish can occur. Fishing for sheefish with nets continues at Kobuk Lake. Hunting for caribou and furbearers occurs away from the coast. Ringed seal hunting increases in February as the daylight becomes longer. In March hunters use the leads in the northern area of the sound described by Whiting et al. (2011) from Cape Blossom to Cape Krusenstern - including the area that is the mouth of the Noatak River and northern Kobuk Lake. Hooking of sheefish at the mouth of the Noatak River continues and on Kobuk Lake (Whiting et al. 2011).

Spring: April marks the beginning of the turn toward spring in this area. The arrival of gulls and waterfowl begins at the end of this month along the coast. Red crab pot fishing continues through the ice off of the Cape Krusenstern coastline. Sheefish hooking continues at Kobuk Lake, at the mouth of the Noatak and sometimes near Kotzebue. During the month of May open water near Cape Blossom provides an opportunity for hunters to harvest ringed seals. Only female ringed seals are harvested at this time as males are rutting and their meat is not preferred. Near Kotzebue ice fishing with hook and line begins for saffron cod and smelt. Sheefish fishing also occurs during the first half of May near Kotzebue. Red king crab fishing continues along the northern coast of Kotzebue Sound. Whitefish are harvested by nets which are set through the cracks in the ice. The harvest of adult bearded seals in Kotzebue Sound begins during break up toward late May when temperatures start to climb. Hunting is dependent on ice conditions along the coast and when rivers are breaking up. Fishing for herring and smelt can occur by with rods and cast nets as the fish move into the inner sound areas before they begin to spawn. Toward the end of May Dolly Varden are sometimes caught near Cape Krusenstern (Whiting et al. 2011).

Summer: June marks the time of the year for bearded seal hunting on the broken ice pack in Kotzebue Sound. Ringed seals, ribbon seals (though considered rare) and walrus traveling into the Chukchi Sea are also harvested during this time period. The beluga whales start to move into the sound in June along the northern coast and where they are then pursued by hunters and are caught by boat or in nets. Along the northern sound Dolly Varden from the Kivalina and Noatak rivers and other freshwater outlets are caught with rods or nets. In mid-June chum salmon are harvested by nets along the northern coast. When the gulls and Arctic terns begin to lay eggs in mid-June harvest occurs on the islands offshore of Kotzebue and in the lagoons. Pots for king crab fishing are not set until the ice has left the northern sound. In July, salmon fishing predominates, with chum, king, pink and occasionally silver and sockeye salmon being caught. King crab fishing continues by set pots. In August, the harvest of salmon continues by net with chum and king salmon comprising most of the catch. Dolly Varden is harvested more toward the end of August (Whiting et al. 2011).

Fall: During September waterfowl are hunted as they migrate through the area and in the lagoons. White fish are caught in the areas where pondweed washes up on beaches and present the opportunity for harvest to occur by a technique called sand trap fishing. Herring are fished for using rods and cast nets close to Kotzebue. In October, the lower Noatak River and lagoons, and inner parts of the sound and Kobuk Lake begin to freeze. Ice fishing resumes on the lagoon on the southeastern side of Kotzebue with saffron cod, arctic cod and smelt being caught. During October, groundswell from storms can wash live clams onto the beaches near Sisualik were they are then collected. In November winter weather can strand marine mammals and fish that create more opportunities for harvest. Overflow can push fish including ciscoes, herring, or smelt through the cracks up onto the ice where they are then shoveled up by locals. If there is open water in front of Kotzebue hunters will hunt spotted seals from boats. Ice trapped spotted seals are occasionally taken at Kobuk Lake as they are unable to migrate back to the sound. Young bearded seals and ringed seals are taken along the northern coast of the sound. Seal hunting also continues at Sisualik and toward Sealing Point if there is open water next to the beaches at these areas. Saffron cod and smelt are fished in the lagoon on the southeastern side of Kotzebue. Sheefish are fished with nets in early November (Whiting et al. 2011).

3.3.2.5 Community Subsistence Harvest Rates

This section summarizes subsistence harvest rates, including quantities produced and the rates of participation in subsistence activities. The importance of subsistence harvests can be shown through the comprehensive household surveys conducted from 1986 through 2007 and reported in the ADFG Subsistence Division subsistence harvest database. Table 3.3-19 (Rates of Participation in Subsistence Activities – All Resources) describes rates of participation of communities within the EIS project area. Data included in this table were gathered from ADF&G's Community Subsistence Harvest Records and reflect years where the most comprehensive resource inventory was completed. Complete data are not available for each community.

Participation on the harvesting and sharing of subsistence foods goes beyond the family and the community. There is an extensive network of exchange that occurs between communities of the Beaufort and Chukchi seas and further to relatives in larger towns such as Anchorage and Fairbanks. For instance, the shares of bowhead whale that each crew member receives after whaling are involved in a secondary redistribution among local relatives and those in other communities. Social and cultural identity is strengthened by serving subsistence foods at home and at feasts and sharing subsistence foods, particularly with elders. The foods that are exchanged strengthen family and regional ties.

Some subsistence foods are exchanged between communities, each noted for its special resources. Point Hope and Barrow are the major suppliers of bowhead whale, with Point Lay contributing beluga whale. Kaktovik is recognized for its sheep and Wainwright its smelt. Nuiqsut is noted for its whitefish and pelts (NSB 2007). As noted by Bill Tracey at the Point Lay February 22, 2010 public scoping meeting for this EIS:

> *It has to do with sharing. If Point Lay catches a beluga whale, that beluga whale is shared with people as far away as Anchorage, Kotzebue, Nuiqsut, it just goes all over the place. So if we get 30 belugas, I wouldn't be surprised if that showed up in 30 villages. So when something affects Point Lay, little old Point Lay in the middle of north nowhere, it's felt in Anchorage in some way, in some fashion. So yes, if there is something big that happens offshore at Point Lay and it contaminates, say, our lagoon system, we're not catching the belugas anymore, people in the whole state of Alaska are going to feel that.*

Kin-based groups form the basis for most harvest and distribution activities. Spring bowhead whaling remains the dominant activity for expressing culturally relevant values of cooperation and sharing in the communities of Point Hope, Wainwright, and Barrow. The nature of the hunt, the size of the whale, and severe weather conditions encountered require cooperation of nearly everyone in the community for success (Worl 1980). Before the season begins, the equipment must be prepared and checked, ice cellars prepared, and the bearded seal skins necessary for covering the whaling boat obtained and sewn by the women (NSB 2007). More recently freezers are being used for storage of subsistence foods (EDAW-AECOM 2007).

Table 3.3-19 Rates of Participation in Subsistence Activities – All Resources

Community	Percentage (%) of Households					
	Using	Trying to Harvest	Harvesting	Receiving	Giving	Average pounds harvested per household – all resources
Kaktovik (1992)	95.7	89.4	89.4	91.5	83	2,713

Source: ADFG 1986, 1988, 1989; NSB 1993, 2007 accessed on April 28, 2011; MMS 2008; Braund and Kruse 2009

Beaufort Sea Communities

Kaktovik

ADF&G (2011) estimated that in 1992 the approximate per capita consumption of subsistence food for Kaktovik was 886 pounds. Approximately 93 percent of the Iñupiat households in Kaktovik participate in the local subsistence economy, while approximately 80 percent of other residents use wild resources obtained from hunting, fishing, or gathering. In 2003, 68 percent of all Kaktovik residents reported that half or more of their diet consisted of local subsistence resources (Shepro et al. 2003).

Levels of harvest change from year to year, depending on species population dynamics, weather, and hunting conditions, among other factors. However, subsistence users adapt. For example, when fewer whales (or smaller whales) are harvested, it is likely that the lower percentage for these species is offset by increases in the use of other resources (EDAW-AECOM 2007). Kaktovik subsistence harvest data is described in Table 3.3-20.

Table 3.3-20 Kaktovik Subsistence Harvest Data

Estimated Pounds Harvested	170,940.00
Mean Household Pounds	2,713.33
Harvested Per Capita Pounds Harvested	885.60

Source: ADFG 2011

Between the 1998 and 2003 surveys, there have been some changes in household consumption of subsistence resources (Shepro et al. 2003). The percentage of households who used very little local foods increased, while the number of households that identified the “more than half” category decreased. The percentage of households that were heavily reliant on subsistence resources (those who consumed all or nearly all of their food from local resources) increased from 35 percent in 1998 to approximately 41 percent in 2003 (Shepro et al. 2003).

Table 3.3-21 Kaktovik's Usage of Local Subsistence Resources in 1998 and 2003

More than half	4	7	18	30
Nearly all	13	24	12	20
All	9	17	9	1
Total	**54**	**100**	**60**	**100**

Source: Shepro et al. 2003

The average expenditure for the 49 households who reported subsistence expenditures was $4,788; the community spent approximately 10 percent of its total income on subsistence activities (Shepro et al. 2003). This includes expenses such as fuel, ammunition, and other supplies needed to participate in subsistence activities.

Nuiqsut

ADF&G (2011) estimated that in 1993 the approximate per capita consumption of subsistence food for Nuiqsut was 742 pounds. Fish (mainly freshwater white fish), terrestrial mammals (caribou and moose), and marine mammals (whales and seals) are harvested in roughly the same amounts (EDAW-AECOM 2007). Other resources harvested in lesser amounts include furbearers and birds. There is no "average" year so that in some years one of the resource components may comprise much more than a third of the actual subsistence resource use (especially in years when few or no whales are taken) (Galginaitis 1990 in EDAW-AECOM 2007).

Table 3.3-22 Nuiqsut Subsistence Harvest Data

Nuiqsut Subsistence Harvest Summary, ADFG (1993)	
Estimated Pounds Harvested	267,818.00
Mean Household Pounds	2,943.05
Harvested Per Capita Pounds Harvested	741.75

Source: ADFG 2011a

Approximately 81 percent of the households in Nuiqsut participate in the local subsistence economy; the participation rate for Iñupiat residents was recorded at approximately 95 percent (Shepro et al. 2003).

Another study of subsistence practices in Nuiqsut (Brower and Opie 1997 in NSB 2005) indicated that of 259 harvest instances, 226 (87 percent) resulted in sharing with others. Sharing harvest resources is known to be one of the most important traditions in the local subsistence lifestyle. The subsistence lifestyle remains a primary cultural choice for Native households. In 2003, approximately 63 percent of local residents said that half or more of their diet consisted of local subsistence resources (Shepro et al. 2003). Table 3.3-23 describes usage of local subsistence resources for Nuiqsut.

Table 3.3-23 Nuiqsut Usage of Local Subsistence Resources in 1998 and 2003

Amount	Householder 1998	Percentage (%) 1998	Householder 2003	Percentage (%) 2003
None	0	0	0	0
Very little	8	13	14	18
Less than half	9	14	16	20
Half	20	31	18	23
More than half	15	23	14	18
Nearly all	7	11	13	17
All	5	8	4	5
Total	**64**	**100**	**79**	**100**

Source: Shepro et al. 2003

The average expenditure for the 50 households who reported subsistence expenditures was over $6,700. Together, these 50 households spent approximately $335,000 on subsistence in 2003, representing about 20 percent of the gross incomes of these families (Shepro et al. 2003).

Barrow

A 2003 survey found that 91 percent of Iñupiat households participated in the local subsistence economy, and 66 percent of the households indicated that half or more of their diet consisted of local subsistence resources (Circumpolar Research Associates 2004 in EDAW-AECOM 2007). In contrast, two-thirds of Barrow's non-Iñupiat households do not use wild resources obtained from hunting, fishing, or gathering. This is likely a result of the high non-Iñupiat population in Barrow and a reason for the lower harvest of subsistence resources on a per capita and per household basis in comparison to Nuiqsut and Kaktovik rates (EDAW-AECOM 2007).

In 1992, from subsistence fish and wildlife harvests in Barrow, 349 pounds per capita of wild resources were harvested (BLM 2005 in EDAW-AECOM 2007). Marine mammals composed approximately 55 percent of the total resources harvested, and land mammals composed 30 percent of the total. In 1992, the total harvest of marine mammals (bowhead whale, walrus, and ringed and bearded seals) accounted for approximately 72 percent of the total village harvest of all species, and bowhead whale provided the single greatest contribution of food to the community at 54 percent of the total harvest. Land mammals (caribou, moose, and Dall sheep) contributed approximately 19 percent of Barrow's total harvest in 1992, and caribou was the principal terrestrial resource (17 percent of the total harvest). Close to half (45 percent) of Barrow households participated in caribou hunting in 1992; caribou is one of the most consistently eaten subsistence resources in Barrow. In 1992, fish constituted approximately seven percent of the total harvest in Barrow, and broad whitefish was the most important fish resource (four percent of the total harvest). Birds, such as eiders and geese, contributed less than two percent of the total harvest by weight; however, participation in bird hunting was high (EDAW-AECOM 2007). ADF&G harvest data for Barrow from 1989 is described in Table 3.3-24.

Table 3.3-24 Barrow Subsistence Harvest Data - 1989

Barrow Per Capita Subsistence Harvest (per capita pounds), ADFG (1989)	
Salmon	4.06
Fish	35.22
Land Mammals	71.18
Marine Mammals	168.5
Birds and Eggs	9.76
Plants	0.44
Barrow Harvest Summary, ADFG (1989)	
Estimated Pounds Harvested by community – all resources	872,092
Average pounds per household - all resources	930.73
Harvested Per Capita Pounds	289.16

Source: ADFG 2011

The average expenditure for the 492 households who reported subsistence expenditures was $3,787, while the median expenditure was $925. Fifty-nine percent of the households that were interviewed reported spending less than $2,000 per year on subsistence (Shepro et al. 2003).

Many studies document the customary and traditional use of subsistence resources by Barrow residents including: ADFG 2000; BOEM 2011b and 2011c; Braund 1993; Braund 1989; Chance 1966; Craig 1987; EDAW-AECOM, 2007; George and Fuller 1997; George et al. 1993; Hess 1999; MMS 2003; MMS 2001; MMS 1998; MMS 1996a and 1996b; MMS 1990; MMS 1986; MMS 1983; MMS 2006b and 2006c, MMS 2007a and 2007c; MMS 2008; MMS 2009a and 2009b Nielson 1977; NSB 2002; NSB 1979; Patterson 1974; Pedersen 1979; Pedersen et al. 1979; Philo et al. 1994; Sonnenfeld 1956; SRB&A 2010; and Wolfe et al. 1986.

Chukchi Sea Communities

Wainwright

Wainwright subsistence users have opportunities for hunting terrestrial, riverine, and marine species, including bowhead whales, though they tend to harvest mostly from the ocean (Fuller and George 1997). Their data indicate that Wainwright residents primarily utilize marine mammals, caribou, and fish in terms of pounds per person harvested. Other resources are also harvested but at lower rates.

Table 3.3-25 Wainwright Subsistence Harvest Data, 1989

Resource	Estimated Number	Estimated pounds	Average pounds	Per Capita pounds
All Resources	-	351,581	2,954.46	751.24
Fish	64,567	17,385.00	146.09	37.15
Salmon	180	1,044.00	8.77	2.23
Non-Salmon Fish	64,387	16,341.00	137.32	34.92
Land Mammals	760	83,389.00	700.75	178.18

Marine mammals	-	243,594.00	2,047.01	520.50
Natures and eggs	2,735	7,211.00	60.60	15.41

Source: ADFG 2011

Approximately 92 percent of the households in Wainwright participate in the local subsistence economy; the participation rate for Iñupiat residents was recorded at approximately 99 percent (Shepro et al. 2003). In 2003, approximately 73 percent of all Wainwright residents said that half or more of their diet consisted of local subsistence resources, while 83 percent of Iñupiat residents were heavily reliant on subsistence resources (half or more of their diet comes from local foods) (Shepro et al. 2003).

The average household expenditure for subsistence activities in Wainwright in 2002 was $4,504, and the median expenditure was $2,500 (Shepro et al. 2003). Subsistence expenses include items such as fuel, ammunition, and other supplies needed to participate in subsistence activities.

Table 3.3-26 Wainwright Household Use of Subsistence Resources by Ethnicity

Level of Use	1998 Total	Iñupiat in 2003	Other in 2003	Total in 2003

Total	**122**	**105**	**17**	**122**

Source: Shepro et al. 2003 (authors noted that results were only of those households responding to the survey)

Point Lay

Caribou, fish, and beluga whale comprise the most significant subsistence resources of Point Lay residents. The reestablished bowhead hunt was successful in 2009 though poor ice conditions in 2010 prevented Point Lay hunters from striking a whale (ADN 2009, AEWC 2011). Seals and walrus are not as intensively used as in the past due to the reduction in dog teams and the present adequate supply of caribou. Other resources are also utilized by the community but at lower harvest levels in terms of pounds per person.

Table 3.3-27 Point Lay Subsistence Harvest Data, 1987

Resource	Estimated Number	Estimated pounds	Average pounds	Per Capita pounds
All Resources	-	107,321.00	2,495.83	890.11

More than half	14	31.80	6	13.60
Nearly all	4	9.10	8	18.20
All	6	13.60	8	18.20
Total	**44**	**100**	**44**	**100**

Source: Shepro et al. 2003 – Authors noted that results include only households participating in the census survey and responding to the question "How much of the meat, fish and birds you and your household ate came from local food sources (fishing and hunting)?"

Thirty percent of the Point Lay households spent less than $500 on subsistence activities. Approximately 40 percent of the households spent $3,100 to $9,500 on subsistence activities (Shepro et al. 2003). Many sources document the customary and traditional use of subsistence resources by residents of this community, and are hereby incorporated by reference: Ahmaogak 1989; Alaska Consultants 1983; Alaska Consultants 1983; Bockstoce et al. 1979; Braund et al. 1988; MMS 2001; MMS 2009; NSB 1979; Suydam et al. n.d.; Suydam et al. 1994; and Worl 1980.

Point Hope

At Point Hope, marine mammals comprised over three-quarters of the harvest by weight (77 percent), including belugas, bowheads, walrus and seals (Fuller and George 1997). Caribou have historically been, and remain, an important subsistence resource for the community; in the 1997 study, caribou were the only non-marine mammal species in the top five species harvested for the year (NSB 2005).

Table 3.3-29 Main Subsistence Resources Harvested at Point Hope, 1992

Resource	Edible Pounds Harvested	Number Harvested	Pounds per household	Pounds per capita	Percent (%) of Total Harvest
Beluga whale	137,172	98	879	196	40.3
Walrus	55,797	72	358	80	16.4
Bearded seal	28,242	160	181	40	8.3
Caribou	26,303	225	169	38	7.7
Bowhead whale	23,365	3	150	33	6.9

Source: Fuller and George 1997

In 2003, approximately two-thirds of all Point Hope residents said that half or more of their diet consisted of local subsistence resources, while three-quarters of all Iñupiat residents were heavily reliant on subsistence resources (half or more of their diet comes from local foods) (Shepro et al. 2003). Approximately 93 percent of the households in Point Hope participate in the local subsistence economy; the participation rate for Iñupiat residents was recorded at approximately 99 percent (Shepro et al. 2003).

Nearly half of Point Hope residents (47.5 percent) spent less than $1,200 on subsistence activities; however 15 percent of residents spent between $9,600 and $20,000 (Shepro et al. 2003). Customary and traditional use of subsistence resources is documented in many sources that are incorporated into this document by reference: ADFG 2000; Foote and Williamson 1966; Foote and Williamson 1961; George and Fuller 1997; Heller 1966; Lowenstein 1980; NSB 1979; Patterson 1974; Pedersen 1979; and Pedersen 1971.

Table 3.3-30 Point Hope Usage of Local Subsistence Resources in 1998 and 2003

Amount	Households 1998	Percentage (%) 1998	Households 2003	Percentage (%) 2003
None	4	2.9	10	7.0
Very little	11	8.2	16	11.3
Less than half	23	17.2	23	16.2
Half	34	25.4	28	19.7
More than half	34	25.4	30	21.1
Nearly all	19	14.2	15	10.6
All	9	6.7	20	14.1
Total	**134**	**100**	**142**	**100**

Source: Shepro et al. 2003 Authors noted that results include only those households responding to the census survey, and the query about the amount of subsistence harvested by the household.

Kivalina

Subsistence harvest data for Kivalina, from 1992 and 2007, show 100 percent of households using subsistence resources during each year with 761 per capita pounds of subsistence resources in 1992 and 594 per capita pounds in 2007 (Braund 2008). The main species harvested tend to be Dolly Varden char, bearded seal, and caribou. Kivalina’s harvest numbers have been extensively studied by Braund (2008) who noted that Kivalina’s recent harvests, compared to pre-mine harvest levels, appear to have steadily decreased from 1,838 usable pounds per person in 1959–1960 to 594 pounds in 2007. This was attributed to less harvest needed to feed to dogs with the shift from sled-dogs to snowmachines as the primary mode of transportation. While Kivalina did not harvest a bowhead during 2004, data from that period indicate that rates of receiving from other communities were high at 64 percent of households receiving bowhead (Braund 2008).

Table 3.3-31 Kivalina Estimated Harvest by Resources, 2007

Resource	Total Pounds	Mean Households pounds	Per Capita pounds	Percent (%) of Total Harvest
All resources	255,344	3,152	594	100
Caribou	36,458	450	85	14.3
Moose	2,075	26	5	0.8
Other large land mammals	201	2	0	0.1
Bowhead	0	0	0	0.0
Beluga	21,890	270	51	8.6
Bearded seal	96,188	1,188	224	37.7
Other seals	5,830	72	14	2.3
Walrus	1,350	17	3	0.5

Resource	Total Pounds	Mean Households pounds	Per Capita pounds	Percent (%) of Total Harvest
Furbearers – small land mammals	39	0	0	0.0
Waterfowl	3,319	41	8	1.3
Eggs	839	10	2	0.3
Upland birds	233	3	1	0.1
Dolly Varden char	67,739	836	158	26.5
Other non-salmon fish	7,596	94	18	3.0

Berries	7,398	91	17	2.9
Plants	654	8	2	0.3

Source: Braund 2008

Kotzebue

The Native Village of Kotzebue conducted a three year harvest survey program (2002 to 2004). Findings of this study indicated that estimated total harvested varied from 1,401,325 pounds in 2002, to 892,782 pounds in 2003 and 1,022,847 pounds in 2004 with a total of 227 households surveyed (Whiting 2006). Household harvests averaged 5,031 edible pounds in 2002, 2,996 pounds in 2003, and 3,237 pounds in 2004. Five species accounted for nearly 90 percent of the harvest in the three study years, namelycaribou, sheefish, bearded seal, chum salmon and moose as the main harvest species (Whiting 2006). Caribou were the most widely harvested species, since they were taken by 69 percent to 85 percent of the households. Findings of this three year study show higher rates of harvest than those that were previously reported as this project included only Alaska Native households. Two earlier single year studies by Georgette (1986) and by Fall and Utermole (1995) surveyed native and non-native Alaskan households. Previous work by Georgette had noted that Alaska Native households harvested five times as much wild food as non-Native households in Kotzebue (Georgette 1986 in Whiting 2006). The 1986 study had similar findings, describing four species – caribou, bearded seal, sheefish, and chum salmon – as contributing 74 percent of the total harvest (Whiting 2006). Whiting (2006) found that, those same four species contributed 82 to 90 percent of the total harvest.

Similarly, more recent data has indicated that levels of harvest in the Kotzebue area are consistent with the earlier surveys. The three main harvested species included caribou, sheefish, and bearded seal (Braund 2008, Magdanz et al. 2010). Other major harvested species include chum salmon, moose, spotted seal, and Dolly Varden char. In 1991, 99 percent of Kotzebue households reported using at least one resource, and at least 90 percent used caribou, berries, and salmon (Braund 2008). The composition of subsistence harvests in Kotzebue is considered to have remained relatively steady, with caribou, bearded seal, and sheefish among the top harvested species before and after the development and operation of nearby Red Dog Mine. The exception noted is the harvest of beluga whales as declines in amounts harvested have fallen since 1990 (Braund 2008). The composition of the subsistence harvests of Kotzebue are similar to comprehensive subsistence harvest information from seven nearby communities (based on 97 surveys) in the Kotzebue Sound area where caribou comprises 30 percent of the subsistence foods harvested (Magdanz et al. 2010).

Table 3.3-32 Kotzebue Estimated Harvest by Resources, 2004

Resource	Percent of Households Harvesting	Total Pounds	Mean Households pounds	Percent of Total Harvest
All resources	-	1,022,847	3,237	100%
Caribou	76	260,459	743	25.5%
Moose	22	51,215	135	5.0%
Other large land mammals	-	472	4	0%
Beluga	5	7,960	74	0.8%
Bearded seal	40	204,272	638	20.0%
Other seals	-	31,113	106	3.0%
Walrus	3	12,320	114	1.2%
Polar bear	1	0	0	0.0%
Waterfowl	-	12,864	33	1.3%
Eggs	-	605	2	0.1%
Dolly Varden char	56	18,287	45	1.8%
Other non-salmon fish	63	245,352	799	24.0%
Salmon	68	164,689	499	16.1%

3.3.2.6 Influence of Climate Change on Subsistence Resources and Uses

While the potential impacts of climate change on subsistence resources and harvests are difficult to precisely predict, Arctic residents have observed some trends that are anticipated to continue. Changes that have been observed in the Arctic by residents include: changes in thickness of sea-ice; increased snowfall; drier summers and falls; forest decline; reduced river and lake ice; permafrost degradation; increased storms and coastal erosion; cooling in the Labrador Sea (associated with increased sea-ice melt); and ozone depletion (MMS 2008).

The communities of the Beaufort and Chukchi seas have voiced increasing concern about the potential for adverse effects on subsistence harvest patterns and subsistence resources from habitat and alterations due to the effects of global climate change. Indigenous peoples have settled in particular locations because of their proximity to important subsistence resources and dependable sources of water, shelter, and fuel. As voiced by Edna Ahmaogk at the March 9, 2010 public scoping meeting in Wainwright for this EIS:

> *[T]here is nowhere else in the world where people are still living as lively as we are, subsistence-wise, and we're not exploiting our natural resources as in most countries. You know, we're doing it for our living. And I don't want to lose that.*

MMS (2008) described how the indigenous communities and their traditional subsistence practices will be stressed to the extent that the following observed changes continue:

- villages and settlements are threatened by sea-ice melt, permafrost loss, and sea-level rise;
- traditional hunting locations are altered;
- traditional storage practices are altered due to melting in ice cellars;
- subsistence travel and access difficulties increase on land and on water; and
- resource patterns shift and their seasonal availability changes.

Changes in sea ice could have dramatic effects on sea mammal-migration routes which could impact the harvest patterns of coastal subsistence communities and increase the danger of hunting on sea ice (Callaway et al. 1999, Bielawski 1997).

Subsistence hunters have already noted such changes:

> *We realize the ecosystem we are in is very healthy and productive. However, the access, due to changing patterns in ice and weather, has affected our ability to access resources. The changes aren't all bad, because in 1990 Savoonga and Gambell started harvesting bowheads in the dead of winter. As a consequence, 40 percent of our harvests are now occurring in winter (November/December timeframe). We have begun to take steps to conduct spring whaling activities earlier so we can adjust to the changes that are now occurring in migration patterns of marine mammals, specifically the bowhead whales.* - George Noongwook, AEWC Vice Chair and representing Savoonga/St Lawrence March 2011 - Open Water Meeting, Anchorage, AK.

In addition changes in ice conditions have influenced the spring bowhead hunt in the Chukchi sea communities. The AEWC noted that *"worsening ice conditionshave made it too dangerous and difficult for our whaling captains and their crews to carry out the larger spring bowhead hunt. Because of the changing conditions, crews from Wainwright, Point Hope and Point Lay have all been conducting fall hunts in an effort to provide for their communities and meet their allotted quotas"* (Comstock 2011).

Social organization is underlain by subsistence in the communities of the Beaufort and Chukchi seas. Disruption of the subsistence cycle by climate change could also change the way social groups are organized and affect rates of harvest and sharing. Widespread changes in patterns of subsistence harvest, particularly serious declines in productivity, would likely result in stresses within a community or between communities.

Populations of subsistence resources of marine and terrestrial animals could be particularly vulnerable to changes in sea ice, snow cover, and changes in habitat and food sources brought on by climate change. The thawing of permafrost and sea-ice melting will continue to threaten and change important subsistence habitats and species. The reduction of sea ice would result in the loss of habitat for marine mammals, including polar bear, ringed and bearded seals, walrus, and beluga whales.

Every community in the Arctic potentially is affected by the anticipated climactic shift (MMS 2008). It is likely that the reduction, regulation, and/or loss of subsistence resources would have severe effects on the way of life for residents of coastal communities in the Beaufort and Chukchi seas who depend on subsistence resources. Shore erosion in communities such as Shishmaref, Kivalina, Wainwright, Barrow, Kaktovik, the Yukon-Kuskokwim Delta in Alaska, and in Tuktoyaktuk at the mouth of the Mackenzie River in Canada has become increasingly severe in recent years, as sea-ice formation occurs later, allowing wave action from storms to cause greater damage to the shoreline and change the usage pattern of local and regional subsistence use areas (MMS 2008).

3.3.3 Public Health

3.3.3.1 Introduction

This section presents an overview of public health in the areas that comprise the affected environment for this EIS. As described below, the affected environment for public health consists of the eight communities in the NSB and one community of the NAB whose residents may be affected by the proposed oil and gas offshore exploration activities in the Beaufort and Chukchi seas.

The description of health conditions presented in this section is considerably broader than what has, until recently, typically been included in EISs to describe the health of affected populations. This wider scope is driven by two reasons. The first reason relates to changing expectations for what constitutes a sufficient examination of human health within the regulatory process. North Slope residents, the NSB municipality, the Alaska Inter-Tribal Council, the Iñupiat Community of the Arctic Slope, the EPA, and the National Research Council (NRC) have all advocated strongly for the inclusion of a more systematic and broad-based appraisal of human health concerns in planning processes and the BLM on the national level is reassessing public health analysis in planning (MMS 2008, NRC 2003b).

The second reason has to do with data availability. Data have only recently become available that allow the health of the affected environment to be described explicitly; previously, most relevant health indicators were available only at the state level, for all rural Alaska populations, or for all Alaska Natives as a group.

In depicting health conditions in the affected environment, this section begins with a description of biomedical health outcomes—rates of disease, injury, and other indicators of ill health—and follows with a description of health determinants—the environmental and social conditions that cause or contribute to biomedical health outcomes. By including both health conditions and health determinants, this section attempts to elucidate the specific pathways through which public health may be affected, as well as the outcomes that may result.

The main health conditions that burden the population in the affected environment are the same ones that are seen elsewhere in Alaska and the U.S.: cancer; heart disease; respiratory diseases and intentional and unintentional injury; overweight/obesity; and diabetes. Overall, the rates of these conditions are parallel to that seen elsewhere in Alaska, although the rates of some conditions are higher in the affected environment.

These diseases and health conditions are multifactorial – that is, they arise from a complex combination of factors that affect populations and the individuals within them. These factors include individual behaviors, environmental conditions, institutional supports, and social and economic circumstances. What is important to note in the context of this EIS is that the factors that are most relevant for disease generation in this population are not necessarily the same as those that apply to populations elsewhere. The unique physical, cultural, and social environments of northern Alaska determine the level of health of the population and of individuals. The health determinants described in this section—such as income and employment and subsistence participation and diet—play a critical role in supporting or undermining the health of the population.

3.3.3.2 Data Sources

Although the data presented in this section derive from a large number of sources, there are three sources in particular that are important to note and that have been used extensively throughout this section. The first of these is the Public Health section of the Affected Environment chapter of the Northeast NPR-A Final Supplemental Integrated Activity Plan/Environmental Impact Statement (IAP/EIS), authored by Dr. Aaron Wernham (BLM 2008a).

The second source of note is a report that was prepared by Dr. Jana McAninch on behalf of the NSB Department of Health and Social Services (McAninch 2012). This report is a comprehensive compilation and analysis of health data pertaining to the communities of the NSB. The report provides extensive information on health, including analyses by age, sex, location and trends over time. The information in McAninch's report derives from the 2010 NSB census health module (described below) and also from previously published information about health conditions and outcomes in the NSB and across Alaska. The report was published in the summer of 2012, and has been cited heavily throughout this section. Wherever there are data presented that are relevant to the NSB without another reference cited, the information originates from this report.

The third key source of information is the 2010 NSB Economic Profile and Census (Circumpolar Research Associates 2010). The census results are also cited extensively in this section, particularly in the tables. Because the methodology of a census or survey influences the results, some relevant information about the census has been provided by Circumpolar Research Associates, the organization that developed and administered the census.

> *The 2010 NSB Census is the fourth in a series of local household surveys undertaken by the NSB to enumerate the local population for each community and examine topics such as employment, subsistence participation, income, housing characteristics, Iñupiaq language proficiency, and residents' attitudes on a variety of topics. Previous censuses were conducted in 1992, 1998, and 2003, although the instrument and survey design have been modified somewhat over that period.*
>
> *After mapping all the occupied structures in each community the 2010 NSB census takers conducted face-to-face interviews, attempting to reach every household in each NSB community. Sampling proportions ranged from 65 percent in Barrow to nearly 90 percent in some of the smaller communities. The total potential households for each community were determined by analyzing utility (primarily electricity) hookup data provided by the Borough. Given such high sampling fractions and absent any reasonable expectation of sampling bias this survey provides an extremely representative picture of the population. Standard errors of the proportion range from 1.9 percent to 7.5 percent depending on the community. For the North Slope Borough as a whole with 1,604 households interviewed out of total of 2,271 the standard error is 1.4 percent.*
>
> *For each household, an attempt was made to interview the adult who identified themselves as the "household head," a household member who was available and likely to have the greatest familiarity with household economics, health of household members, level of subsistence participation, etc. The respondents, or "household heads" were asked all the questions as they pertained to themselves and then a smaller subset of questions as they pertained to all other household members, acting as a proxy. Household heads participating in the census were 48 percent male and 52 percent female.*
>
> *Household heads participating in the census were 69 percent Iñupiat, 19 percent Caucasian, and 12 percent of other ethnic groups* (Circumpolar Research Associates 2011).

Two last points are important to note about the data presented in this section. First, the population of the affected communities is relatively small, and when de-aggregated into individual villages, it is smaller still. Small populations mean small numbers of cases on an annual basis, with potentially large fluctuations from year to year. For example, two cases of cancer one year and three cases of cancer the next may appear as a 50 percent increase, although the difference between two and three is unlikely to be statistically significant. For this reason, rates of uncommon diseases or health conditions in the affected environment must be interpreted with caution.

Second, the tables often contain data that have been obtained from different sources. In this case, the original questions or methods used to obtain the data may vary between sources, and thus comparisons between these data sets should be made cautiously.

3.3.3.3 Study Area and Population Demographics

The affected environment for the Public Health section of this EIS comprises the communities whose residents may be affected by social or environmental changes that result from the proposed oil and gas offshore exploration activities in the Beaufort and Chukchi seas. This includes the communities of Kaktovik, Nuiqsut, Anaktuvuk Pass, Atqasuk, Barrow, Wainwright, Point Lay, Point Hope, and Kivalina. Anaktuvuk Pass and Atqasuk are not on the coast of either the Beaufort or Chukchi seas and are not included in the affected environment of many other sections of this EIS. However, residents of these two communities use the seas for subsistence activities, a key health determinant, and therefore these communities are included in the affected environment for public health. Kotzebue is not included in this assessment as there are no proposed offshore exploration activities occurring in this area.

The population of the communities in the affected environment is described in Table 3.3-33 below. There is one larger community: Barrow, but the majority of communities are small, with populations fewer than 1,000 residents. The majority of residents in all communities (roughly 90 percent except in Barrow) are Iñupiat or Alaska Natives. The population is very young, with the median age between 20 and 25 years old and children comprising 34 percent of the population in the NSB. This age structure influences the health conditions likely to be observed in the affected environment, since younger populations are more likely to experience higher rates of infectious diseases, injuries, and some mental illnesses. Older populations, in contrast, tend to exhibit higher rates of chronic disease such as heart disease, diabetes, arthritis, and cancer.

Table 3.3-33 Population Demographics in Affected Environment Communities

Community	Population size	Percent (%) Iñupiat/Alaska Natives	Median Age	Proportion of residents over the age of 65	Proportion of residents under the age of 18
North Slope Borough (NSB) Communities					
Anaktuvuk Pass	346	88	25.7	4%	36%
Atqasuk	250	91	26.3	6%	39%
Barrow	4,429	61	28.8	5%	32%
Kaktovik	286	88	32.1	10%	30%
Nuiqsut	416	92	23.8	6%	31%
Point Hope	764	91	21.8	8%	37%
Point Lay	260	86	20.8	5%	40%
Wainwright	556	94	24.5	8%	35%
Northwest Arctic Borough (NAB) Community					
Kivalina	388	97	20.8	n/a	n/a

Data: NSB 2011a, ADCCED 2010, Advameg, Inc. 2009. Note that these data are derived from the 2000 and 2003 census.

The focus of the analysis of impacts in Chapter 4 will consider the entire affected environment to the degree to which effects are predicted for each community. In this chapter, current health conditions are described more intensively for the eight communities of the NSB than for Kivalina in the NAB. This is primarily because more specific and fine-grained data about health conditions exists for the NSB communities, as described in Section 3.3.3.2 (Data Sources). However, Kivalina shares many common features with the NSB communities, including many lifestyle, environmental, social, economic, and cultural conditions that determine health outcomes, such as reliance on subsistence resources, including the Western Arctic Caribou Herd, remote location, small population comprised mainly of Iñupiat people, limited infrastructure, housing type, and availability and limited economic opportunities. In addition, many of the health outcome indicators described in this chapter indicate that biophysical health outcome measures are likely to be similar for the populations in NSB and NAB communities. As a result, the impact pathways between proposed alternatives and human health outcomes are likely to be similar for NSB communities and Kivalina, as are the effects that will be experienced. The additional fine-grain of detail available for NSB communities therefore provides an extra source of information that will help in the analysis of impacts; but the lack of this same level of detail for Kivalina will not preclude a full assessment of impacts for that location.

3.3.3.4 Biomedical Health Outcomes

This section presents an overview of biomedical health outcomes and diseases experienced by the population in the affected environment. Biomedical health refers to illnesses, diseases, injuries, and other health states experienced by individuals.

General Health Indicators

General health indicators provide a picture of the overall health status of the population. The health indicators presented in this section reflect important measures of population health and wellness that can be compared across time and across different regions to understand how the health of one population compares with the health of others.

Table 3.3-34 General Health Indicators in the NSB

	Anaktuvuk Pass	Atqasuk	Barrow	Kaktovik	Nuiqsut	Point Hope	Point Lay	Wainwright	All NSB	All Alaska
Reported health status, adults										
"Very good" or "excellent" general health	32%	21%	53%	38%	39%	36%	52%	35%	46%	56%[a]
"Fair" to "Poor" general health	4%	34%	13%	19%	22%	21%	10%	21%	16%	14%[a]
Reported health status, children										
"Very good" or "excellent" general health	41%	38%	68%	66%	55%	66%	70%	54%	63%	89%[b]
"Fair" to "Poor" general health	4%	9%	4%	10%	16%	7%	1%	7%	6%

Chronic Lower Respiratory Diseases	3	10	144.3	n/a	n/a	n/a	5	42.5
Suicide	5	10	53.3	4	30	79.5	6	22.7

Notes: Rates are per 100,000 persons, age-adjusted to U.S. year 2000 standard population. Ranks are based on age-adjusted rates.
Source: State of Alaska Department of Health and Social Services 2008, AN Epicenter 2008

As can be seen from the data in Table 3.3-34, residents of the NSB report lower rates of excellent/very good health and higher rates of fair/poor health than residents of Alaska as a whole, both for children and for adults, with considerable diversity among the different NSB communities. Self-rated health is one of the strongest, most consistent predictors of illness, premature death, health care utilization, and hospitalization (Idler and Benyamini 1997). The observation that NSB residents experience poorer overall health than other Alaskan residents is supported by data that show the NSB ranking 17th out of 22 Alaskan census areas for overall health outcomes, based on a combination of standard health indicators (MATCH 2010).

Life expectancy and mortality are also commonly used to evaluate and compare the health of populations. Between 1999 and 2008, the life expectancy at birth for a resident of the NSB was estimated as 71.9 years, approximately four years shorter than for Alaskans overall (75.6 years), although the estimate was similar to that for Alaska Natives statewide (State of Alaska Department of Health and Social Services 2008). However, rates of adult and infant mortality have declined in the NSB over the past three decades, representing overall health improvements in the area.

Since the early 1990s, the leading causes of death in the NSB have been fairly constant. Cancer is the leading cause of death in both the NSB and across Alaska, followed by heart disease and respiratory disease (Table 3.3-35). In the NAB, the leading causes of death in Alaska Natives, which make up 97 percent of the population are cancer, heart disease, and unintentional injuries (Table 3.3-35) (AN Epicenter 2008). Rates of death for all leading causes of death are much higher in the affected environment than in the State of Alaska.

Chronic Diseases

Table 3.3-36 Chronic Disease in the NSB

	All NSB	All Alaska
Proportion of adults who report a health professional diagnosis of:		
High blood Pressure	20%	26%[a]
Heart disease	5%	3%[b]
Thyroid problems	4%	9% (U.S.)[c]
In the past 12 months, percent who experienced:		
Chronic breathing problems (adults)	8%	10%[d]
Chronic breathing problems (children under 18))	5%	5-6%[d]
Daily pain or arthritis that limits activities or requires prescription pain medicine	21%	22%[a]

Notes:
[a] CDC 2009
[b] CDC 2008 (Heart disease: Alaska estimate includes only diagnoses of angina, heart attack, coronary heart disease. NSB estimate may include other types of heart disease such as congestive heart failure, heart rhythm problems, or valvular heart disease)
[c] Melzer 2010
[d] Based on CDC 2004, Gessner and Utermohle 2006, CAHMI 2007
Source: Circumpolar Research Associates 2010, with the exception of those noted here

Important chronic diseases in the affected environment include chronic respiratory disease, cancer, and cardiovascular conditions. The leading causes of self-reported health problems among Iñupiat adults (over age 16) participating in a 2004 survey were high blood pressure (reported in 29 percent of respondents), arthritis/rheumatism (21 percent), asthma (21 percent), stomach problems or intestinal ulcers (15 percent), chronic bronchitis, emphysema, or shortness of breath (12 percent), and heart problems (9 percent) (Poppel et al. 2007).

Chronic lower respiratory disease (CLRD) is one of the most frequently cited health concerns among community members in the NSB and has been the fifth leading cause of death in the Borough for most years since 1990. Mortality rates from CLRD in the NSB remain almost twice statewide rates and nearly three times the mortality rate for the U.S. (144 per 100,000 residents compared with 43 per 100,000) (McAninch 2012). Approximately eight percent of NSB adults and five percent of NSB children report having chronic breathing problems (Table 3.3-36). These values are slightly lower than state or national rates; however, the difference is not statistically significant. Asthma rates are fairly evenly distributed amongst Alaska residents with no differences seen between urban and rural or Native and non-Native populations (McAninch 2012). A number of environmental factors are known to trigger or exacerbate asthma and CLRD symptoms, including exposure to tobacco smoke, exhaust from heating sources and nearby vehicles, and outdoor and indoor air quality. Arctic residents are particularly vulnerable to indoor air pollution due to tightly sealed houses and poor ventilation, as well as prolonged time spent indoors (Gordian 2004). High rates of smoking in the NSB may be a primary cause of high respiratory disease rates. However, because there are no available data on local fine particulate concentrations, hazardous air pollutants, indoor air quality, and little data on intra-regional variation in other EPA-criteria pollutants, it is not possible to estimate the possible contribution of environmental factors to chronic respiratory disease in the area (NRC 2003b).

Cancer is the leading cause of death across Alaska, among Alaska Natives, and in the NSB, and it is understandably a major community health concern in many areas. Between 1996 and 2009 there were a total of 288 cases of cancer reported in the NSB (McAninch 2012). This corresponds to an age-adjusted annual incidence rate of 530.1 cancers per 100,000 population, compared with 487.1 for all of Alaska and 467.4 for the U.S. Because the numbers of cancers in the NSB are small, there is the potential for a large margin of error, and a great deal of year-to-year variation, and therefore the differences between the NSB and Alaska/the U.S. are not statistically significant.

The most common cancers in the NSB are lung/bronchus, colon/rectum, prostate, and breast. These are also the most common four cancers across the state and the U.S., and it is likely that this trend is the same in Kivalina. Age-adjusted rates of lung and colorectal cancers in the NSB for the years 1996 to 2009 are approximately double the national rates; however, rates of prostate and breast cancers are much lower than the national rate. For other cancer sites, the number of cases across the NSB is so small that it is difficult to compare the rates with those in other jurisdictions.

While many people in the NSB, like people in many other places, are concerned about environmental contamination as a possible contributor to cancers, there is no easy way to determine whether or to what extent environmental factors play a role. What is known is that tobacco smoking is currently a large contributor to cancers in the NSB and among Alaska Natives and circumpolar Inuit and directly contributes to high rates of lung cancer and overall cancer mortality.

Cardiovascular disease has been a leading cause of death in the U.S. for many decades and is currently the second leading cause of death in Alaska. The amount, or prevalence, of cardiovascular disease has been increasing in the NSB, but death from cardiovascular disease has been decreasing, which has frequently been attributed to improvements in medical intervention. Smoking, excess weight, and diabetes, all of which have been increasing in the NSB, are risk factors for cardiovascular disease. Rates for heart disease in the NSB are slightly higher than the state average (Table 3.3-36).

Arthritis refers to a number of separate conditions affecting joints, bones, and supporting tissue. Rates of arthritis in the NSB are around 21 percent (Table 3.3-36), which is very similar to the national average.

Diabetes is another chronic disease of great importance in the NSB due to its association with dietary factors and is discussed below in the section titled Nutritional Outcomes.

Infectious Diseases

Infectious diseases disproportionately impact Alaska Natives, illustrated by higher incidence rates and higher rates of hospitalization than non-Natives (Holman et al. 2001). The main infectious diseases that are often impacted by resource development are sexually transmitted infections (STIs) and infectious respiratory diseases, including tuberculosis (TB).

The reported rates of the STIs chlamydia, gonorrhea, and hepatitis C have increased since mandatory reporting began in 1996. Gonorrhea increased dramatically in 2007 with 59 new cases reported in the NSB, compared with between six and 30 cases per year for the six years prior (Cecere 2008). For all three of these infections, incidence rates are substantially higher in the NSB than the Alaska average; however, the trend of increasing incidence parallels similar trends seen in the state and across the nation (McAninch 2012, NCSTDD 2005). Higher rates prevail among all Alaska Natives compared with non-Natives; STI rates between two and six times higher have been reported for chlamydia, gonorrhea, syphilis, and hepatitis for Alaska Natives statewide, compared to non-Alaska Natives (NCSTDD 2005). There have been no new reported cases of Human Immunodeficiency Virus (HIV) in the NSB since 1995 (McAninch 2012).

Infectious respiratory diseases are common and include lower respiratory tract infections (LRIs), such as pneumonia and respiratory syncytial virus, and upper respiratory tract infections (URIs), such as colds, flus, and the common complication of ear infections. URIs account for almost one-third of visits with assessments in the NSB (Golnick 2009) and contribute to days missed at work/school, increased health care costs, and can sometimes lead to more serious health problems. LRIs can be very serious; in 2006 to 2007, an outbreak of respiratory syncytial virus occurred on the North Slope, resulting in the hospitalization of 53 infants and young children in Barrow. Twenty-eight children required transport to Anchorage for intensive care (McAninch 2012).

TB is another infectious disease of great public importance, particularly given the devastation wrought by TB in rural Alaska half a century ago. There has been an average of less than one new case a year reported in the NSB over the past 25 years; however, the state of Alaska is hoping to reduce this rate even further (Pearson 2002).

A disease of concern among Alaska Natives is *Helicobacter pylori* (*H. pylori*) infection. *H. pylori* is commonly found in conditions with inadequate sanitation and causes chronic inflammation of the stomach and small intestine, and may be associated in Alaska Natives with iron deficiency and anemia among children (DiGirolamo et al. 2007, Baggett et al. 2006) and possibly with stomach cancer among adults. Unusually high rates of *H. pylori* have been found among Alaska Natives. Based on a sample of approximately 2,000 stored blood samples taken between 1980 and 1986, rates of *H. pylori* infection were estimated to be about 75 percent among Alaska Natives (Parkinson 2000). While the reasons for these high rates are not clear, the strain of the bacteria is unusually resistant to treatment (Centers for Disease Control 2011).

Few parasitic diseases have been reported in the literature as presenting a significant medical problem in Alaska. The parasitic diseases most likely to cause problems in humans in the area are giardia, brucellosis, and trichinella. However, concern has been raised that changing of the landscape, water supply, and subsistence food practices (including food harvesting, preparation and storage) caused by climate change, development activities, or other causes, could cause an increase in the rates of parasitic diseases experienced by humans (Brubaker et al. 2011).

Nutritional Outcomes

Diet and nutrition play an important part in health. Healthy diets prevent disease and are important to maintain at community and individual levels. Native populations in Alaska and elsewhere have experienced marked changes in disease patterns stemming from the rapid transition from a healthy subsistence diet to a more Western diet and lifestyle, resulting in drastic increases in obesity, diabetes, and other chronic diseases (Kuhnlein and Receveur 1996).

Table 3.3-37 Nutritional Outcomes Among Adults in the NSB

	Anaktuvuk Pass	Atqasuk	Barrow	Kaktovik	Nuiqsut	Point Hope	Point Lay	Wainwright	All NSB	All Alaska
Diabetes									6%	6%[a]
Overweight (BMI 25-29.9 kg/m^2, based on self-reported height and weight)^2									33%	37%[a]
Obese (BMI 30 kg/m^2 or higher, based on self-reported height and weight)^2									39%	28%[a]
Percent of households that found it difficult to get the foods they needed to eat healthy meals in the past year	57%	59%	28%	40%	38%	36%	51%	46%	35%	
Percent with household members who at times did not have enough to eat	40%	20%	14%	19%	25%	24%	22%	30%	19%	

Notes: [a] CDC 2009

Table 3.3-38 Nutritional Outcomes Across Alaska

Indicator	All Alaska	American Indian / Alaska Native	All Rural Alaska
Proportion of Alaskan adults with pre-diabetes or borderline diabetes	8.1% (95% confidence interval: 7.0% - 9.4%)	10.1% (95% confidence interval: 7.4% -13.6%)	6.5% (95% confidence interval: 4.9% - 8.6%)
Proportion of Alaskan adults with non-gestational diabetes	6.7% (95% confidence interval: 5.7% - 7.8%)	8.2% (95% confidence interval: 5.7% - 11.6%)	5.7% (95% confidence interval: 3.9% - 8.1%)

Source: Parnell et al. 2008

Overweight, obesity, and diabetes present significant health burdens to NSB (Parnell et al. 2008). This constellation of disorders is linked with increased risk of developing a number of other chronic health problems, including high blood pressure, heart disease, arthritis, certain cancers, and some types of respiratory problems.

As shown in Table 3.3-37, in 2006 to 2008 the NSB had substantially higher estimated adult obesity rates than the Alaska average, with almost two-thirds of residents self-reporting as overweight or obese. One-half of children in the NSB are overweight or obese, making rates of childhood obesity in the NSB well above the state average for Alaska. Between 1990 and 2005, the prevalence of diabetes in the Barrow service unit increased by roughly 130 percent, or by nearly three times the overall U.S. rate (ANMC

2010). Across all of Alaska, rates of overweight individuals are similar in Natives compared to non-Natives, although rates of obesity are significantly higher in Alaska Natives (38.1 percent vs. 26.1 percent) (Parnell et al. 2008).

Rates of diabetes among adults in the NSB vary substantially depending on the data source. The NSB census data show rates very similar to those of adults across Alaska, and this similarity has also been found in the Behavioral Risk Factor Surveillance Survey telephone survey data (Tables 3.3-37 and 3.3-38). However, the Alaska Native Medical Center's diabetes program that maintains a statewide diabetes registry found the age-adjusted diabetes prevalence for the Barrow service area to be the second lowest in the state, estimated at only 2.8 percent (ANMC 2010). As has been happening across the country and state, rates of diabetes have risen rapidly in the NSB over the last several decades. Between 1985 and 2005, the crude prevalence of diabetes seen in the NSB more than doubled (McAninch 2012).

Food insecurity and a change away from subsistence food sources may contribute to the risk for obesity and the associated chronic illness for residents in the NSB. Food insecurity refers to an inability to secure sufficient healthy food for a family. Those facing food insecurity tend to consume cheaper, high-calorie food with low nutrient value (ADPH 2005, Bersamin et al. 2006, Bersamin and Luick 2007, Bersamin et al. 2008). This is often because processed or packaged foods are cheaper and more readily available in rural/remote areas than fruits and vegetables, often because of their longer shelf life. Rates of food insecurity are high in the NSB with 19 to 40 percent of households reporting not having enough food to eat at times (Table 3.3-37). Food availability from subsistence foods is discussed further in Section 3.3.2.5, Community Subsistence Harvest Rates.

Injuries

Injuries are an important health outcome that can lead to lost worker productivity and income, increased health care costs over the short and long term, disability, and even death (McAninch 2012). Injuries not only impact those involved; caregivers and family members can also experience mental anguish and decreased quality of life. In Alaska, injuries account for a large proportion of premature death, particularly in children and within Native populations (McAninch 2012).

Table 3.3-39 Leading Causes of Injury Hospitalization for Alaska Natives in the EIS Project Area, 1991-2003 (rate per 10,000)

Injury Type	North Slope	Northwest Arctic	All Alaska Natives
Falls	39.9	34.8	38.7
Suicide attempt	24.2	34.8	20.4
Assault	19.7	21.8	18.5
Snow machine	15.1	21.2	7.7
All-terrain vehicle	14.6	14.1	6.1
Motor vehicle	11.2	4.6	13.7
All unintentional injury	119.4	115.4	99.8

Source: ANTHC 2008

Table 3.3-40 Leading Causes of Injury Death for Alaska Natives in the EIS Project Area, 1999-2005 (age-adjusted rate per 100,000)

Injury Type	North Slope Borough	Northwest Arctic Borough	All Alaska Natives	All U.S.
Suicide	61.3*	81	37.9	10.7
Drowning	n/a	37.1*	n/a	n/a
Off road vehicle	n/a	33.3*	n/a	n/a
All unintentional injury	106.8	132.4	101.8	36.3
Total injury	188.1	243.9	154.9	54.8

Source: ANTHC 2008; Note: *fewer than 20 cases reported, interpret rate with caution; n/a – data not available

In the NSB, injury (which includes unintentional injuries, suicide, assault, and homicide) is the second leading cause of death, as well as the second leading reason for hospitalization, and disproportionately impacts younger populations (NRC 2003b). The Alaska Trauma Registry reports that the NSB has the highest rates of hospitalizations due to injuries in the state (141 per 100,000 residents), over double the state average (NRC 2003b). Hospitalization rates due to different types of injuries are presented in Table 3.3-39 for Alaska Natives in the NSB and the NAB. Overall, hospitalization rates are comparable across Alaska Natives in the NSB and NAB. High risk-taking behavior, much of which is associated with alcohol consumption, is thought to contribute to many injuries. The unique social and physical environments in Alaska's north also contribute to high injury rates in this area. Unusual ice patterns, resulting from changes to the climate are also making ice travel more dangerous (Brubaker et al. 2011). The number and severity of injuries may be substantially underreported, due to a lack of hospital facilities in the communities and limited hospital beds in Barrow, which results in many injuries being treated as outpatient visits rather than hospitalizations.

Death due to injury also disproportionately affects Alaska Natives compared to other population groups. Injury is the leading cause of death amongst Alaska Natives (ANTHC 2008). The rate of mortality for unintentional injury is approximately 3.5 times higher for Alaska Natives than U.S. Caucasians (Day et al. 2006). Table 3.3-40 depicts these trends for suicide, drowning, off road vehicles, all unintentional injuries and total injury for Alaska Natives and compares the rates to those in the U.S. Rates of death due to injury in the affected area for Alaska Natives are many times more the rates than for the general U.S. population.

Social Pathologies and Mental Health

Social and psychological problems, including alcohol and drug problems, unintentional and intentional injury and suicide (a high percentage of which are associated with alcohol use), depression, anxiety, and assault and domestic violence, are now highly prevalent on the North Slope (as they are in many rural Alaska Native and Arctic Inuit villages in Canada and Greenland) and cause a disproportionate burden of suffering and mortality for these communities (MMS 2008). These problems rarely occur in isolation, but usually arise in the context of specific sociocultural and physical environments that shape human behavior. Research in circumpolar Inuit societies suggests that social pathology and related health problems, which are common across the Arctic, relate directly to the rapid sociocultural changes that have occurred over the same time period (Bjerregaard et al. 2005, Curtis et al. 2005, Goldsmith et al. 2004).

Table 3.3-41 Social Pathologies in the NSB

	All NSB	All Alaska
In the past 12 months, felt a household member had been hurt by drugs or alcohol[1]	30%	n/a
In the past 12 months, felt the health of their community had been hurt by drugs or alcohol		
Often	57%	n/a
Sometimes	35%	n/a

Table 3.3-42 Mental Health Across Alaska

Indicator	All Alaska	American Indian / Alaska Native	All Rural Alaska
Proportion of Alaskan adults with current moderate-to-severe depression	7.6% (95% confidence interval: 5.9% - 9.7%)	9% (95% confidence interval: 6% - 15%)	8% (95% confidence interval: 5% - 11%)

Source: Parnell et al. 2008

Alcohol and drug misuse, which usually comprise a significant component of and contributor to social pathologies. As shown in Table 3.3-41, a large proportion of NSB residents feel that their families and communities have been hurt by drug or alcohol use.

In 2006 to 2008, suicide was the fourth leading cause of death in the NSB. Since 1990, age-adjusted suicide mortality rates in the NSB have averaged twice the statewide average and four times the national average. Alaska Natives are at particular risk of suicide, comprising 39 percent of all suicides in the state (AIPC et al. 2006). In the NSB, young people are particularly susceptible to suicide; in 2009 the suicide rate for young men aged 15-24 was 56 per 100,000; this compares to an overall rate of 20 per 100,000. Suicide rates among young Alaska Native males (aged 15-24 years) illustrate the severity of the health disparity showing a suicide rate of 142 per 100,000 (McAninch 2012). Overall, true suicide rates are thought to be higher than the rates reported, as a significant percentage of accidental injury deaths are thought to be due to suicidal risk-taking behavior (McAninch 2012).

Mental health is a critical part of overall health. The Survey of Living Conditions in the Arctic estimated that six percent of adult Iñupiat in the NSB were likely suffering from depression (Poppel et al. 2007). This figure appears similar to statewide estimates for Alaskan adults, although the figures are not directly comparable due to differences in survey methodology. Rates of depression for Alaska Natives are reported as being slightly higher than the state average (Table 3.3-42). However, underreporting of mental health problems is common, especially in some Native populations (McAninch 2012). Other societal factors, such as high rates of domestic violence and suicide mentioned above, as well as high rates of child maltreatment, indicate that mental health status in the NSB might be worse than what these statistics imply (McAninch 2012). In both the NSB and in other populations, depression and anxiety are often higher among youth than adults.

Rates of assault and domestic and sexual violence in Alaska are consistently among the highest in the nation. The NSB is no exception to this trend. The U.S. Department of Health and Social Services reported that between 2000 and 2003 rates of rape and assault in the NSB were 8 to 15 times greater than the national average (NRC 2003b). During 2004 to 2006, 29 percent of adult respondents reported having been hit, hurt, or threatened by an intimate partner sometime in their lifetime. Although this figure is not markedly different than the state average of 22 percent, it is still concerningly high (CDC 2006). Within the NSB, there can be considerable variation among communities; in Barrow in 2003, rates of reported domestic violence were six times higher than reported in the rest of the state (ANDVSA 2004). Across the state, Alaska Natives suffer disproportionately higher rates of domestic violence than non-Alaska Natives (Rivera 2010).

Maternal and Child Health

Indicators of maternal and child health provide insight into overall health status and social wellbeing at a societal level, since they are highly sensitive to changing social and environmental conditions. The infant mortality rate for the NSB was reported as 9.2 per 1,000 live births between 1998 and 2007. Although this rate has been steadily declining in the NSB since 1977, this rate is still higher than the state rate of approximately 6.5 deaths per 1,000 live births and is above the state target of 4.5 per 1,000 live births (Pearson 2002). However, the NSB has the lowest 10-year average infant mortality rate of all the northern, southwest, and interior rural Alaskan regions (ABVS 2007).

Child mortality among all Alaska Natives is higher than among Alaska non-Natives, and this health disparity has persisted over many years. Between 2003 and 2005, child mortality among children ages 1 to 4 was 103.4 per 100,000 population in Alaska Native children vs. 23.7 per 100,000 for non-Native children (Schoellhorn et al. 2008). The proportion of deaths due to unintentional injuries among all Alaska Natives increases from young children to adolescents to teenagers. While homicide is the second leading cause of death in children aged 0 to 9, suicide becomes the second leading cause of death for youth and teens (Schoellhorn et al. 2008).

Mortality is not the only indicator of child health. Of particular relevance to the NSB is tooth decay, a health issue that is predominant in Native populations across the country. Rates of untreated tooth decay in Alaska Native and American Indian children have been two to five times the rates for non-Native children (IHS 1999, Riedy 2010), and high intakes of sugar-sweetened beverages appear to be a causative factor. As discussed earlier in the section titled Nutritional Outcomes, diabetes and obesity also greatly impact youth of the NSB and represent serious public health concerns.

Health Disparities

Although population-level health data are usually presented in a way that aggregates individual experience and shows the "average" experience of health, it is important to note that significant health disparities exist among individuals, and also among subsets of the population. While some people and some groups will always be healthier than others, systematic health disparities—also termed *health inequities*—generally arise along predictable lines. Groups that experience some areas of disadvantage, such as economic disadvantage, environmental injustice, or social dysfunction, are usually those that experience health disparities.

In Alaska, these health inequities can generally be found when looking at differences between rural and urban populations, and among racial and socioeconomic groups. Alaska Natives, people living in rural areas, and the poor are generally worse off in terms of almost all measurable health outcomes.

Examples of health disparities between Alaska Natives and non-Natives can be seen in a large number of health outcome indicators. In the year 2000, the life expectancy for Alaska Natives was 69.5 years, lagging the life expectancy of 76.5 years for the general U.S. population (Parkinson 2006). Rates of unintentional injury are higher in Natives, as is cancer mortality, social pathologies (including suicide, homicide, family and intimate partner violence), smoking-related illness such as lung cancer, and CLRD (Day et al. 2006, Lanier et al. 2006). Indicators of maternal and child health are also worse for this group.

Disparities are neither fixed nor uniform. While patterns may be observed in the population at large, the health of individuals within any group will vary widely. And regardless of disparities, many disadvantaged groups in Alaska have seen substantial improvements across a wide range of health indicators over the last several decades.

3.3.3.5 Health Determinants

To a large extent, health is determined by where we live, the state of our environment, our income and education levels, our jobs, and our relationships with friends, family, and the larger community. These critical factors are often called *health determinants* (or determinants of health) because of their roles in shaping health in individuals and communities. Some health determinants are under the direct control of individuals, for example, the choice to use alcohol or to smoke, to eat healthy foods, or to use snow machines or four-wheeler helmets. Other health determinants are more closely tied to the physical environment (e.g. air and water quality; subsistence resources); activities under the control of governments (public utilities, land use, access to alcohol and tobacco); working conditions (jobs, income); or the social environment (social, emotional, and religious supports).

The biomedical health outcomes described in Section 3.3.3.4 share the fact that rates of disease incidence, prevalence, and mortality are driven in large part by these determinants, although other factors, such as genetic factors, also play a role. The effects of individual health determinants on disease rates often persist even after controlling for standard risk factors such as smoking rates, cholesterol and blood pressure levels, and overall poverty.

The following sections describe a number of health determinants that are relevant for the affected population and to potential development that may stem from the proposed oil and gas offshore exploration activities in the Beaufort and Chukchi seas.

Table 3.3-43 shows where there is an evidence-based interaction between the health determinants presented below and the biomedical health outcomes presented above, especially those that may be applicable for the affected population (Driscoll 2009).

Income and Employment

The economy is one of the fundamental drivers of population health and wellness. A large body of research has explored the links to health of both societal-level economic structure (such as disparity) and individual-level wealth (such as income and job satisfaction). At its most basic, income provides the ability for individuals to meet their core needs: shelter; food; clothing; and other necessities. However, the health benefits of a "good job" go far beyond bare necessity. Work that provides an identity, social networks, a sense of worth and opportunities for personal growth can drive health outcomes, such as longevity, reductions in chronic disease, and a greater sense of well-being (Doyle et al. 2005). At the same time, workplace hazards—for example, from physical risks through chemical exposures—can be a significant source of ill-health in a community.

The EIS project area, like most of rural Alaska, faces fluctuating employment markets with limited job opportunities and chronic levels of unemployment and underemployment. Iñupiat residents have identified the lack of good jobs as a priority issue (Poppel et al. 2007). Importantly, residents state that they would prefer to participate in a combination of wage-based and traditional subsistence activities (Poppel et al. 2007). Section 3.3.2.2 describes the subsistence activities and wage economic opportunities which are well developed and highly interdependent (Kruse et al. 1981, Kruse 1981, 1982). Subsistence harvest activities are both cash dependent and highly cash efficient. The small increments of cash that are utilized in subsistence activities produce great quantities of subsistence food resources that in turn support networks of sharing and cultural and ceremonial practices.

Poverty has a devastating negative impact on health, particularly for children, due to its association with chronic stress, poor nutrition, increased exposure to crime and victimization, fewer opportunities, and problems with access to health care. From 2001 to 2008, the NSB estimated rates of residents living below the poverty level were above state levels (Circumpolar Research Associates 2010) despite the oil and gas development that occurred during this time. Poverty may disproportionately affect the Iñupiat population, which has substantially lower median household incomes than non-Iñupiat NSB residents (Circumpolar Research Associates 2010).

Economic indicators for NSB communities are discussed extensively in Section 3.3.2, Socioeconomics.

Subsistence Participation and Diet

Table 3.3-44 Food and Nutrition in the NSB

	Anaktuvuk Pass	Atqasuk	Barrow	Kaktovik	Nuiqsut	Point Hope	Point Lay	Wainwright	All NSB
Times last year when household found it difficult to get the foods they needed to eat healthy meals[1]	57%	59%	28%	40%	38%	36%	51%	46%	35%
If yes, because not able to get enough subsistence foods	71%	34%	34%	44%	53%	59%	48%	36%	43%
If yes, because not able to get enough store foods	80%	100%	90%	88%	87%	86%	96%	95%	90%
Households that get at least half of their meals from subsistence sources	67%	58%	44%	67%	67%	64%	61%	67%	54%

Notes: [1]Includes all head of households (survey respondents)
Source: Circumpolar Research Associates 2010

Diets in the NSB include both traditional, or subsistence foods, and non-traditional, or store foods. Traditional diets are associated with numerous health benefits and reduced risk of many chronic diseases including diabetes, high blood pressure, high cholesterol, heart disease, stroke, arthritis, depression, and some cancers (Reynolds et al. 2006; Murphy et al. 1995; Adler et al. 1994, 1996; Ebbesson et al. 1999, Bjerregaard et al. 2004).

While evidence of dietary habits in the NSB is limited, subsistence sources are an important food source to NSB residents. Subsistence foods include fish, seal, walrus, beluga and bowhead whale from the Beaufort and Chukchi seas, as well as land-based animals and certain migratory birds and eggs. In the 2010 NSB census, 54 percent of households indicated that they get at least half of their meals from subsistence sources. Data from the 2003 NSB census show that virtually all Iñupiat households reported relying on subsistence resources to some extent and that subsistence foods make up a large proportion of healthy meals (Table 3.3-44) (Circumpolar Research Associates 2010). The NSB also has among the highest per capita harvests of subsistence food in Alaska (McAninch 2012).

Seventy-two percent of adults in the NAB reported participating in hunting, fishing, and harvesting for subsistence (Poppel et al. 2007). The most important sea animals for residents of Kivalina include the bearded seal, beluga and bowhead whale and Arctic char (Brubaker et al. 2011). Household heads with full-time employment relied heavily on traditional food sources (McAninch 2012) and often produce large quantities of subsistence foods that are widely shared throughout the community. However, it should be noted that increased income does not appear to substantially reduce participation in subsistence activities. In some communities there are “super households” that harvest subsistence resources at higher levels in comparison to other households, and through sharing, provide food for a large network of households. The “super households” often have secure cash incomes within which they use to purchase reliable subsistence equipment (i.e. boats, motors, snow machines) and defray the operating costs of subsistence activities, especially fuel.

Section 3.3.2 (Subsistence Resources and Uses) contains detailed information regarding subsistence harvest patterns of the Iñupiat communities in the affected environment. The section describes the cultural importance of subsistence activities to the Iñupiat, emphasizing its role in economic and nutritional outcomes and in maintaining cultural identity. Data are also provided on the community levels of subsistence harvesting by species. It is noted in this discussion that marine mammal harvest contributes a high percentage of subsistence foods in the communities that make up the affected environment. Additional subsistence activities include harvesting of fish and waterfowl.

Research and anecdotal evidence from the NSB and surrounding areas suggest a trend away from subsistence food sources, particularly in younger people (Ballew and Tzilkowski 2006). Two recent studies in Alaska found greater consumption of traditional foods by elders and more nontraditional foods by younger people (Nobmann et al. 2005, Bersamin and Luick 2007). The NSB communities are similar to many other Arctic communities in this respect: people across the circumpolar regions are increasingly replacing traditional subsistence foods, which are associated with numerous health benefits, with store-bought foods that are often high in sugar, calories, and unhealthy types of fat. NSB residents are also consuming high levels of sodas and other sugared beverages (Circumpolar Research Associates 2010).

Subsistence harvest patterns and rates of change of harvest are complex. Elders often remain very much attached to preferred subsistence foods, long after they are able to harvest these foods directly. As an example, the rates of harvest of bowhead whales remain high, and sharing networks are very active for this resource which remains central to the cultural identity of the Iñupiat. At the same time, many rural residents have expressed concerns that some subsistence foods may be contaminated. A common explanation for the trend away from some subsistence food sources in some areas of the Arctic has been residents’ concern over the quality of traditional foods. The issue of contamination is complex, and the potential for harm due to ingestion of contaminants has not been definitively answered. Nonetheless, the perception of contamination (regardless of whether or not any “real” contamination exists) may lead people to avoid healthy traditional foods and rely more heavily on store-bought foods, with resulting health consequences. The may be several elements for some residents to choose store-bought foods over traditional foods. In some cases a family structure may not have anyone to hunt for the family and lack of transportation and/or time, high costs of fuel required for operation of equipment (boats/snow machines) or traditional knowledge to hunt and gather. Younger generations may have changing food preferences, and changing values regarding activities on the land

A limited availability and variety of store-bought food is particularly prevalent in rural Alaska due to small community sizes, high costs, and limited transportation. This results in a predominance of foods that have a longer shelf-life, which tend to be high in fat, salt, and calories.

Health Care Services

Table 3.3-45 Health Insurance in the NSB

	All NSB	All Alaska
Have health insurance, including IHS eligibility	97%	82%[a]
Have health insurance, other than IHS eligibility	64%	

Notes: Includes all head of households (survey respondents)

Health care resources play a specific role in prevention—and a widespread role in treatment—of disease and illness. The adequacy of health care resources is dependent on both universality of access and availability of resources. The provision of health care services may be limited, especially in rural areas, by the unavailability of health care providers. Rural areas often have problems with both recruitment and retention of medical personnel, and some areas are chronically understaffed and underserved. Access to specialist care (and some of the allied health professions, such as mental or nutritional health) is also quite limited in rural areas, unless the patient travels to a major population center.

Provision of health care in the NSB is the joint responsibility of the NSB and the Arctic Slope Native Association (ASNA). Other than Barrow, all NSB communities of the NSB maintain a clinic that is staffed by Community Health Aide/Practitioners. None of these communities have a physician or physician's assistant in residence. Barrow houses the Samuel Simmonds Memorial Hospital, a 14-bed hospital with an outpatient unit that consists of a six-room clinic and a two-bed emergency room (ASNA 2010). The hospital in Barrow offers an ambulatory care clinic, dental and eye clinics, pharmacy, and a specialty clinic. Barrow acts as the tertiary care center for the NSB communities, with cases referred to Fairbanks or Anchorage if they cannot be taken in Barrow. Barrow also offers outpatient behavioral or mental health services. A wellness center in Barrow houses both NSB and ASNA services. NSB services include a public health nurse, an eye clinic, and an allied health program, while the ASNA has a "Screening for Life" program that includes screening for STIs and, breast and colon cancers.

Health services in and near the NAB are provided through the Maniilaq Association, which is responsible for the provision of extensive health, tribal, and social services to residents of rural Northwest Alaska. Kotzebue houses the Maniilaq Health Center, a primary health care facility that offers an emergency room, an ambulatory care clinic, dental and eye care clinics, a pharmacy, a specialty clinic, and an inpatient wing with 24 beds. In Kivalina, the Community Health Aide/Practitioner program operates a village clinic staffed by two to four Health Aides. The clinic is supported by electronic access to the Maniilaq Health Center in Kotzebue. Several times a year, specialized doctors, dentists, and eye doctors make regularly scheduled visits to the clinic to provide specialized care not usually offered in the area (Maniilaq Association 2010).

Alaska Native Health Service provides health insurance to all Alaska Natives, and over 97 percent of adult NSB residents have health insurance compared to 82 percent of adults statewide (Table 3.3-45). Rural Alaskans also have lower rates of insurance coverage than the overall population, although the rates remain high (Table 4.4-43). While insurance coverage is very good, access to services is severely inhibited by the remote location of the communities and severity of the climate. The costs and inconvenience of travel necessary for many services is cited as a barrier (McAninch 2012). People may have to travel by airplane to the nearest hospital. Bad weather can lengthen the time it takes to get to the hospital or back home from the hospital. Another barrier is the fragmentation of services and complications resulting from the coordination of multiple parties in different locations to provide care. Finally, most of the communities suffer from chronic health care workforce shortages and turnover, to the extent that the U.S. Health Resources and Services Administration characterize the NSB and the NAB as medically underserved and health professional shortage areas.

The Alaska Native Tribal Health Consortium has supported the development of telehealth technologies to support health-related communications in Alaska, through the Alaska Federal Health Care Access Network. Although NSB Health and Community Health Aides/Practitioners have been trained in using telehealth, challenges in staff turnover at the Samuel Simmons Memorial Hospital have prevented its full implementation.

Emergency medical services are also considered a part of health care services in the affected community. The NSB maintains a centralized headquarters to coordinate the provision of fire, rescue, and emergency medical services and oversees nine fire rescue stations, all of which house, at a minimum, an ambulance, engine, and tanker to provide Emergency Medical Services (EMS) response and fire protection to the community (NSB 2011b). Following considerable investment by the Borough, an estimated 94 percent of NSB households have modern water and sewer service as of 2008, compared with an average of 76 percent for Tribal Health Regions statewide (AN EpiCenter 2009, Circumpolar Research Associates 2010, McAninch 2012). The *Healthy Alaskans 2010* target is for 98 percent of households across the state to have modern water and sewer service. The cost and complexity of maintaining and repairing expensive water and sewer systems in the NSB are ongoing concerns.

The NAB maintains a number of public services designed to protect public safety, including a fire department and fire prevention programs for all communities, a search and rescue department, an emergency management department, a public safety program, and shelter cabins. The borough has drafted a 5-year safety plan that will strengthen public services in all communities, and is in the process of revising their Emergency Preparedness Plan (NAB 2010).

Alcohol and Drug Misuse

Table 3.3-47 Alcohol Misuse Across Alaska

Indicator	All Alaska	American Indian / Alaska Native	All Rural Alaska
Binge drinking: Proportion of males having 5 or more drinks or females having 4 or more drinks on at least one occasion in the past 30 days.	15.1% (95% confidence interval: 13.6% - 16.7%)	18.3% (95% confidence interval: 14.8% - 22.4%)	14.4% (95% confidence interval: 12.1% - 17.0%)
Excessive drinking: Proportion of males having more than 2 drinks per day or females having more than 1 drink per day in the past 30 days.	6.2% (95% confidence interval: 5.1% - 7.5%)	5.8% (95% confidence interval: 3.5% - 9.2%)	5.1% (95% confidence interval: 3.6% - 7.2%)

Source: CDC 2008

Alcohol abuse is linked to chronic disease, interpersonal violence, injuries, disintegration of family structure and well-being, and adverse home environments for children. Within the NSB, alcohol is involved in an estimated 40 percent of snow machine-related injury hospitalizations, 70 percent of assault injuries, 57 percent of suicide attempts, and 45 percent of motor vehicle-related injury hospitalizations. Many incidents of interpersonal violence or injury in particular are associated with "binge," or episodic, heavy drinking.

In the NSB, the sale and importation of alcohol is prohibited in all communities but Barrow, which prohibits the sale but not the importation of alcohol. Restrictive alcohol policies in rural Alaskan communities are associated with decreased incidence of alcohol-related injuries and other health problems (Chiu et al. 1997, Landon et al. 1997), and the NSB's laws appear to be moderately effective: binge drinking and prenatal drinking in the NSB seem to have decreased since the 1990s. Currently, there does not appear to be a significant difference in self-reported periodic heavy, or "binge," alcohol consumption compared to the state of Alaska or the nation. In 2005 to 2007 the rate of binge drinking among adults in the NSB was estimated at 17 percent (McAninch 2012), similar to the rates shown in Table 3.3-47. In 2005, the rate of self-reported consumption of any alcohol among NSB high school students was significantly lower than the national average, and self-reported binge drinking among NSB high school students was not significantly different from state or national estimates.

In the NAB, a 2010 vote allowed the selling of liquor in the community of Kotzebue via a city-run package store and distribution center.

Culture and Language

Culture and ethnicity are important determinants of health, as they influence almost all aspects of how we live. Culture and language provide the framework in which we understand and interpret our surroundings and provide a set of "ready-made" choices about lifestyle and behavior (e.g. eating and physical activity patterns, use of tobacco, risk-taking behavior, interaction with health care alternatives, etc.).

The NSB has made several efforts towards strengthening culture and language among the Iñupiat peoples. The school curriculum in the NSB now includes Alaska Native culture, history, and language (Circumpolar Research Associates 2010), and language ability among NSB Iñupiat compares very well to neighboring regions of Bering Straits and the NAB. The NAB has a Rosetta Stone Language program in place for the Northwest Iñupiaq language, and the NSB is finalizing plans for its own Iñupiat Eskimo Rosetta Stone Language program.

However, there are several threats to culture and language in the NSB. Younger residents do not have the fluency of older residents with Iñupiaq language (Circumpolar Research Associates 2010; et al. 2007).

Subsistence foods—believed by many Iñupiat and other Alaska Natives to be the very foundation of health and well-being—are increasingly viewed as threatened in terms of both availability and potential contamination, and this may impact participation in subsistence activities and food sharing social networks (McAninch 2012).

Environmental Contamination

Residents of the NSB are quite concerned about environmental contamination, particularly as it relates to contamination of subsistence food sources. In a recent survey, 44 percent of Iñupiat village residents reported concern that fish and animals may be unsafe to eat (Poppel et al. 2007).

Environmental contaminants have the potential to affect human health in a number of ways. First, exposure to contaminants via inhalation, ingestion, or absorption may induce adverse health effects, depending on a number of factors, including the nature of the contaminant, the amount of exposure, and the sensitivity of the person who comes in contact with the contaminant.

Aside from actual exposure to environmental contamination, the *perception* of exposure to contamination is also linked with known health consequences. Perception of contamination may result in stress and anxiety about the safety of subsistence foods and avoidance of subsistence food sources (CEAA 2010, Joyce 2008, Loring et al. 2010), with potential changes in nutrition-related diseases as a result. It is important to note that these health results arise regardless of whether or not there is any "real" contamination at a level that could induce toxicologic effects in humans; the effects are linked to the perception of contamination, rather than to measured levels.

The issue of exposure to environmental contaminants is contentious, and few data exist to support or deny resident concerns regarding degradation of environmental quality and local health impacts. In general, the field of public health addresses this concern through efforts to control exposure to environmental contaminants, rather than through responding to specific increases in disease rates related to a known exposure. Other sections of this chapter, including those related to air quality (Section 3.1.5), water quality (Section 3.1.7), and environmental contaminants and ecological processes (Section 3.1.8) discuss some of the media through which humans could be exposed to contamination.

Public Health and Climate Change

Rural Arctic communities are particularly vulnerable to the health effects of climate change, and global warming is increasingly becoming recognized as a determinant of health in the Arctic (ICIA 2005). Changing weather and ice patterns have the potential to affect a wide range of health-related outcomes. Climate change may affect both subsistence food availability and storage and may increase risks associated with subsistence activities, which in turn may lead to dietary and cultural change. Climate change can also affect water, sanitation, housing, transportation infrastructure, cultural continuity, community stress levels, the spread of infection, and even the types of diseases and infections to which the population is susceptible (ACIA 2004, Brubaker et al. 2010, Brubaker et al. 2011).

Communities in the NSB are already experiencing some effects of climate change: erosion problems; thawing ice cellars; less reliable ice conditions; and subsequent higher risk to hunters and spring whalers. Several communities south of the Brooks Range (Kivalina, Shishmaref, and Newtok) are actively planning to relocate due to climate-induced erosion problems. Climate change will likely result in rapidly changing physical environment and health conditions for this population in the coming years.

Other Determinants of Health

The health determinants discussed above are thought to be relevant for the assessment of public health impacts potentially resulting from offshore oil and gas exploration activities in the Beaufort and Chukchi seas. There are, however, other health determinants that impact upon population health in the affected population. These include education, smoking, physical activity, and motor vehicle safety. Although each of these determinants plays an important role in determining the health of the population in the affected area, they are not discussed because of their irrelevance to the proposed activities.

3.3.3.6 Summary

The population in the affected area is experiencing health trends similar to that of the rest of Alaska and the U.S.; however, health outcomes in the affected area tend to be worse off, especially for health outcomes like diabetes, obesity, respiratory illness, and injury. The health determinants that play a role in altering the impacts of these health outcomes comprise of those similar to all populations, as well as ones unique to the environment and culture in northern Alaska. A consideration of this local health data and accepted determinants of health will allow for recognition of important risks associated with a project and the eventual development of effective mitigation strategies.

3.3.4 Cultural Resources

3.3.4.1 Introduction

Cultural resources include archaeological sites and historic structures and features that are protected under the National Historic Preservation Act of 1966, as amended. Cultural resources also include traditional cultural properties (TCPs) that are important to a community's practices and beliefs and that maintain a community's cultural identity. Cultural resources that meet the eligibility criteria for listing on the National Register of Historic Places (NRHP) are considered significant resources and, when present, must be taken into consideration during the planning of federal projects. Federal agencies also are required to consider the effects of their actions on sites, areas, and other resources (e.g., plants) that are of religious significance to Native Americans and Alaska Natives, as established under the American Indian Religious Freedom Act. Native American and Alaska Native graves, burial grounds, and associated funerary objects are protected by the Native American Graves Protection and Repatriation Act.

Pursuant to Section 106 of the National Historic Preservation Act (*16 U.S.C. 470f*), and its implementing regulations (36 CFR 800), the alternative identified in this EIS may have the potential to cause effects to offshore prehistoric and historic resources, including submerged prehistoric sites and historic shipwrecks, as well as onshore prehistoric and historic resources, including camps, village sites, artifact scatters, historic structures, and World War II and Cold War era facilities. Offshore impacts may be incurred throughout the project area in conjunction with seismic testing activities. Onshore impacts would be restricted to areas of shore-based activities, including Prudhoe Bay, Barrow, Wainwright, and Nome.

3.3.4.2 Cultural Setting

With the exception of Antarctica, the New World appears to have been the last major land mass on earth to have been colonized by a human population, most likely due to the high latitude of land that had to be traversed to reach this hemisphere. This high-latitude area is most often referred to as Beringia, a term used as early as 1937 to include those portions of the continental shelf between the present shores of northeast Asia and Alaska that were exposed during periods of lowered sea level. Archaeologists commonly use a broader definition that expands Beringia to include northeastern Siberia, western Alaska, Kamchatka, and much of northwestern Canada (Hoffecker 1996). While Beringia is a geographic concept, it is also defined by temporal boundaries that are a function of climate and sea level. Early chronologies had Beringia, at a depth of 50 m (164 ft) below present sea level, flooded as early as 15,000 to 14,000 years ago. New data, including fossil insects from submerged peat deposits in the Chukchi Sea dating to 11,330-11,000 years BP, have expanded the temporal boundaries of Beringia, since the last glaciations, to roughly 25,000 to 10,000 years B.P. During this period, the continental shelf was exposed, forming a vast land bridge between Asia and North America over 1,000 km (621 mi) wide from north to south (Elias 1996, Hoffecker 1996).

The archaeology of Beringia remains in a relatively early phase of development, as archaeologists on both sides of the Bering Strait continue to build cultural chronologies for the continental shelf and adjacent areas of northeast Asia, Alaska, and the Yukon (Hoffecker 1996). In eastern Beringia, the region comprised of Alaska and adjacent portions of Canada that were not covered by the massive continental glaciers, a small number of archaeological sites revealing evidence of very early occupations have been identified. These include the two Trail Creek cave sites on the Seward Peninsula, which contained traces of lithic artifacts and bone deeply buried in cave deposits, underlain by bone deposits lacking lithics but dated to approximately 13,000 to 16, 000 years ago. Additional early sites in this region have largely been found in central Alaska and consist of open localities on terraces, ridges, or knolls above major rivers. These sites typically contain deposits in Aeolian sediments varying in thickness from a few centimeters to several meters, with dates from the end of the Pleistocene through the Holocene, or roughly from 12,000 years ago to the present (Hoffecker 1996, West 1996). Important among these are the Campus Site, near Fairbanks, first assigned dates ranging to between 12,000 and 8,000 years ago but perhaps only 3,000 years or so in ages (Mobley 1996); the Chugwater Site on Moose Creek Bluff, also near Fairbanks and dated to perhaps 11,000 years BP (Lively 1996); and the Broken Mammoth Site, at the confluence of Shaw Creek and The Tanana River near Delta Junction, with evidence of occupation as old as 11,800 – 11,200 BP (Holmes 1996). These sites, and others like them, are largely limited to lithic materials and bone fragments, though plant macrofossils, insects, mammal hair, and pollen have also been recovered (Holmes 1996), and indicate that remains of early occupations can be found elsewhere, both offshore on those portions of the continental shelf exposed during periods of low sea level, and onshore, in areas devoid of retreating ice masses. The retreat of the glaciers at the end of the Pleistocene opened up new areas of Beringia for colonization, both at higher elevations like the Alaska Range, as well as low-lying coastal areas of Alaska that had been completely inundated by ice. Sites in these areas date to the early Holocene and later (10,000 – 9,500 years BP and younger) and include locations along Cook Inlet, the Kenai Peninsula, and the mainland coast and islands of southeastern Alaska (Hoffecker 1996).

More specific to the current project area, the northwestern American Arctic, extending from Nome, Alaska, to the Mackenzie River delta in Canada, includes the lands occupied in the twentieth century by the western Inuit. Archaeologically, this area is noted for its important role in the development of early American Arctic cultures and, more recently, the development of Arctic Eskimo culture. While the prehistory of the region is not well understood, over 1,200 archaeological sites have been recorded in the Alaska Heritage Resource (AHRS) files of the Alaska Office of History and Archaeology. As currently interpreted, regional prehistory has been divided into five periods that reflect significant changes in culture and habitat: full-time tundra hunting, from earlier than 11,000 years ago to about 8,000 years ago; adaptation to taiga-tundra hunting and fishing, from 8,000 to 4,200 years ago; development of seasonal and year-round coastal hunting and fishing, from 4,200 to 1,500 years ago; prehistoric Eskimo culture, from 1,500 years ago to 1778; and historic Eskimo culture, from 1778 to the present (Anderson 1984). There is abundant evidence of human presence in North America soon after 11,500 years ago, while at least one site, Monte Verde, in Chile, gives secure evidence of a still-earlier presence. This site, and its distance from the presumed Beringian entryway to North America, indicates people arrived in the New World at least 12,500 years ago (Meltzer 2009:192. Two finds were reported in early 2011 that support the early presence of humans in North America. One of these is a child cremation associated with the remains of a semi-subterranean house in central Alaska, dated to 11,500 years ago (AAAS 2011). The second is an even older site located in central Texas, where a pre-Clovis archaeological assemblage has been identified and dated to between 13,200 and 15,500 years ago (Waters et al. 2011). Closer to the area in question are the Broken Mammoth site on the Tanana River in central Alaska, dated to 11,800 years ago; the Mesa Site on Alaska’s North Slope, dated to near 12,000 years ago; and the Nenana Complex sites of the Nenana and Tanana river valleys of interior Alaska (Meltzer 2009:190, 217, 304-305; West 1996: 537-549). Evidence from these and other sites in interior and coastal North America and elsewhere have led some archaeologists to postulate alternative models to the traditional Bering land bridge explanation of the populating of North America, including coastal migration with later inland movement and settlement (Dixon 1999:243-256).

The earliest well-documented archaeological tradition in the northwestern Arctic, representative of the tundra-hunting era, is the American Paleo-Arctic tradition, identified from the coast of the Arctic Ocean to both shores of the Bering Strait, south along the Alaska coast to the Alaska Peninsula, as well as into interior areas. Sites of this tradition are known for containing wedge-shaped microblade cores, microblades, blades and blade cores, bifacial cores, and slotted antler arrows with microblades. These sites are known to be located in both coastal and interior regions and extend from western Alaska to the northern Yukon Territory; providing a well-defined indication of a Pleistocene population migrating south from Alaska (Anderson 1984:81-82; Meltzer 2009:193-194).

By 8,000 years ago, as a result of the post-Pleistocene warming trend and the melting of glacial ice, sea level had risen to between 25 and 40 feet below its present height and for the most part, the Arctic coastline was within one mile of its current position. Archaeological cultures of this time, identified as part of the Northern Archaic Tradition, begin to resemble those of the North American boreal woodlands. Diagnostic artifacts include side-notched projectile points and half-rounded lithic artifacts worked on both surfaces, (semilunar bifaces), bifacial knives, end scrapers, notched pebbles, microblades, and cobble choppers. The oldest site of this tradition is the Tuktu site in Anaktuvuk Pass, in the Brooks Range. In addition to open camps, sites from this tradition include semi-subterranean houses and stone-lined tent rings; the latter two types are known from sites both on the North Slope and in the Brooks Range (Anderson 1984). Anderson (1984:82) proposes that beginning about 6,000 years ago, the North Alaskan cultures shifted from a nearly exclusive land-based, hunting subsistence-base to taiga-tundra hunting and fishing.

Between 4,500 and 4,200 years ago, as sea levels stabilized, evidence for coastal habitation in the Arctic becomes plentiful. Sites of this era reflect the characteristics of the Arctic Small Tool tradition, known for the presence of small, finely flaked stone tools. First discovered at Cape Denbigh in 1948, sites of this tradition have been identified throughout the coastline. Artifacts include wide microblades, microblade cores, tiny end and side blades used as weapon insets, tanged end scrapers, semilunar bifacial knives, flaked burins, unifacially flaked knives, and notched stones, probably used for net weights. Coastal sites were occupied during the late spring and summer, while late summer, fall, and winter sites were located near tundra lakes, elevated lookout points in the Brooks Range, and in the woodlands, especially along the Kobuk River. Faunal remains at sites are almost exclusively caribou with some evidence of fish, while coastal sites contain seal and caribou (Anderson 1984:82-84).

By about 1,500 years ago, Prehistoric Eskimo cultural phases emerged along the north coast of Alaska, reflecting a substantial change from the preceding cultures. These ancestral Iñupiat or Iñupiaq cultures resulted either from movement of people from Siberia or the transfer of new sea mammal hunting technology. In either case, there were significant changes in the material culture, especially related to food acquisition and processing (Anderson 1984:90-93). The Birnirk cultural phase, documented at the Point Barrow type site, indicates a return to whale hunting after a 500-year hiatus. Their primary food supply included seals, fish, caribou, and birds hunted with a variety of hunting implements. Material used to make artifacts include ground slate, chipped stone, antler, bone, ivory, clay, wood, and baleen.

The Western Thule phase developed out of the Birnirk phase along the north coast of Alaska between 1,000 and 750 years ago. Western Thule material culture appears to be an elaborate combination of Birnirk artifacts with specialized tools with whale, caribou, and seal hunting being the major subsistence activities. Houses were similar to Birnirk, with large settlements developed around the group sizes required for whale hunting. However, settlement size also decreased in response to declining whale populations in the Kotzebue area. Current archaeological evidence suggests that there is an apparent gap in large, year-round coastal settlements between Point Barrow and the Mackenzie Delta. However, several archaeological excavations at many sites and contemporary Eskimo villages indicate continuous occupation from the late-prehistoric culture. During the early Western Thule phase, groups expanded both onto the North Slope and into the Brooks Range. Sites that date from late in this phase and that have Athabascan Indian artifacts have been documented in the central and eastern Brooks Range and on the North Slope (Anderson 1984:91-93).

The late prehistory and history of the coastal region focuses primarily on the Iñupiat of the North Slope who continued to have settlements based on hunting and gathering seasonal rounds. They relied heavily on fish and sea mammals, as well as caribou and smaller terrestrial animals. In the nineteenth century, a series of "battles" and famines took place in the Interior, which caused population shifts leading anthropologists to suggest that the current ethnic boundaries may have fluctuated. While direct contact with Euroamericans may not have occurred until the mid-nineteenth century, the Iñupiat Eskimo established trade routes to exchange goods along the coast and into the Interior for at least 100 years prior. Trade goods found at historic Eskimo sites include glass beads, metal knife blades, and brass fittings from trade muskets (Anderson 1984:93).

Vitus Bering explored the coastal areas of Alaska in 1741; within a short time, Russian fur hunters began to exploit the rich sea otter grounds along the Aleutian chain. In 1778, Captain James Cook arrived in southern Alaska where, at Cook Inlet, Tanainas came to his ship to exchange furs and fish for iron. Cook noted that at this time, a few European goods were already in the possession of the Indians. At this time, while southern Alaska Indians and Eskimos were eager to trade with Europeans visiting in ships, attempts at settlement were opposed. As a result, with the exception of the Aleuts, Alaska's inhabitants remained relatively free of European influence (VanStone 1984:149,152).

The historic period of the northwestern Arctic begins with direct encounters between the Iñupiat with European explorers along the north and northwestern coasts of Alaska. By 1762, Russian fur hunters had reached Kodiak Island, well to the south of the current area of interest. The Russian fur traders soon established a post on the island, which was destined to become one of the major headquarters of the Russian-American Company. Within 20 years, additional posts were established on the Kenai Peninsula and at Sitka, and several native groups were drawn more actively into the fur trade (VanStone 1984:150-153).

European exploration quickly expanded to the north along the Alaska coastline, most notably with the voyages of Captain James Cook, who explored the area between Bristol Bay and Icy Cape between 1776 and 1780. By 1850, commercial whaling ships began to frequent the waters of the Arctic Ocean in large numbers every summer, trading in large quantities with northern Eskimos. From the 1850s to the 1920s, commercial Euroamerican whaling activities often included an Iñupiat labor force. Many impacts to traditional lifeways, the economy, and material culture occurred as a result of commercial whaling (VanStone 1984:155-156).Whaling persisted until the baleen market collapsed after 1916 (Spencer 1984:278-281). Foreign diseases decimated Native populations and caused major demographic and traditional territorial shifts. Direct contact with Euroamerican missionaries, who arrived in Barrow in 1890, also led to changes in traditional religious practices and resulted in the acceptance of Christianity by many Native Alaskans. Other Euroamerican commercial interests attracted northern Native societies into the larger Western economic sphere. Domestic reindeer herding, introduced at Wainwright and Barrow, developed into large herds up to about 1915, but a reduction of meat and hide markets in the early 1930s led to the demise of caribou herding among the North Slope settlements (VanStone 1984:156-157). Also, the fur industry sought Arctic fox pelts, providing a brief economic boost for some Natives trappers for nearly a decade after World War I. With prolonged contact, Euroamerican trade goods entered the Native material culture realm as local populations traded for them or earned them in exchange for monetary wages. As commercial whaling and trading expanded, contact caused the disruption and eventual demise of long established Native trade networks as the Iñupiat sought western goods. By the 1920s, mass-produced items produced in the U.S. substantially replaced items of Native manufacture. Archaeological remains of Native historic activities associated with seasonal subsistence activities, and

Euroamerican trade goods lay among sod house ruins and tent rings that can be found along the coast and inland to the foothills and valleys of the Brooks Range (Spencer 1984:278-281).

Beaufort Sea

Offshore Prehistoric Resources

The presence of offshore prehistoric resources is difficult to assess. Approximately 19,000 years ago, at the height of the late Wisconsinan glacial advance, sea level was approximately 120 meters lower than at present. During this time, large expanses of what is now the outer continental shelf were exposed as dry land (MMS 2007c). The exact elevation of past sea levels in relation to present sea level varies geographically, depending primarily on the location of the area in relation to the major glacial ice masses. In the northwestern Arctic region of Alaska, relict fluvial channels and shoreline features evident at the seafloor suggest that sea level was probably between 50 and 60 m lower than present at about 12,000 B.P. (years before present). As a result, a conservative estimate of 60 m below present is used for relative sea level at this time, a date by which current research indicates prehistoric human populations were almost certainly present in the area (MMS 2007c; Dixon et al. 1986.). The location of the 12,000 B.P. shoreline is roughly approximated by the 60-m bathymetric contour. The continental shelf shoreward of this contour would have potential for prehistoric sites dating later than about 12,000 B.P. Seismic-survey and borehole data that have been collected in the Beaufort Sea indicate areas of well-preserved Holocene sedimentary sequences and landforms that have potential for containing prehistoric archaeological deposits (MMS 2007c). In some areas of the Beaufort Sea, available remote-sensing data indicate little evidence of ice gouging at the seafloor and areas of well-preserved landforms, such as river channels with levees and terraces just below the seafloor. Although these features have not been directly dated, their stratigraphic position indicates that they are most likely Holocene in age. The presence of these preserved landforms just beneath the seafloor indicates that there also is potential for preservation of prehistoric archaeological sites that may occur in association with the landforms. The potential for the occurrence of archaeological resources in the Beaufort Sea seaward of the barrier islands, however, is probably much lower than for those areas landward of the barrier islands and in areas protected by floating, landfast ice during the winter (MMS 2007c).

Offshore Historic Resources

Much like prehistoric resources, offshore historic resources are likely to be present in the project area, but are equally difficult to identify or quantify. Available documentation indicates that between 1851 and 1934, at least 34 shipwrecks occurred within a few miles of Barrow; another 13 wrecks occurred to the west and east of Barrow in the waters of the Beaufort and Chukchi seas. No surveys of these shipwrecks have been made; therefore, no exact locations are known. If intact remains are present, these wrecks would be valuable finds, providing significant information on the historic whaling industry (MMS 2007c).

Onshore Prehistoric and Historic Resources

The coast of the Beaufort Sea suffers from active erosion, damaging or destroying important coastal cultural resources. Of the more than 1,200 North Slope prehistoric sites, very few are located in the coastal region (AHRS files). As noted above, onshore resources, such as vehicles used for onshore support operations and infrastructure, that may be subject to impact from the current undertaking would likely be limited to those in the vicinity of Barrow and Prudhoe Bay, where land-based activities may occur. AHRS records on file with the Alaska Office of History and Archaeology indicate that as many as 16 prehistoric and historic resources have been included within a two-mile radius of Barrow. These include three historic Iñupiat village sites; prehistoric camp sites and burial locations; a late nineteenth century whaler's refuge facility, World War II and Cold War era Navy, Air Force, and Army facilities; and one paleontological resource location. Fewer resources have been documented in the vicinity of

Prudhoe Bay. Four of these have been recorded within a two-mile radius of Prudhoe Bay, including one prehistoric camp site, two historic camp sites, and the site of the original discovery well.

Chukchi Sea

Offshore Prehistoric Resources

The potential for the presence of offshore prehistoric resources in the Chukchi Sea area is similar to that of the Beaufort Sea. Analyses of shallow geologic cores obtained by the U.S. Geological Survey in the northeastern Chukchi Sea indicate the presence of well-preserved coastal plain sedimentary sequences of Holocene age just beneath the seafloor. Radiocarbon dates on in situ freshwater peat contained within these deposits indicate that relative sea level in the Chukchi Sea area would have been approximately 50 m below present at 11,300 B.P. The location of the 11,300-B.P. shoreline is roughly approximated by the 50-m bathymetric contour. The continental shelf shoreward of this contour would have potential for prehistoric sites dating subsequent to approximately 11,300 B.P. The presence of preserved nonmarine Holocene sedimentary sequences in the Chukchi Sea indicates that there also is potential for preservation of prehistoric archaeological sites. Even in some areas of intense ice gouging, such as off Icy Cape, the Holocene sediments are thick enough that any archaeological sites that occurred in the underlying Late Pleistocene deposits would be below the depth affected by ice gouging (MMS 2007c:; Dixon et al. 1986).

Offshore Historic Resources

Like the Beaufort Sea, shipwrecks were a relatively common occurrence on the Chukchi Sea, and remains of these incidents may very well be present. At Point Belcher near Wainwright, 30 ships were frozen in the ice in September 1871; 13 others were lost in other incidents off Icy Cape and Point Franklin. Another seven wrecks are known to have occurred off Cape Lisburne and Point Hope. From 1865-1876, 76 whaling vessels were lost because of ice and also because of raids by the Confederate battleship *Shenandoah*, which was sent to the Pacific with the goal of destroying the Union whaling fleet. The *Shenandoah* burned 21 whaling ships near the Bering Strait during the Civil War. The possibility exists that some of these shipwrecks have not been completely destroyed by ice and storms. This likelihood is reinforced by the 2010 discovery by Parks Canada archaeologists of the HMS Investigator, a British ship abandoned in the ice in 1853 along the northern coast of Banks Island in Canada's western Arctic during a search for the Northwest Passage. This shipwreck is remarkably well-preserved, standing upright in approximately 11 meters of water (AIA 2011). The likelihood for good preservation has been determined particularly high around Point Franklin, Point Belcher, and Point Hope (MMS 2007c).

Onshore Prehistoric and Historic Resources

Onshore archaeological resources near the Chukchi Sea coast receive less damage from the eroding shoreline than those on the Beaufort Sea coast, which is subjected to more slumping because of water action and permafrost. As a consequence, archaeological resources have been recorded in greater numbers in the Chukchi Sea area, and unknown resources are more likely to be present. There are 200-300 known archaeological sites in the Hope Basin area, and the area around Point Hope is especially rich in archaeological resources. Many of the known sites are of Kukmiut and Iñupiat tradition and include villages, graves, whaling camps, and fishing/hunting camps (MMS 2007c).

Alaska Heritage Resource Survey (AHRS) records indicate that at least 18 historic and prehistoric sites have been documented within a two-mile radius of Wainwright. These include at least two historic Iñupiat village sites; several prehistoric camp sites; the possible remains of a settlement established by Roald Amundsen during his polar exploration efforts of 1925; partial remains of the 1871 whaling fleet, discussed above, scattered over 30 miles of shoreline; and Cold War era communication facilities.

Twenty-four resources are documented in the AHRS files within a two-mile radius of Nome. These include the remains of an historic Eskimo village and a historic fishing camp, but are largely dominated by historic structures related to the community of Nome; World War II facilities are also present.

3.3.5 Land and Water Ownership, Use and Management

The United States government is the sole owner of the Beaufort Sea and the Chukchi Sea Outer Continental Shelf lands, the energy (conventional and renewable) and mineral reasources are managed by the BOEM, but living and non-living resources are managed by other federal agencies, including NMFS and USFWS. However, the adjacent nearshore and onshore areas reflect multiple owners, including the federal government, state government, borough government, Alaska Native corporations and Alaska Native allottees (the Bureau of Indian Affairs holds in trust many of the lands owned by Alaska Native allottees). With the exception of the tidelands offshore of the ANWR (Shalowitz and Reed 2000), the State of Alaska owns all tidelands and submerged lands along the coast out to 3 nautical miles (nmi), which includes three miles out from barrier islands that are owned by the State of Alaska. Lands bordering the coast are within the NSB, and the NAB, and most lands within these boroughs are held by a few major landowners. The predominant landowner within the NSB is the federal government, which owns the ANWR, managed by the USFWS, and the National Petroleum Reserve—Alaska, managed by the Bureau of Land Management (BLM). Other major landholders include the State of Alaska, Alaska Native village corporations, and the Arctic Slope Regional Corporation. Along the coast within the NAB lies the Cape Krusenstern National Monument, managed by the National Park Service (NAB 2004). See Figure 3.3-28 for general ownership patterns on the North Slope of Alaska near the Beaufort and Chukchi seas.

3.3.5.1 Land and Water Ownership

<u>Federal Ownership</u>

Federal Waters

Beyond the 3-mile limit owned by the state, the United States has sovereign rights and control over the living and non-living natural resources of the seabed, subsoil and the waters above them out to 200 nautical miles from the point of average low tide (normal baseline) or to the international maritime boundary (Office of the Press Secretary 1983, NOAA n.d.).

Federal Lands

The federal government owns the land in the ANWR, containing about 30,135 square miles, the NPR-A, containing about 3,906 square miles, Alaska Maritime National Wildlife Refuge, containing about 7,656 square miles, and most of the Cape Krusenstern National Monument, containing about 1,016 square miles, all of which abut the coastline of the Beaufort or Chukchi seas.

<u>State Ownership</u>

State Waters

With the exceptions of federal lands described above and some privately owned tidelands, the state owns the surface and subsurface estate of all tide and submerged lands along the coastline, as well the bed of navigable waters within its boundaries. Tidelands include the land between mean (average) high and mean low tide. Submerged lands are seaward of mean low tide to three miles offshore. The state's claim of title for submerged lands is based on the "Equal Footing" Doctrine, the Submerged Lands Act of 1953, and the Alaska Statehood Act of 1958. The Submerged Lands Act of 1953 held such lands in trust for the state and title was transferred at statehood in 1959.

State Lands

The State owns the majority of the land located between ANWR and the NPR-A containing the Prudhoe Bay onshore oil fields, as well as various parcels near the coast of the Chukchi Sea from the western boundary of the NPR-A to just south of Point Hope.

State Selections

When Alaska gained statehood in 1959, the state was authorized to select about 104 million acres of federal land, to be chosen from lands that were unreserved and unappropriated for any purpose, claimed, or withdrawn. Although the Statehood Act provided for the State of Alaska to select lands, in some instances, certain selections have not been transferred and remain in federal ownership due to legal considerations, conflicting Native selections or similar reasons. In the project area, most of these State selected, but unconveyed, lands are located in the Point Hope area.

Native Ownership

Corporation Lands

In 1971, Congress passed the Alaska Native Claims Settlement Act (ANCSA). The act settled Alaska Native land claims with a grant of 44 million acres and payment of $1 billion. It also provided for village and regional corporations to manage that land and money. Part of the reason for this land grant was to help provide a long-term economic base for the corporations. Corporations were to select mainly from tracts the federal government withdrew near villages, but when there was not enough available land there, they could also choose from other unreserved federal land (UAA 2000). The EIS project area has several of these sections. There are large tracts around the communities of Kaktovik, Nuiqsut, Barrow, Wainwright, Point Lay and Point Hope, as well as scattered pieces along the North Slope.

In Alaska, ownership of land is often characterized by a "split estate" interest, in which rights to the surface estate are separate from the subsurface estate. Surface owners receive title and rights include the use of soil, timber, and lands beneath non-navigable waters. Subsurface owners receive title to rock, gravel, and sand as well as oil, gas, and minerals. Village corporations, established by the ANCSA, generally receive title to the surface estate for their land entitlement. The corresponding subsurface estate is typically conveyed to the ANCSA regional corporation.

ANCSA village corporation surface estate lands are generally selected and conveyed in the vicinity of their home communities. However, ANCSA Regional corporation subsurface estate may also be located in areas away from existing communities.

Corporation Selections

Although ANCSA provided for Native land selections, in some instances, certain selections have not been transferred and remain in federal ownership due to legal considerations, conflicting State selections, incomplete land surveys or similar reasons.

Native Allotments

In 1906, the Native Allotment Act was passed, whereby Natives could apply for up to 160 acres, if they could demonstrate use and occupancy of the land for a minimum of five years. The Native Allotment Act was repealed in 1971 with the passage of ANSCA; however, ANSCA allowed those applications pending before the U.S. Department of the Interior to continue through processing. The lands under application by a Native Allotment applicant are managed by the federal government, or in some instances a state agency pending the recovery by the federal government, until the lands are conveyed to the Native allotee. BLM issues upon conveyance a certificate of title to the Native allotee which lands are held in trust by the U.S. under the administration of the Bureau of Indian Affairs. In some instances, the BIA has authorized federally recognized tribal governments to act as their administrative representative for Native allottees. Several Native allotments occur along the Beaufort and Chukchi Sea coasts. There are a few that dot the border of the ANWR outside of Kaktovik and continue along the coast in the Prudhoe Bay area, and are scattered throughout the NPR-A. The allotments run along the coast between Cape Lisburne and Point Hope, and all through the Point Hope region.

Borough and Other Municipal Lands

Under the Alaska Statehood Act, municipal governments are entitled to select lands from the State of Alaska. In the project area, the NSB and the NAB have selected lands from the State. The NSB's municipal land entitlement is 89,850 acres. Lands conveyed to date are primarily in the vicinity of communities, and some parcels in the Prudhoe Bay/ Deadhorse and Cape Simpson areas. The ability to select and receive conveyance of the Borough's remaining entitlement has been delayed (URS 2005).

The NAB is also entitled to select lands from the State of Alaska, but completion of selection and receipt of its total conveyance has been also been delayed. Borough-owned lands along the Chukchi Sea coast are likely to be limited to village areas.

The incorporated villages within both Boroughs also retain title to municipal lands, generally located in the vicinity of the communities. Villages are entitled to select land from ANCSA village corporations under Section 14 (c) 3 of the act; however, many villages have not completed their selections.

3.3.5.2 Land and Water Use

Land use has many definitions and methods of classification. For this EIS, land use concerns the physical ways in which land is used and modified for different human purposes (UN 1993). The classifications below are based on the nationally standardized scheme by Anderson et al 1976, and the Michigan Resource Information System (MIRIS).

Recreation

This classification refers to the use of land in an outdoor setting for purposes of rest, sport or relaxation. In the context of this EIS, recreation activities are closely related to enjoyment of the natural environment (MIRIS). Recreation occurs at generally low levels of use in the EIS project area. Key recreational activities include wildlife viewing and flightseeing. Recreation is discussed in detail in Section 3.3.8.

Subsistence

Subsistence, which refers to harvest activities involving hunting, fishing, trapping, and gathering as a way of life, is a wide-spread land use throughout the EIS project area. Further details are discussed in Section 3.3.2.

Industrial

Industrial areas include a broad spectrum of facilities, from heavy manufacturing plants to a loading device or storage shed (Anderson et al 1976). Most major industrial uses in the EIS project area are related oil and gas activities and occur in Barrow, and Deadhorse/Prudhoe Bay. In these areas, industrial uses are supported by docks, airstrips, warehouses, roads, pipelines, and other essential infrastructure and facilities.

Residential

This classification refers to land uses that serve as a place of permanent residence (MIRIS). Residential land use occurs in small communities throughout the project area. The communities that would be most proximate to proposed offshore oil and gas exploration and seismic activities are adjacent to the Beaufort and Chukchi seas and include Kaktovik; Prudhoe Bay/Deadhorse; Nuiqsut; Barrow; Wainwright; Point Lay; Point Hope; Kivalina; Kotzebue; and Nome. Section 3.31 discusses population and classification of these communities.

Mining

Mining involves the use of land for mineral extraction purposes using both surface and subsurface methods. Red Dog Mine is the biggest source of mineral extraction in the EIS project area. Located east of the village of Kivalina, it is the second largest zinc mine in the world, and the fourth largest lead mine.

Red Dog Mine covers over 2,000 acres and also includes supporting land uses such as an airstrip, a road to the coast, a dock and dock facilities (Tetra Tech 2009).

Exploration activities are occurring in the Western Arctic coal deposits, between Point Lay and Point Hope, but no mine yet exists (Szumigala et al 2009).

Protected Natural Areas

This classification applies to lands that are set aside in their natural state for the purpose of ecological preservation. In the EIS project area, this includes ANWR, particularly the wilderness and 1002 areas discussed below, Alaska Maritime National Wildlife Refuge, and Kasegaluk Lagoon.

Transportation

Land used for transportation systems can be considered a supporting component of other uses, such as industrial facilities. However, since it can influence the land uses around it; it is considered as its own, separate classification (Anderson et al 1976). In the context of this EIS, Transportation land uses includes the Dalton Highway, industry road systems within the general Prudhoe Bay/Kuparuk filed area, aircraft and shipping infrastructure, and the road to Red Dog Mine.

Commercial

Commercial areas are those used predominantly for the sale of products and services (Anderson 1976). There is only a small amount of land devoted to commercial use in the EIS project area mostly centered within Prudhoe Bay and the communities within the project area.

3.3.5.3 Land and Water Management

Federal Lands Management

Arctic National Wildlife Refuge

The ANWR, managed by the USFWS, was established in 1960 as the Arctic Wildlife Range and expanded in 1980 to nearly 20 million acres and incorporated in the National Wildlife Refuge system pursuant to the Alaska National Interest Lands Conservation Act (ANILCA). The area contains three Wild rivers and the largest designation of Wilderness areas in the National Wildlife Refuge System (USFWS 2000b). The refuge has five management categories: Intensive, Moderate, Minimal, Wild River, and Wilderness. Due to controversy over management of the coastal plain, Section 1002 of the ANILCA established a 1.5 million acre Coastal Plain Resource Assessment Area to develop a baseline study to quantify the extent of oil & gas resources and to characterize important biological resources in that portion of ANWR. This area, referred to as the "1002 Area" is the northernmost section of the refuge adjacent to the Beaufort Sea. The United States Geological Survey estimates the total quantity of technically recoverable oil from the 1002 Area to be between 4.3 and 11.8 billion barrels (USGS 1998), however, at this time, oil extraction is not permitted. The 1002 Area is currently managed as a "Minimal management" area, which is directed at maintaining the existing condition of the areas that have high wildlife and fish values. Activities such as subsistence practices, outfitting, float planes and motor boats, and oil and gas studies are permitted under this management category (USFWS, 1998). Currently, the USFWS is updating the Comprehensive Conservation Plan for the ANWR, with a final revised plan expected to be released in 2013 (USFWS 2011a).

National Petroleum Reserve—Alaska

The NPR-A is 9.4 million acres in north-central Alaska managed by the BLM. The reserve was established in 1923 to provide oil for military purposes, and transferred to the Department of the Interior in 1977 to meet the economic needs of oil for the rest of the nation. The reserve is divided into three Planning Areas: the Northeast, Northwest, and the South. Both the Northeast and the Northwest

Planning Areas include large stretches of coastline off the Beaufort and Chukchi seas (BLM 2005). In the Northwest Planning Area, site-specific restrictions are implemented on all oil/gas related operations within the boundaries of the NPR-A to protect important natural resources such as water quality, vegetation, wetlands, fish/wildlife habitat cultural and paleontological resources subsistence uses and access, scenic and recreation values (BLM 2003). In the Northeast Planning Area, an Integrated Activity Plan outlined land allocations for immediate oil and gas leasing, adopted performance-based stipulations on operating procedures, and detailed required studies and monitoring (BLM 2008a).

Alaska Maritime National Wildlife Refuge

The Alaska Maritime National Wildlife Refuge is managed by the United State Fish and Wildlife Service and contains approximately 4.9 million acres of Alaska coastland and islands. The refuge was created by ANILCA in 1980, consolidating 11 preexisting refuges, adding 1.9 million acres of new land, and combining the majority of Alaska's seabird habitat within a single refuge. The refuge is divided into five distinct geographic units: the Chukchi Sea Unit, the Bering Sea Unit, the Aleutian Islands Unit, the Alaska Peninsula Unit, and the Gulf of Alaska Unit. The refuge encompasses approximately 3,000 headlands, islands, inlets, and pinnacle rocks, used by 80 percent of Alaska's seabird population, about 40 million nesting seabirds. The Chukchi Sea Unit is included in the project area and covers nearly 300,000 acres, 4 percent of the total refuge. It does not extend to the entire coastline, but is made up of non-contiguous areas of offshore public lands on islands, islets, rocks, reefs and spires. There are a few larger land groupings such as at Cape Thomson (USFWS 1988).

A Comprehensive Conservation Plan and Wilderness Review for the Alaska Maritime National Wildlife Refuge was adopted in 1988 that designated areas according to their resources and values, outlined programs for conserving fish and wildlife resource values, and specified uses compatible with the major purposes of the Refuge. The refuge has four management categories: Intensive Management, Moderate Management, Minimal Management, and Designated Wilderness. 99 percent of the Chukchi Sea Unit is managed with Minimal Management, which is directed at protecting existing fish and wildlife populations. Management activities focus on biological monitoring, eradication of introduced predators/rodents, and research and regulation. Oil and gas leasing is not permitted (UWFWS 1988).

Cape Krusenstern National Monument

Cape Krusenstern National Monument was designated pursuant to ANILCA and contains approximately 660,000 acres. The National Park Service manages the monument; the main policies are to protect archeological sites in the area and protect the habitat for wildlife and subsistence resources. The monument is a coastal plain stretching along 70 miles of the Chukchi Sea shoreline, and archeological sites dating back 5,000 years can be found in the beach ridges (NPS 2011).

State Lands Management

Area Plans

The State of Alaska prepares land management plans called Area Plans to govern the use of state lands. Area Plans describe intended uses of state lands. Specifically, the plan contains management guidelines and classifications for specific management units. The document identifies what land should be retained by the state and what land may be sold or granted to municipalities through the municipal entitlement process. Area plans can open and close areas to mineral entry and can recommend legislative designations (for example, parks). The Northwest Area Plan was completed in 1989, and contains 10,000,000 acres of land. It includes lands on the Seward Peninsula, in the NAB and in the western segment of the NSB. An Area Plan has not been prepared for the North Slope Region, which contains 12,252,000 acres of land.

Oil and Gas Lease Sales

The State leases lands and waters for resource development, including oil and gas, minerals, and timber. Annually, ADNR prepares and presents a 5-year program of proposed oil and gas lease sales to the legislature. Currently, Division of Oil and Gas conducts competitive annual areawide lease sales, offering for lease all available state acreage within five areas (North Slope, Beaufort Sea, Cook Inlet, North Slope Foothills, and Alaska Peninsula). The lease sale area is divided into tracts, and interested parties that qualify may bid on one or more tracts. Since the first lease sale in 1964, the State has held 56 onshore and offshore oil and gas lease sales on the North Slope involving Beaufort Sea and North Slope acreage (ADNR 2009).

Municipal Lands Management

Community and Borough Planning

Boroughs and cities vested with land use authority in the State of Alaska are required to prepare a comprehensive plan, which is intended as a long-range vision of possible future development. Generally the planning process involves community members, public officials, planning committees, and any relevant stakeholders. Comprehensive plans do not provide enforcement power. Instead, they are intended as a tool for policy makers to consult in making land development decisions (URS 2005). There are two boroughs that have jurisdictional boundaries along the Beaufort and Chukchi seas. The NSB spans 89,000 square miles across the top of Alaska from the Canadian border to Point Hope and from the Brooks Range to the Arctic Ocean. The NAB comprises approximately 39,000 square miles in the northwest of the state, on the coast of the Chukchi Sea and south of the NSB. Both boroughs have comprehensive plans discussed below and contain eight coastal communities of predominantly Iñupiat populations: Kaktovik, Nuiqsut, Barrow, Wainwright, Point Lay, Point Hope in the NSB and Kivalina, and Kotzebue in the NAB. With the exception of Kotzebue, these communities have no comprehensive plan in place, although the NSB is working with Kaktovik, Nuiqsut, Barrow, Wainwright, Point Lay, and Point Hope to develop village plans that are either in process or planned to begin in 2011.

North Slope Borough Comprehensive Plan and Title 19

In 2005 the NSB Assembly adopted a comprehensive plan to aid the long-range growth and development of the Borough. The vision and goals outlined in the plan helped guide the Borough Assembly when updating and writing ordinances for the region, particularly Title 19, which outlines land use regulations for the Borough and is considered part of the Comprehensive Plan (URS 2005).

Title 19 describes Borough management practices through nine different zoning districts, with four being the most relevant for offshore activities. Barrow Industrial and Storage districts are characterized by terminals, loading docks, storage sheds and airports and are intended to provide uses that support aviation, shipping and other transit. Resource Development Districts (RDDs) are intended to accommodate large-scale resource extraction and related activities, while balancing protection of subsistence resources. Existing RDDs include Badami, Duck Island, Prudhoe Bay, Mine Point, and Kuparuk River. RDDs are generally focused along the north coast of the Borough and the Beaufort Sea, centered on Prudhoe Bay. Transportation Corridor districts are established to accommodate linear transportation facilities such as pipelines and roads. The most significant corridor is the Dalton Highway and Trans-Alaska Pipeline System that runs from Prudhoe Bay to the NSB's southern border (NSB 1990). Communities are zoned as Village Districts, aimed at maintaining traditional values and lifestyle. With the exception of Barrow, there are no further zoning regulations within the Village Districts. Title 19 also outlines policies pertaining to villages, economic development, offshore development, coastal management (reflecting the enforceable policies of the 1988 Coastal Management Program), and transportation corridors. The policies are meant to guide development and uses within the North Slope Borough while protecting the subsistence resources and cultural resources (NSB 1990).

Northwest Arctic Borough Comprehensive Plan and Title 9

The NAB Assembly approved a comprehensive plan in 1993 that addresses land use controls and planning and zoning issues in the borough. At the time of the plan, permits were the primary means of land control. Permits allowed the borough to control land and water use, materials, timber, minerals, certain activities, and lease sales. The comprehensive plan has strategies for the NAB to use in determining land selections under ANCSA, and deciding on land use controls for the development and adoption of zoning ordinances. It details land management strategies, involving zoning, platting, and methods of village planning.

The plan divides the borough into six zoning districts. Subsistence Conservation Districts, General Conservation Districts, and Commercial Recreation Conservation Districts would make up most of the borough land and be oriented towards conservation of habitat, renewable resources and subsistence protection. In addition, the Subsistence Conservation Districts would prohibit development that would negatively affect subsistence resources, the General Conservation Districts would accommodate resource development on a limited scale and encompass undeveloped areas outside the boundaries of other districts, and the Commercial Recreation Conservation Districts would accommodate commercial recreation as long as it is consistent with the conservation of wildlife habitat and other resources, and effects on subsistence could be mitigated. Village Districts would be the boundaries of villages in the borough and reinforce lifestyles and values. Resource Development Districts would accommodate major resource development, most notably Red Dog Mine. The Transportation Corridor District would allow control over location and development of transportation corridors, such as roads, railroads, and pipelines, and supporting transportation facilities (NAB 1993).. Title 9 of the Borough code contains the Zoning Ordinance.

<u>Federal Waters Management</u>

Federal jurisdiction of the coastal waters extends from the three-mile limit, which is under state jurisdiction, to 200 nmi from the point of average low tide. The first 12 nmi from the coast are managed as territorial seas, within which the United States holds complete sovereignty yet ships or aircraft of any country can have the right of transit and innocent passage (64 FR 173 1988). 24 nmi from the coast are managed as the contiguous zone, where the United States has the right to exercise control to prevent or punish infringement of its customs, fiscal, immigration, or sanitary laws (64 FR 173 1999). 200 nmi from the normal baseline is the Exclusive Economic Zone, within which the United States has sovereignty over the mineral deposits and living resources (Office of the Press Secretary 1983).

In the wake of the Deepwater Horizon event in the Gulf of Mexico in April 2010, the President issued an Executive Order (EO) in July 2010 adopting the Final Recommendations of the Interagency Ocean Policy Task Force for management of federal waters off the coasts of the U.S. and the Great Lakes. The EO established a national policy to ensure protection, maintenance and restoration of the health of coastal and ocean ecosystems (Office of the Press Secretary 2010). The policies outlined in the EO seek to ensure that the oceans, coasts and the Great Lakes are healthy and resilient, as well as safe and productive (CEQ 2010b).

In general, the management practices used by BOEM, Alaska OCS Region, rely on federal laws and regulations to govern the waters in federal jurisdiction. These acts and executive orders designate appropriate uses for the waters, while at the same time ensuring the protection of the human, marine, and coastal environments. The OCS Lands Act gives the U.S. Department of the Interior responsibility to manage the offshore energy (conventional and renewable) and minerals resources, which includes the leasing, exploration, development, and production of those resources on the federal OCS. Other acts that heavily influence management of the federal waters are the National Environmental Policy Act, the Marine Mammal Protection Act, the Magnuson-Stevens Fishery Conservation and Management Act, the Endangered Species Act, the Clean Air Act, the Clean Water Act the Oil Pollution Act, and the Coastal Zone Management Act.

State Waters Management

Waters owned by the State of Alaska were subject to the Alaska Coastal Management Program (ACMP) until 2011. The ACMP included statewide standards and coastal district enforceable policies that balance development and the protection of natural resources within the coastal zone. Oil and gas leases within the 3-mile limit are sold by the Alaska Department of Natural Resources, Division of Oil and Gas and were in that category (ADNR 2011, ADNR 2005). As a result of the ACMP expiration, oil and gas lease sales are not expected to adhere to a coastal management program.

3.3.6 Coastal Zone Management

The State of Alaska operated the federally-approved ACMP from 1979 to 2011 as a voluntary state partner in the National Coastal Management Program. In 2011, the state legislature failed to pass legislation required to extend the ACMP. By operation of Alaska State law (Alaska Statutes 44.66.020 and 44.66.030), this meant that the Alaska Coastal Management Program officially expired on July 1, 2011, resulting in a withdrawal from participation in the National Coastal Management Program. Consequently, the CZMA federal consistency provision, Section 307, no longer applies in Alaska and Alaska is no longer eligible for CZMA grants under Sections 306, 306A, 308, 309 or 310. Because a federally approved coastal management program must be administered by a state agency, reinstatement of the program would require approval by the state legislature. As of February 1, 2013, information about the expired ACMP is available on the ADNR website (http://www.alaskacoast.state.ak.us/).

3.3.7 Transportation

3.3.7.1 Air Transportation Systems

Kaktovik

Air travel provides the only system for year round access to Kaktovik. The airport at Kaktovik is on Barter Island, which is owned by the U.S. Air Force and operated by the NSB. The length of the runway is 1,469 m (4,820 ft). It is serviced daily by ERA Alaska (formerly Frontier Flying Service) (ADCCED 2011b). Chartered aircraft also use this airport.

Nuiqsut

Air travel provides the only transportation system for year round access to Nuiqsut. The 1,324 m (4,343 ft) long by 27 m (90 ft) wide gravel airstrip is owned and operated by the NSB. This airport is serviced by ERA Alaska (ADCCED 2011b). The airport is equipped with a rotating beacon, approach lights, high-intensity runway lights, and visual-approach slope-indicator systems; though the runway is unattended and unmonitored (BLM 2003). Daily flights carry passengers, cargo, and mail, and commercial flights connect Nuiqsut to Barrow and Deadhorse. Chartered and private aircraft also use the airport on a regular basis.

Prudhoe Bay/Deadhorse

There are three major airstrips in the Prudhoe Bay/Kuparuk area--the state-owned and operated Deadhorse airport and the privately owned and operated Prudhoe Bay and Kuparuk airstrips. The airport at Deadhorse services the oil and gas facilities on the North Slope in the Prudhoe Bay area. The airport located at Deadhorse is the primary means of public transportation to the North Slope industrial areas. The state-owned asphalt and gravel airstrip at Deadhorse is 1,981 m (6,500 ft) long by 46 m (150 ft) wide, and a state-owned heliport is located at Prudhoe Bay. The Deadhorse airport is served daily by a variety of aircraft and can accommodate Boeing 737 sized jet aircraft. The airport has a small passenger terminal, hangars, storage warehouses, and equipment for freight handling. It accommodates mostly oil company and support company personnel passengers (BLM 2003). Commercial cargo service is also provided into Deadhorse and to satellite oil field airstrips. Alaska Airlines, ERA Alaska, and private charters service this airport. There are no services beyond Deadhorse (ADCCED 2011b).

Barrow

The state-owned Wiley Post-Will Rogers Memorial Airport serves as the regional transportation center for the NSB. This airport has a 2,164 m (7,100 ft) long by 46 m (150 ft) wide asphalt runway. Jet service is regularly provided on a daily basis. This airport is serviced by commercial air carriers including: Alaska Airlines and ERA Alaska (ADCCED 2011b). Freight arrives by air cargo year-round. This airport is the transportation hub for villages on the North Slope. Alaska Airlines provides regularly scheduled jet passenger flights into Barrow from Anchorage and Fairbanks and other air carriers offer shuttle service from Barrow to various North Slope communities. The Barrow airstrip is accessible year round with use constraints involving severe weather, an occasionally obstructed runway, and migratory waterfowl that may be in the area during spring and fall. Airport facilities include two large hangars, storage warehouses, and equipment for freight handling. Barrow airport has the ability to provide medical evacuation service to larger communities in Alaska and, as a result, could be used as a medevac location for offshore exploration activities for emergencies.

Wainwright

Wainwright's only year-round access is by air travel. The 1,370 m (4,494 ft) long by 27 m (90 ft) wide gravel airstrip is owned and operated by the NSB and is the primary airstrip. A 914 m (3,000 ft) long by 30.5 m (100 ft) wide gravel airstrip exists at the old Wainwright Air Station. This airport is serviced daily by commercial and chartered service by ERA Alaska (ADCCED 2011b). Freight arrives by cargo plane. Wainwright’s airport could be used as a base for offshore exploration activities in the Chukchi Sea given its proximity to active lease exploration programs. It is equipped with a rotating beacon, approach lights, high-intensity runway lights, and visual-approach systems.

Point Lay

A public 1,372 m (4,500 ft) long by 30.5 m (100 ft) wide gravel airstrip, owned by the U.S. Air Force is Point Lay's only year-round access. ERA Alaska provides daily commercial airline service to this community (ADCCED 2011b). Freight arrives by air cargo year-round. Federal government chartered aircraft also use this airport on a limited basis.

Point Hope

The state-owned 1,219 m (4,000 ft) long by 23 m (75 ft) wide paved airstrip provides Point Hope's only year-round access. Bering Air, ERA Alaska (daily), Grant Aviation (by charter), and Tanana Air Service (by charter) provide service to this community (ADCCED 2011b). Freight arrives by air cargo year-round. Federal government chartered aircraft also use this airport on a limited basis.

Kivalina

The primary means of transportation into this community is by plane which lands on the state-owned 914 m (3,000 ft) long by 18 m (60 ft) wide gravel airstrip. Daily flights are available from Kotzebue (ADCCED 2011b). Bering Air, ERA Alaska (daily), Grant Aviation (by charter), and Tanana Air Service (by charter) fly to this community (ADCCED 2011b).

Kotzebue

Air transportation is the primary means of year-round transportation. The state-owned Ralph Wien Memorial Airport supports daily jet service to Anchorage and several air taxis to the region's villages. This community has a 1,798 m (5,900 ft) long by 46 m (150 ft) wide main paved runway and 1,181 m (3,876 ft) long by 27 m (90 ft) wide crosswind gravel runway. A seaplane base is also operated by the state in Kotzebue. This airport is serviced daily and throughout the week by the following carriers:

Alaska Airlines; Baker Aviation; Bering Air; ERA Alaska; Grant Aviation (by charter); and Tanana Air Service (by charter) (ADCCED 2011b).

<u>Other Aircraft Traffic</u>

USCG aircraft presence in the Arctic region has expanded in recent years. The USCG "Arctic Domain Awareness Flights" in the Beaufort and Chukchi seas region use HC-130 Hercules aircraft to support operations and exploration and promote an understanding of the region. These types of flights provide the USCG with opportunities to test their personnel and equipment capabilities, survey sea ice, and monitor vessel traffic. The NSB's Search and Rescue Department provides aircraft (helicopter and jet) and trained personnel for airborne response, medevac, search and rescue, and support to the NSB communities.

Scientific surveys are conducted by aircraft along the coastlines of the Beaufort and Chukchi seas predominately during a portion of the open water season. For instance, BWASP aerial surveys have been conducted by fixed wing aircraft in the region annually since 1979. The Chukchi Sea Planning Area (CSPA) was surveyed often during the open water seasons between 1979 and 1991 by contractors under contract to BOEM. The COMIDA surveys began in 2008 for the CSPA; this program is now *"part of the Aerial Surveys of Arctic Marine Mammals project, which is funded by BOEMRE and coordinated through NMML"* (NMFS 2010c). Oil and gas industry support aircraft (usually helicopters) are more frequent in the summer months in areas of active exploration and production. Small private aircraft and charters are also associated with recreational hunting activities along both coastlines and inland.

3.3.7.2 Marine Transportation Systems

<u>Community Vessel Traffic</u>

Marine transportation in the region is dominated by freight deliveries but also includes relatively small inboard and outboard-engine watercraft used by villagers and less frequently by scientific research vessels. Marine transportation provides an economical means of transporting heavy machinery and other cargo with a low value-to-weight ratio (BLM 2003). Marine shipments along the Beaufort and Chukchi coasts are limited to a seasonal window between late July and early September, when the Arctic coast is ice free.

During the open water period, local skiffs are used for hunting and for transportation between villages and camps. Barge resupply operations for the coastal communities occur during the months of July, August, and September when the Arctic pack ice traditionally recedes and a navigable lead forms along the Alaskan coast. Tugs with barges are the main vessel types used to resupply the communities along the coastline during the ice free months with dry goods, fuel, raw building materials, and other commodities that cannot be flown in on aircraft. Tug and barge operations generally consist of a tug towing several barges. There is no major maritime industrial infrastructure or port in the Beaufort or Chukchi seas that supports transporting goods between major ports. There are small port facilities on the North Slope ranging from shallow-draft docks with causeway/road connections to Prudhoe Bay to beach-landing areas in the local communities. As there is no deep water port, cargo ships and oceangoing barges are typically offloaded to shallow-draft or medium-draft ships for lightering to shore.

<u>Industrial traffic</u>

Tugs and barges are used as sealift operations for transporting large building units, drill rigs, and modules used in the oil and gas development on the North Slope and travel occurs mainly along the nearshore waters of the coast during the open water season. Sealifts have decreased over the last several years (two to three per year or less) as onshore production has declined in the oil fields, and less exploration and development has occurred onshore (MMS 2008). Oil spill response vessels are used in the marine areas near Prudhoe Bay and existing oil and gas infrastructure during the open water season to practice effective response strategies.

Along the Beaufort Sea coast at Prudhoe Bay, there are three dockheads for unloading barges, one at East Dock and two at West Dock. A 335 m (1,100 ft) long causeway connects East Dock to a no-longer-used 30.5-by-82 m (100- by-270-ft) long wharf constructed from grounded barges (BLM 2003). West Dock, a 3,993 m (13,100 ft) long by 12 m (40 ft) wide, solid-fill, and gravel causeway runs along the northwestern shore of Prudhoe Bay east of Point McIntyre. There are two unloading facilities off the gravel causeway at West Dock. One facility is 1,372 m (4,500 ft) from shore and has a draft of 1.2 to 1.8 m (4 to 6 ft). The second facility is about 2,438 m (8,000 ft) from shore and has a draft of 2.4 to 3 m (8 to 10 ft). On the Chukchi Sea, the DeLong Mountain Terminal south of Kivalina is the only port facility that can accommodate large vessel traffic, and it is used to ship processed ore from Red Dog Mine.

The closest developed port facilities to the Beaufort and Chukchi seas are located at Nome and include docks that industrial vessels use for fueling and supplies. The City Dock on the causeway is equipped with marine headers to handle the community's bulk cargo and fuel deliveries. The City Dock is approximately 61 m (200 ft) in length with a depth of 7 m (22.5 ft). The West Gold Dock is 58 m (190 ft) in length with a depth of 7 m (22.5 ft). The West Gold Dock handles nearly all of the exported rock/gravel for the Nome region and is the primary location to load/unload heavy equipment. There is also a small boat harbor at Nome which offers protected mooring for recreational and fishing vessels alongside two floating docks. Smaller cargo vessels and landing crafts load village freight and fuel at the east, west and south inner harbor sheet pile docks, east beach landing, and west barge ramp for delivery in the region (City of Nome 2011b). The Port of Nome is used routinely by USCG Cutters Alex Haley and Munro and the USCG bouy tenders Sycamore and Hickory during logistical support operations and shore leave (Michels 2012). Design concepts for the Port of Nome – specifically to accommodate an increased USCG presence in the Arctic – include lengthening the current causeway to accommodate larger vessels such a polar class and fast response cutters (Michels 2012). As noted by the Port of Nome, vessel traffic has increased from 94 dockings in 1990 to 296 port calls in 2011 (Michels 2012).

Potential offshore development in the Beaufort and Chukchi seas would increase the numbers of support and supply ships transiting the region. The service vessels to support offshore oil and gas exploration activities can be categorized as supply, crew, and utility vessels (seismic and icebreaking). Each of these types of vessels produces noise, discharges, and air emissions (MMS 2008). Exploratory drilling programs would be expected to use several support vessels, including spill response vessels and vessels for ice management. In 2012, Shell Oil Co. launched a 360-foot tug supply vessel the M/V Aiviq which is an anchor-handling icebreaker. This vessel is classified as a Polar Class 3 ship that according to international shipping standards will allow it to operate year round in second year ice (Beilinson 2012).

Large Vessel Traffic

The Bering Strait, with a width of 50 nautical miles between Alaska and Russia, is considered the entrance to the Arctic Ocean. It is also considered a choke point for marine traffic in and out of the Arctic Ocean from the Pacific. With lessening of sea ice and increased open water periods, the Northern Sea Route along the northern coast of Siberia and the Northwest Passage along the northern coast of North America have become more viable maritime options for commercial transportation. Vessel traffic through the Bering Strait is in a rapid state of growth, which is likely to continue as the period of open water continues to lengthen. Shipping routes are (and likely in the future) only used for certain months of the year due to seasonal transition periods where the risks of such use increase due to ice conditions. The Northern Sea Route has become an opportunity for Russia (and China) to bring services and commodities transported on large vessels escorted by icebreakers (including petroleum products via ice strengthened super tankers) to the Asian markets (Whitney 2012). The estimated volume of cargo shipped through the Northern Sea Route is expected to reach a record high in 2012 (Bennett 2012). In 2011 there were 34 ships that shipped 820,000 tons of cargo along the Northern Sea Route (Bennett 2012) compared to 46 ship transits in 2012 (Pettersen 2012). Vessel traffic through the Bering Strait is in a rapid state of growth, which is likely to continue as the period of open water continues to lengthen. There is a need for a vessel traffic service through the Bering Strait and aids to navigation and safety infrastructure (Strader

2012). Growth in all sectors of Arctic marine traffic is expected to occur, including bulk natural resource shipments, scientific exploration, fishing, military activities, and tourism (Arctic Council 2004 and 2009, Brigham and Ellis 2004, U.S. Arctic Commission 2010, US Navy Arctic Roadmap 2009). Transits through the Bering Straits have steadily increased in the past four years (2008 – 2012). In 2011 there were approximately 410 Bering Strait transits; in 2010 approximately 420; in 2009 approximately 280 and in 2008 approximately 220 (Whitney 2012). Vessel traffic of tank vessels, cargo and tugs have increased the most in the 2008 to 2011 timeframe (Whitney 2012). The larger vessels transiting the Bering Strait on the Russian side with smaller tugs and barges which bring supplies to coastal Alaskan communities transiting along the U.S. side of the Strait (DeMarban 2012).

Shipping in the Arctic, including the Beaufort and Chukchi seas, is focused on the transport of regional community goods, and the shipment of natural resources out of the Arctic to world markets (Arctic Council 2009). For instance, Red Dog Mine is one of the world's largest producers of zinc and lead and must carefully plan bulk ore shipments to occur before the fall ice forms. Approximately 25 large commercial ships (bulk carriers) annually sail north through the Bering Strait region (in the ice-free season) to the DeLong Mountain Terminal. Large bulk carriers, *Panamax* and *Handymax* which range in size up to 65,000 tons, visit Red Dog Mine in Alaska during this open water season (Arctic Council 2009).

The USCG is responsible for maritime safety, security, and stewardship, and its mission applies to U.S. Arctic waters as well. Search and rescue missions by the USCG mainly occur in the Gulf of Alaska and the Bering Sea. However, with increased open water in the Arctic and increased vessel traffic, the USCG has expanded its missions in the Beaufort and Chukchi seas and sent assets into the region in several ways (USGC 2009). In recent years during the open water months, summer operations called Arctic Crossroads have been conducted in an effort to integrate local knowledge of the region with military expertise to meet the challenges of Arctic operations. This operation involves USCG, U.S. Air Force, Army National Guard, Air National Guard, and U.S. Public Health Services personnel. This program aims to build Arctic domain awareness, involves cutter operations (including icebreaking, buoy tenders and cutters), deployments to villages, community engagement, and search and rescue exercises. The USCG cutter *Hamilton* entered Arctic waters for the first time in 2009 to conduct search and rescue drills. Use of cutters in the Arctic is considered a challenge as the hulls of these vessels are not ice reinforced. The USCG has indicated that the current infrastructure and small boats and short range helicopters are not effective for long distance search and rescue operations in the Arctic and limit response capabilities for emergencies and response to potential oil spills.

In response to the growing need for the USCG to be able to fulfill mandated missions in the Arctic in 2012 the USCG conducted Arctic Shield 2012 in Alaska. The purpose of conducting this USCG action was to provide a consistent and reliable USCG presence in the Arctic during the summer operational window as a result of the substantial increase in maritime activity in the Arctic during the summer of 2012 (USCG 2012a). The intent of Arctic Shield 2012 was to provide the USCG with Arctic domain awareness and opportunities to respond to any maritime safety, maritime security, or maritime stewardship mission demands. In addition the program provided the USCG with operational experience in the Arctic, including operation of their assets, deployment of personnel, and conducting exercises, especially the deployment of several types of oil spill response equipment from USCG vessels (USCG 2012a).The only USCG icebreaker currently available to operate in the Arctic is the *Healy*. The USCG icebreaker *Polar Sea* is scheduled to be decommissioned in 2011, and the USCG *Polar Star* icebreaker is currently in the process of being reactivated for service but is not expected to be commissioned again until 2013 (Colvin 2011, USCG 2010). Polar region ice breaking activities by the USCG are performed as part of scientific and national security activities, including joint scientific, search and rescue exercises. The USCG seasonally has small boat operations off Point Barrow and Prudhoe BayThe University of Alaska, Fairbanks expects to have a new vessel – the *R/V Sikuliaq* - a research vessel that is ice strengthened and able to work in moderate seasonal ice in the Arctic region available by 2013 to 2014 (UAF 2011, 2012).

A key finding of the Arctic Climate Impacts Assessment was that reductions in seas ice will likely lead to increase in marine transportation and access to resources and development (Ellis 2007, Arctic Council 2009, U.S. Arctic Commission 2010). In 2004, the bulk transport of commodities, including oil gas and minerals such as ore, were a large portion of the total of Arctic vessel traffic (Arctic Council 2009). The types of vessels now entering the Bering Strait have changed and now includes tugs, Arctic research vessels, oil and gas related vessels, cruise ships, government vessels, adventurers (12 in 2009 and 17 in 2010), and government vessels (Colvin 2011). As the open water season increases, as predicted by climate change, it is likely that ships related to a spectrum of uses could eventually be found in the EIS project area, including fishing, hard minerals/mining, science and exploration, tourism, and offshore oil and gas development (Colvin 2011).

The USCG has initiated a Port Access Routing Study to increase safety of vessel traffic that transit the Bering Straits (Colvin 2011). Eventually vessel fairways (also called safe vessel routes) could be established and listed on nautical charts with International Maritime Organization approval. The need for this action was spurred in part by the sharp increase of vessels entering the Bering Strait from 2008 to 2010. Navigation aids are currently limited in the Beaufort and Chukchi seas, as is the ability of the USGS to respond to maritime emergencies. Needs for enhancing Arctic marine safety, protecting Arctic people and their environment, and building marine infrastructure, were identified as important issues in 2009 (Brigham and Sfraga 2009).

Hydrographic surveys have provided the available charting information for limited areas along the northern coast of Alaska (Arctic Council 2009). The expansion of charting knowledge for the currently used routes in the Arctic was identified as important for development of alternative courses when ice conditions are hazardous, for entry to points of refuge for vessels and to support the expected expansion of access to natural resources (Arctic Council 2009). The Arctic Regional Hydrographic Commission was established in 2010 with representatives from the U.S, Canada, Denmark, Norway and Russia to develop nautical charts that will improve the safety of mariners transiting the Arctic (NOAA 2010). NOAA's Office of Coastal Survey and the U.S. Naval Oceanographic Office charting efforts are intended to provide additional hydrographic survey data that would be used to support safe navigation in the Arctic. As a foundation for building safe infrastructure for marine transportation throughout the Arctic, the Office of Coastal Survey has developed a nautical charting plan that sets forth the layout of additional nautical chart coverage and describes the requisite activities needed to build and maintain nautical charts

(NOAA 2011e). In 2012 the NOAA ship Fairweather conducted a mission to collect information that will determine NOAA's future efforts for charting survey projects in the Arctic. The goal is to collect depth measurements that will allow NOAA cartographers to eventually guide charting decisions and update nautical charts and future new hydrographic surveys (NOAA 2012d).

Cruise ships and ecotourism vessels are a new presence in U.S. Arctic waters. In 2009, two passenger vessels cruised through the Northwest Passage, stopping in the communities of Nome, Point Hope, and Barrow. The majority of cruise ships and adventurer ships recently present in Arctic waters are not purpose-built for Arctic operations and are built for voyaging in open water in lower latitudes and warmer climates and are not ice reinforced (Colvin 2011). Arctic marine tourism poses a risk, as there is no infrastructure in local communities to respond to emergencies. At present commercial fishing vessels in the Bering Sea/Aleutian Island fleets do not enter the Chukchi Sea due to fishing moratoriums in this area. However, changing fishing grounds could bring commercial vessels and fleets northward from the Bering Sea into the Arctic Ocean. In that event, changes to current fishery management plans would be required under the Magnuson-Stevens Fishery Conservation and Management Act.

3.3.7.3 Increased Aircraft and Vessel Traffic Concerns

The increase in the length of the open water season and increase in offshore oil and gas exploration is leading to an increase in aircraft and vessel traffic along the coastlines. This is viewed as a disruption to marine species by indigenous people and first nations whose culture and way of life are based on subsistence harvests. With regard to presence of increased air traffic, hunters have noticed:

- *We have a lot of air traffic, not just from the oil companies but from tourist stuff going on. Hunters traveling along the coast, too, so we were having to deal with that on top of the helicopters and stuff doing their routes to Point Thompson already. They're flying in the same migration -- or the times as the migration of the caribou and stuff, and I'd just really hate to see more of it happen because I think it's going to -- the cumulative impact is going to have a great negative impact on our community.* – Carla Sims Kayotuk at Kaktovik Scoping Meeting, March 12, 2010
- *They're [airplanes and oil planes] flying all over now around here, and it's impacting us. And more of the things that's happening now, it's impacting us. And we're a subsistence hunters. And I don't want to see more of that. It's our garden.* – Marie Rexford, Kaktovik Scoping Meeting, March 12, 2010
- *These are our only times during the summer [on calm days] that we have access to hunting caribou that go down to the coast. If activity, support activity, such as aircraft or helicopters or other support activities are near the coast -- and we have many people that can make oral statements that during the summer when they're getting close to caribou, either a small plane or helicopter show up and drive the caribou further inland.* – Fenton Rexford, Native Village of Kaktovik, March 12, 2010

Subsistence hunters have also expressed concern about the impacts of vessel traffic and increased ship presence on the animals and on their hunting practices. Oil spills from marine vessels are one of the largest concerns, as are air emissions impacts as well. The accidental release of oil or toxic chemicals can be considered one of the most serious threats to Arctic ecosystems as a result of shipping and increased large vessel marine transportation. The Arctic Council (2009) noted "*potential conflicts between increased ship traffic and indigenous marine resource use in the Bering Strait region include but are not limited to an increased amount of:*

- *Ambient and underwater ship noise;*
- *Ship strikes on large marine mammals;*
- *Potential for collision between coastal and offshore large ship traffic and small open boats using marine resources; and*
- *Pollution affecting the availability and quality of offshore, coastal and beachcast marine resources, due in part, but not limited to lack of navigational and rescue infrastructure in an extremely challenging physical and marine environment; concern for infrastructure to secure a large vessel in distress; concern for infrastructure to assess and respond to an oil and/or chemical spill."*

Concerns regarding the increase in vessel traffic and the relationship between vessel traffic and marine subsistence harvests have been expressed by scientists and residents of the Beaufort and Chukchi communities:

- *What we're expressing now is that on exploration (indiscernible) the barges do interfere and every year we have barges from Outside, coming from Canada going to Prudhoe or Barrow or even from another way around, coming from down through Barrow and get to Prudhoe. What we are facing is that it's pretty hard for us to hunt whales nowadays because all the whales that* *we've been trying to catch are all spooked and pretty hard to catch and never had any whales last year because of early migration or the whales were not in their migration route. That's the barge activities, that absolute reason.* - Eli Napageak, Nuiqsut Government to Government Meeting, March 11, 2010.

- *We had spotted that whale inside the barrier island and went between it. I don't know where -- the boats come from Prudhoe heading to Badami. And then we see that barge – that whale right in between the barges and the whaling. We never see that whale again and what -- which it was disrupted there.* - Eli Napageak, Nuiqsut Government to Government Meeting, March 11, 2010.
- *I was going east to my crew, almost -- there was just hundreds of whales just constantly passing by and the last one I saw that was in front of me, it was a calf and then the mother came up, put her arm around the calf and then they went down. And then that barge came by about five minutes later, five, ten minutes later, and then there was no whales for like 15 miles to my whaling crew. And so barge activity does divert a lot of whales, our whales we were hunting in the Beaufort Sea and Camden Bay.* – Thomas Napageak, Mayor of Nuiqsut and Whaling Captain, Nuiqsut Government to Government Meeting, March 11, 2010.
- *What concerns me here from the AEWC and from different whaling association – shipping is a concern, fishing industry is another and encroachment moving north into our hunting areas. These are the other two potential threats that are out there.* - Harry Brower at Open Water Meeting 2011, Anchorage, AK.
- *We've been able to tag quite a few belugas in Point Lay over the years and we've learned they use a huge amount of the ocean. We need to keep this in mind as we think about what is happening in the Chukchi Sea with vessels, drill ships and seismic in June and July. If there is a bunch of activity out there before Point Lay hunts, there is a potential to disrupt the movement of the belugas.* - Robert Suydam - 2011 ABWC Subsistence Harvest Updates at Open Water Meeting 2011, Anchorage, AK.
- *I'm [Caleb Pungowiyi] also concerned about the cumulative impacts that other activities will have on our subsistence resources. Not only the exploration activities, but other activities associated with that activity. Support vessels, aircraft, vessels going back and forth to restock and provide support to the activity. We also see some potential increased vessel traffic if the area opens up for international commercial ship traffic for shipping between the European countries and the Asian countries through the Arctic Ocean, especially through the northern route or through the northwest passage.* – Caleb Pungowiyi, Kotzebue Scoping Meeting, February, 18, 2010.
- *The impact we are seeing is on our spring hunt. The transporters are ramming the ice and you could see when the belugas were coming. Every time the marine lines are trying to push the ice out of the way, the belugas head back east. We are feeling it. When we are trying to harvest, they are trying to get to Red Dog early. We try to stop it and we get a call from Shishmaref saying they are being disturbed.* - George (unable to hear), Manilliq, Kotzebue at Open Water Meeting 2011, Anchorage, AK.

Aquatic Invasive Species

With respect to transportation, the introduction of invasive and non-native species into the marine environment could occur through the discharge of ballast waters (National Research Council 1996) or through hull fouling (see Section 3.2.1 for a full discussion of current information on aquatic invasive species).

3.3.8 Recreation and Tourism

Recreation and tourism occur at generally low levels of use in the EIS project area. The affected environment for recreation and tourism will be described by setting and activities. It is important to distinguish between recreation and subsistence uses. The vast majority of fishing, hunting, and boating that occurs in the project area are *subsistence*-based, managed completely apart from recreation-based activities, with separate rights and privileges (see Section 3.3.2, Subsistence for further discussion). This section discusses only recreation-based activities, a small portion of the total of human uses in the area.

3.3.8.1 Setting

The EIS project area is a vast Arctic region, with a great deal of opportunities for recreation. The undeveloped setting is conducive to recreation activities such as wildlife viewing and photography, sailing, float boating, hiking/backpacking, camping, fishing, hunting, and winter sports (BLM 2008b). The remoteness of the area, even by Alaska standards, and the vast areas of undeveloped landscape can offer recreationists experiences unlike anywhere else. Possible areas for recreation include the Beaufort and Chukchi seas, Arctic National Wildlife Refuge, the NPR-A, Alaska Maritime National Wildlife Refuge (AMNWR), Cape Krusenstern National Monument, lands managed by the State of Alaska, and communities along the North Slope. However, the area has few facilities to support recreation and tourism and is difficult and costly to access. Most of the North Slope areas are underused for recreation and have the potential to support much more in the future (BLM 2008b).

The EIS project area is described via three recreation settings: offshore, onshore, and coastal communities. The offshore setting is away from the coast of the Beaufort and Chukchi seas. There are presently no facilities located in the offshore setting; marine vessels and aircraft transit the area, but the setting is largely undeveloped and offers abundant opportunities for solitude. The nearshore environment (within three miles of land) contains facilities related to oil and gas development and production in the Beaufort Sea, as well as docks and other industrial support facilities (NSB 2005). While facilities have been located for many years in the vicinity of Prudhoe Bay and Barrow, there are also facilities dispersed across the nearshore environment between Kaktovik and Prudhoe Bay, and in the vicinity of Nuiqsut and the Colville River. A few facilities (not directly related to oil and gas activities) also exist in the nearshore environment of the Chukchi Sea, with larger facilities generally located in the larger communities such as Kotzebue (The City of Kotzebue 2000). While facilities exist in the nearshore environment setting, there are many opportunities for recreation in an undeveloped setting.

The landscape in the vicinity of the coastal communities is typically vast reaches of tundra, with ponds, small drainages, or the rivers running out into the seas. Recreation activities in the project area often are based from the coastal communities that have facilities and services to support recreation or tourism activities, such as flight services and accommodations. Several of the communities have limited facilities to accommodate tourism activities or a more developed range of recreation activities. A small private lodge exists in Kaktovik, which also offers flight services, wildlife viewing, and other services (Waldo Arms Hotel 2006); Barrow and Kotzebue are larger hub communities in the region, and each hosts hotels and several firms that offer wildlife viewing and sightseeing activities (City of Barrow 2011, The City of Kotzebue 2000). Recreation activities in the coastal communities may occur in a rural setting, within sight and sound of structures and human activities. The communities may also serve as a gateway to backcountry recreation opportunities, which would occur in undeveloped settings. BOEM (2012) indicated that recreation and tourism are not major sources of employment in the NSB and NWAB with total employment of 619 in these sectors in 2008.

3.3.8.2 Activities

Low levels of recreation activities are estimated to occur in the project area. As mentioned above, the vast majority of hunting, fishing, and boating in the area are subsistence-based and rarely considered as recreation or pleasure. While estimated to occur at very low levels, local and non-local residents engage in recreation activities in the project area, including the offshore environment, nearshore environment, as well as in the vicinity of the coastal communities evaluated in this document.

No agency currently tracks dispersed recreation in the offshore environment. The USCG has noted the increased presence of small cruise ships and recreational/expedition sailboats venturing through the offshore area en route through the Northwest Passage in recent years (Loomis and Murphy 2012). The State of Alaska and the NSB manage activities in the nearshore environment, but there is little recreation use data compiled for this area. Federal agencies, including the BLM and the USFWS, as well as the State of Alaska and the NSB manage activities on lands in the vicinity of the project area.

Offshore

Offshore recreation activities in the project area generally require the use of large boats, including sail boats, cruise ships, and other large motorized vessels. Wildlife viewing by boat is also a featured recreation activity in the area. There are a number of whale watching tours and wildlife viewing/photographing boats available for charter along the Beaufort and Chukchi seas, primarily out of Barrow, Kaktovik, and Kotzebue. A limited number of flight services also offer wildlife viewing opportunities (Alaska PhotoGraphics 2011, Arctic Air Guides 2009, Kaktovik Arctic Tours 2010).

Residents in the NSB and NWAB also have observed an increase in yachts or personal pleasure boats traversing the project area. Opportunities exist for expeditions to the North Pole that would traverse through the EIS project area. It is expected that as transportation increases in the Northwest Passage that the presence of recreational vessels and yachting expeditions transiting though the offshore will also increase.

Nearshore

In the nearshore environment, many recreation activities are supported by small, personal watercraft, both motorized and non-motorized. This type of recreation is usually residents of the coastal communities, because access is difficult and costly, particularly for transporting watercraft. Beachcombing, wildlife viewing, and photography are also common activities in the nearshore environment. Guided trips or flight seeing, based from the coastal communities, typically serve non-local residents (NSB 2005).

Coastal Communities

The communities along the coast are hundreds of miles apart with vast stretches of federal and state lands in between. Access to the undeveloped areas is difficult and costly and occurs primarily in the summer months as winter conditions are a limiting factor. Some winter recreation may occur but would be infrequent due to harsh and hostile conditions. As a result, much of the recreation occurs around the coastal communities in the summer and early fall, where some infrastructure exists, such as airports, hotels, and guide services. Package tours, wilderness adventures and sport hunting and fishing are the three main types of recreational tourism that occur in the NSB (NSB 2007). Several options for commercial flightseeing are available out of Kaktovik, Barrow, and Kotzebue as packaged tours. In the NSB, Barrow is the community that has the most developed tourism sector with access by air (BOEM 2012). Charter boats are available in towns for wildlife viewing and photography. Hikers and rafters coming out of the Arctic National Wildlife Refuge may end in Kaktovik using chartered aircraft of access and pick up and drop off (BOEM 2012). Hiking and backpacking opportunities out of Kaktovik, Barrow, and Kotzebue exist, although there are no specific facilities or services in the backcountry to support these activities, and no designated trails. Three rivers are used by rafters for wildlife viewing within the Arctic National Wildlife Refuge including the Hulahula, Kongakut, and the Sheejek rivers with float times lasting 10-12 days (NSB 2007). Within the NPR-A recreational guided boating on rivers occurs mainly on the Colville, Etivuk, Nigu and Utukok rivers (BLM 2011). The aurora borealis also draws visitors, and these tours are often paired with wildlife viewing or other guided activities (Alaska PhotoGraphics 2011, Arctic Air Guides 2009, Kaktovik Arctic Tours 2010).

Guided and unguided sport hunting, fishing, and hiking occur in the vicinity of coastal communities, as well as on state and federal lands. The Alaska Department of Fish and Game permits sport hunting, trapping, and fishing on the North Slope in Game Management Units 26 and 23, with certain restrictions (ADFG 2010b). Independent sport hunters and fishers tend to charter aircraft to areas along the Brooks Range and coastal communities but can also access the area via the Dalton Highway (BOEM 2012). Caribou, moose, brown bear, and Dall sheep are the main species hunted by sport hunters. There is a hunting lodge operated in Umiat, located on the Colville River (NSB 2007). Sport fishing is largely an incidental activity conducted opportunistically during game hunts (BLM 2011).

Wildlife is a big draw to the North Slope for tourists; interest in polar bear viewing has increased as the species gets more media attention from the threat of climate change and the recent listing of the species as threatened under the ESA. Several guided tours are available for polar bear viewing from Kaktovik, Prudhoe Bay, and Barrow (Alaska PhotoGraphics 2011).

Organized tours of the Prudhoe Bay are available as packages with travel from air or bus from Fairbanks along the Dalton Highway. These types of tours involve tours of the oil fields, wildlife viewing and visiting the Arctic Ocean. Independent tourists are not able to drive past Deadhorse due to security inside the oilfields.

Kotzebue is the hub of recreation and tourism activities in the NWAB. Attractions to the area surrounding Kotzebue include organized tours related to Alaska Native life and cultural experiences, city tours and tundra walks, drop offs to the nearby national parks, wildlife viewing, hunting and fishing, backcountry trips and ecotourism (NWAB 2006). Independent and structured adventure tourism occurs mainly in the summer months and departs from Kotzebue to areas including the Noatak National Preserve, Gates of the Arctic National Park and to the Noatak and Kobuk Rivers (NWAB 2006). Outfitters and guides provide recreational opportunities from Kotzebue for sport fisherman and hunters seeking more remote caribou and moose hunts in Northwest Alaska (NWAB 2006).

3.3.9 Visual Resources

3.3.9.1 Analysis Area

The analysis area for visual resources includes onshore and offshore areas. Onshore areas included native communities located along the shoreline between Kotzebue, on the western shore of the Arctic Coastal Plain (ACP), across the north edge of the ACP to the U.S.-Canadian border. This portion of the analysis area was established to assess views of the EIS project area from these locations. Offshore areas include the Beaufort Sea, located north of the ACP, between Point Barrow and the U.S.-Canadian border, and the Chukchi Sea, located between Point Barrow and Kotzebue. Both the Beaufort and Chukchi seas are located in the Arctic Ocean. The geographic extent of the offshore portion of the analysis area was defined by the boundary of the EIS project area (Figure 1.1).

3.3.9.2 Methods

Visual resources of the project area were assessed from onshore and offshore locations, and from the air, using methods adopted from the BLM visual resource inventory methodology (BLM 1986). The goal of the assessment was to establish a scenic quality rating for the EIS project area.

Scenic quality is defined as "a measure of the visual appeal of a tract of land." The highest scenic quality ratings are assigned to landscapes that have the most variety and most harmonious composition in relation to the natural landscape. For the purpose of this assessment, the analysis area was subdivided into four scenic quality rating units (SQRUs) based on changes in physiography, land use, or offshore development. The geographic extent of each SQRU is described as follows:

- *West Beaufort Sea*: On- and offshore portions of the analysis area extending from Point Barrow, east to the border between ANWR and the North Slope Foothills Areawide Oil and Gas Lease Sale Area.
- *East Beaufort Sea*: On- and offshore portions of the analysis area extending from the border between ANWR and the North Slope Foothills Areawide Oil and Gas Lease Sale Area, to the Alaska-Canada border.
- *North Chukchi Sea*: On- and offshore portions of the analysis area extending from Point Barrow, west to the border between the National Petroleum Reserve and the Alaska Maritime National Wildlife Refuge (Chukchi Unit).
- *Southern Chukchi Sea*: On- and offshore portions of the analysis area extending from the border between the National Petroleum Reserve and the Alaska Maritime National Wildlife Refuge (Chukchi Unit), west to Point Hope, and south to Kotzebue.

The visual quality of landforms/water, vegetation, and structure within each SQRU was assessed in terms of texture, color, form, and line. Visual quality within each SQRU was then ranked using seven factors, including: landform; vegetation; water; color; adjacent scenery; scarcity; and cultural modification. Factors were ranked based on an understanding of the visual landscape of the area, and by reviewing photographs of the project area. A final score was then calculated for each SQRU by totally scores for each key factor. Based on these results, each SQRU was assigned a scenic quality rating of A, B, or C.

Visual quality is typically assessed within the framework of three prevailing distance zone: Foreground / Middleground (3 to 5 miles); Background (5 to 15 miles); and Seldom Seen (beyond 15 miles). For the purpose of this analysis, no distance zones were established. The rationale for this decision is twofold: 1) it is assumed that offshore viewers see the analysis area from various locations, and therefore no fixed point can be established; and 2) views of the analysis area from onland locations are generally unobstructed, and therefore could extend to a distance of 15 miles. For both on- and offshore viewers, it is assumed that landscape components are most easily discerned within the foreground / middleground distance zones. During winter months visibility may be limited to areas within one mile, depending on the level of light present in an area.

In addition to quantifying scenic quality, additional qualitative indicators were assessed, including seasonality and motion. Seasonality will influence the visibility within the project area due to lighting and atmospheric conditions. Motion was evaluated to provide a baseline of activity level within the analysis area.

3.3.9.3 Regulatory Framework

The project area includes inland areas administered by the NPS, the USFWS, the State of Alaska, the NSB and the NAB. Land use and planning documents for all federal and state agencies do not contain management provisions for offshore visual resources. Borough requirements under its Title 19 Land Management Regulations provide guidance to reduce potential effects to visual resources. The guidance is similar to mitigation measures that have been required in local and federal permits for nearshore and offshore development, and that have been included in Records of Decision for NEPA compliance documents.

3.3.9.4 Viewer Sensitivity

Viewer sensitivity was assessed for three predominant viewer groups: Native communities; recreators (including Arctic marine tourists); and industrial workers. Viewer groups and their anticipated exposure to the proposed project area are described below.

- *Native Communities*: Native communities include Kaktovik, Nuiqsut, Barrow, Wainwright, Point Lay, Point Hope, Kivalina, and Kotzebue. These communities are situated on or near the coastline and contain views of the offshore portion of the analysis area. Individuals from these communities may also engage in offshore subsistence activities, where they may experience views of the project area.
- *Recreators*: Recreational viewers include land-based user groups located in the Cape Krusenstern National Monument, the Alaska Maritime National Wildlife Refuge and ANWR. Recreators situated near shorelines in these locations experience views of the offshore portion of the project area. Other recreation groups include those accessing the area by boat. Recreators may also experience views of the project area from the air when traveling to/from recreation destinations.
- *Arctic Tourists*: Arctic tourists include individuals traveling through the project area by ship. These individuals may experience views of the project area from the offshore perspective.
- *Industrial Workers*: Industrial workers are primarily situated in Oil and Gas lease areas located on the north shore of the ACP.

Visual sensitivity was determined using criteria provided by the BLM Sensitivity Level Analysis procedure. Sensitivity level rating units (SLRU) coincided with SQRU, and included: 1) the west Beaufort Sea; 2) the east Beaufort Sea; 3) the northeast Chukchi Sea; and 4) the southern Chukchi Sea.

For each SLRU, visual sensitivity was established by evaluating the following factors:

- *Type of Users*: Visual sensitivity is expected to vary with the type of user. For example, recreational sightseers may be highly sensitive to any changes in visual quality, whereas industrial workers who pass through the area on a regular basis may not be as sensitive to change.
- *Amount of Use*: Areas seen and used by large numbers of people are potentially more sensitive. Protection of visual values usually becomes more important as the number of viewers increase.
- *Public Interest*: The visual quality of an area may be of concern to local, state, or national groups. Indicators of this concern are usually expressed in public meetings, letters, newspaper or magazine articles, newsletters, land-use plans, etc. Public controversy created in response to proposed activities that would change the landscape character should also be considered.
- *Adjacent Land Uses*: The interrelationship with land uses in adjacent lands can affect the visual sensitivity of an area. For example, an area within the viewshed of a residential area may be very sensitive, whereas an area surrounded by commercially developed lands may not be visually sensitive.
- *Special Areas*: Management objectives for special areas such as Natural Areas, Wilderness Areas or Wilderness Study Areas, Wild and Scenic Rivers, Scenic Areas, Scenic Roads or Trails, and Areas of Critical Environmental Concern frequently require special consideration for the protection of the visual values. This does not necessarily mean that these areas are scenic, but rather that one of the management objectives may be to preserve the natural landscape setting. The management objectives for these areas may be used as a basis for assigning sensitivity levels.

Native communities, including individuals engaged in subsistence, recreators, and air travelers, were assigned a high visual sensitivity. Industrial workers were assigned a low visual sensitivity. The sensitivity level analysis and determination of visual sensitivity is presented in Table 3.3-48.

Table 3.3-48 Sensitivity Level Analysis for Viewer Groups Located Within the Visual Resources Analysis Area

SLRU[1]	Viewer Location	Public Interest	Adjacent Land Use	Special Areas[3]	Type of User	Amount of Use	Other Factors	Overall Visual Sensitivity
West Beaufort Sea	Onshore	Moderate	ANWR[2]	N/A	Native community of Nuiqsut (HIGH)	Prolonged; small population (LOW)	Traditional use area (HIGH)	HIGH
					Industrial workers (Oil & Gas) centered on Prudoe Bay and Deadhorse (LOW)	Variable and at specific locations (LOW)	Located in and adjacent to well established industrial nodes	LOW
	Offshore	High	N/A	N/A	Individuals engaged in subsistence (HIGH)	Year-round; low numbers (LOW)	Well-established sense of place (HIGH)	HIGH
					Industrial workers (LOW)	Seasonal – low numbers (LOW)	N/A	LOW
					Arctic tourists expecting to see oil & gas activity (LOW)	Seasonal – low numbers (LOW)	N/A	LOW
East Beaufort Sea	Onshore	High	N/A	ANWR[2] (HIGH)	Native Community of Kaktovik (HIGH)	Prolonged; small population (LOW)	Traditional use area (HIGH)	
					Recreators located in the ANWR[2] (HIGH)	Seasonal – low numbers (LOW)	N/A	HIGH
	Offshore	High	N/A	N/A	Individuals engaged in subsistence (HIGH)	Year-round; low numbers (LOW)	Well-established sense of place (HIGH)	HIGH
					Industrial workers (LOW)	Seasonal – low numbers (LOW)	N/A	LOW
					Arctic tourists expecting more pristine views associated with ANWR[2] (HIGH)	Seasonal – low numbers (LOW)	N/A	HIGH
Northeast Chukchi Sea	Onshore	Moderate	AMNWR[4]	N/A	Native Communities of Barrow and Wainwright (HIGH)	Prolonged; small populations (LOW)	Traditional use area (HIGH)	HIGH
					Industrial workers (Oil & Gas) (LOW)	Variable and at specific locations (LOW)	Located in and adjacent to well established industrial nodes	LOW

SLRU[1]	Viewer Location	Public Interest	Adjacent Land Use	Special Areas[3]	Type of User	Amount of Use	Other Factors	Overall Visual Sensitivity
	Offshore	High	N/A	N/A	Individuals engaged in subsistence (HIGH)	Year-round; low numbers (LOW)	Well-established sense of place (HIGH)	HIGH
					Industrial workers (LOW)	Seasonal – low numbers (LOW)	N/A	LOW
					Arctic tourists (HIGH)	Seasonal – low numbers (LOW)	N/A	HIGH
South Chukchi Sea	Onshore	High	Noatak National Preserve; Cape Krusenstern National Monument (HIGH)	HIGH	Native communities of Point Lay, Kivalina, and Kotzebue (HIGH)	Prolonged; small population (LOW)	Traditional use area (HIGH)	HIGH
					Recreators located in the AMNWR[4] (HIGH)	Seasonal – low numbers (LOW)	N/A (HIGH)	HIGH
	Offshore	High	Cape Krusenstern National Monument (HIGH)	N/A	Individuals engaged in subsistence (HIGH)	Year-round; low numbers (LOW)	Well-established sense of place (HIGH)	HIGH
					Arctic tourists (HIGH)	Seasonal – low numbers (LOW)	N/A	HIGH
ALL SLRUs	Onshore / Offshore	High	HIGH	N/A	Air travelers (industrial workers, tourists, researchers / scientists)	Variable; dependent on work rotations and seasonal access	Short viewer duration; variable angle of observation.	HIGH

Notes:

[1] SLRU = Sensitivity Level Rating Unit, [2] ANWR = Arctic National Wildlife Refuge, [3] N/A – Not Applicable, [4] Alaska Maritime National Wildlife Refuge
Cape Krusenstern National Monument: http://www.nps.gov/cakr/parkmgmt/lawsandpolicies.htm

3.3.9.5 Regional Landscape

The EIS project area is located offshore, to the north and west of ACP and Arctic Foothills physiographic province (Arctic Research Consortium 2011). Physiographic features represent geographic areas that are classified largely based on homogenous topography within a province. Each province is distinct, and differences across adjacent features are readily apparent (Wahrhaftig 1965).

The ACP physiographic province is bounded on the north and the west by the Arctic Ocean and stretches eastward nearly to the international boundary between Alaska and the Yukon Territory, Canada. When viewed from offshore locations, the area is characterized by expansive, flat topography that extends approximately 200 miles south to the Brooks Range. Numerous thaw lakes dot the province, creating a contiguous network of water bodies that extend across the plain between Wainwright and Prudhoe Bay. The predominant vegetation cover is low growing, and the area is devoid of trees and shrubs. Oil and gas development is concentrated in the center of the ACP and appear as isolated developments connected by a network of pipelines and roads. The Dalton Highway, the primary terrestrial route connecting the region to the southern part of the state, extends in a north-south trajectory from Prudhoe Bay. The ANWR occupies the eastern edge of the ACP.

The Arctic Foothills physiographic province consists of a wide swath of rolling hills and plateaus that grades from the coastal plain on the north to the Brooks Range on the south. The east-west extent of the ecoregion stretches from the international boundary between Alaska and the Yukon Territory, Canada, to the Chukchi Sea. The hills and valleys of the region have better defined drainage patterns than those found in the coastal plain to the north and have fewer lakes. The province is underlain by thick permafrost and many ice-related surface features are present. The province is predominantly treeless and is vegetated primarily by mesic graminoid herbaceous communities. The western edge of the Arctic Foothills physiographic province is occupied by the Alaska Maritime National Wildlife Refuge, and Cape Krusenstern National Monument.

3.3.9.6 Seasonality

A high degree of seasonality exists within the EIS project area. Winter conditions persist for much of the year, with extensive snowpack between the months of October to June. Nearshore conditions are marked by extensive ice pack (described below). Summers are marked by inland thaws that expose extensive wetlands, rivers, and low-growing vegetation. Periods of darkness and light vary across the year, bracketed by extremes of 24-hour daylight and the mid-winter "day" devoid of direct sunlight. Between extreme periods of light and darkness are long periods characterized by low-angle sunlight and prolonged periods of darkness. Visibility in winter and spring may be obscured by "Arctic haze" that results from the transport of industrial pollutants from Europe and Asia, which can limit visibility during winter and spring months.

3.3.9.7 Activity and Viewpoints

Activities within the EIS project area are supported by air, marine vessel, or snowmobile travel. The modes of travel in the project area provide common means of viewing the project area. (For more detailed information on transportation, refer to Section 3.3.7.)

Onshore and offshore portions of the EIS project area are frequently viewed via regularly scheduled air travel on commuter airlines. Occasional unscheduled air travel (fixed wing and helicopter) may provide viewpoints in support of recreation, tourism, scientific research, or oil and gas activity (MMS 2008).

Two forms of vessel traffic provide viewpoints of the offshore environment during the Arctic Ocean open-water season: smaller vessels, or skiffs, used for hunting and between-village transportation, and larger barges that deliver goods to local communities. Tug and barge traffic associated with the onshore oil development provide viewpoints mainly in nearshore waters along the coast. Offshore, nearshore, and coastal areas may be viewed from marine vessels.

Industrial workers and residents use snowmachines for local travel, with views of onshore and nearshore areas. Snowmachine traffic commonly runs along many of the same routes each year, often following the coastline, major rivers, or industrial support trails (MMS 2008).

3.3.9.8 Characteristic Landscape Description

The analysis area is described as a broad panoramic that extends to the edge of the horizon. Views from and toward the analysis area are largely unobstructed, with the exception of isolated oil and gas facilities, including structures and, in onshore locations, associated roads and pipelines. Views from within the project area toward land, though still largely panoramic, include the backdrop of the Brooks Range.

Landscape character elements, including landform/water, vegetation, and cultural modification are described below.

Landform/Water

Visual resources within the EIS project area across all units are dominated by characteristics of the Beaufort and Chukchi seas. The visual characters of these waterbodies undergo dramatic changes across seasons, due in large part to the dynamic seasonal cycle of sea ice. Despite the season, views from on-shore portions of the analysis area (i.e. Native communities, recreation areas) and from within the analysis area (i.e. Arctic tourists, individuals engaged in subsistence activities) are marked by the bold horizontal line of the horizon. Views of both seas may be seen from beaches, such as along the East and West Beaufort analysis units, or from seaside cliffs, such as those characterizing the more rugged coastlines of the North and South Chukchi analysis units.

During the fall, winter, and spring seasons, both the Beaufort and Chukchi seas are covered by sea ice. The southern portion of the Chukchi Sea is typically ice-free for one to two months longer than the Beaufort Sea; however a large amount of inter-annual variability in the formation and breakup patterns of sea ice exists in both waterbodies. Sea ice occurs in three distinct forms, landfast ice, stamukhi ice, and pack ice each of which imparts a different appearance (Figures 3.3-8 and 3.3-9). All ice forms appear predominantly white, although variation in color and texture occurs across ice forms, and may change seasonally as ice thins. Ice formation, deformation, and melt processes create variability in appearance, and overall surface roughness (MMS 2008). For further discussion of sea ice forms, refer to Section 3.1.2.

In late spring, leads – or areas of open water between large pieces of ice – form within the pack-ice zone and particularly around the seaward landfast ice edge (MMS 2008) (Figure 3.3-10). Leads may expose large areas of open water along the shoreline, creating contrast in color and texture between sea ice, land, and sea. A distinct pattern of leads occurs in the western and west-central Beaufort Sea exists creating large arc-shaped areas of open water that emanate from Point Barrow and Harrison Bay. These leads separate a region of largely immobile ice in the southeastern Beaufort Sea from the more mobile pack ice in the west. The Chukchi Sea also exhibits large leads along the northern coast. In May through June, open water can extend up to 4 km at the northern end, and up to 100 km at the southern end. Patterns created from leads are most visible from the air, where large areas can be seen (MMS 2008).

After the first openings and ice movement from late May to early June, the areas of open water with few iceflows expand along the coast and away from the shore, and there is a seaward migration of the pack ice (Figures 3.3-11 and 3.3-12). Although the concentration of ice flows generally increases seaward, the movement of the ice is variable, and can change across years. Summer months expose panoramic views of the waters of the Beaufort and Chukchi seas that extend, largely uninterrupted, to the Arctic Sea.

Vegetation

Vegetation within the analysis area is limited to low-growing herbaceous forbs and shrubs, exposed only during the snow-free summer months (Figure 3.3-13). As vegetation is not present in the offshore portion of the analysis area, the contribution of on-land vegetation serves only as a back drop of views from within the analysis area toward land. When viewed from the sea, on-land vegetation imparts a green, golden, and brown color to the tundra. Because of the short stature of vegetation in the area, predominant lines created by vegetation follow that created by the predominant topography of the area.

Structures

Structures within the analysis area exist primarily in onshore locations, however offshore development does exist. Structures occur as oil and gas developments (including industrial nodes and associated pipelines, roads, and landing strips), and Native communities. In general, structures related to oil and gas development that are visible from on land and near shore locations are largely confined to the West Beaufort Sea analysis unit. Structures related to oil and gas exploration and possible development in the North Chukchi Sea would potentially be located over 113 km (70 mi) offshore and would not be visible from land locations. The appearance of Native communities across all analysis units is similar, with each characterized by a dense collection of one or two-story residential and commercial structures, limited roads, and a single airstrip. Night time lighting is present in Native communities and areas of industrial development.

Oil and Gas -- Large scale oil and gas exploration is a major component of the landscape character of the West Beaufort Sea analysis unit. Oil and gas-related development has occurred in this area since the 1940s, with major onshore development in Prudhoe Bay and offshore exploration in the Beaufort Sea underway by the 1970s. Development and production in the near shore Beaufort Sea began in the early 1980s. Industrial development is primarily situated on the Beaufort Sea. The primary onshore and near-shore (within three miles) activity extends from the Town of Barrow, east to the Badami Unit, and includes discrete industrial facilities connected by a network of roads and pipelines. Oil and gas related development is the most defining landscape characteristic separating the West Beaufort Sea analysis unit from other analysis units. This unit is characterized by ongoing oil and gas activity. Views of the project area from native communities and industrial nodes along the shoreline of this unit would experience views of existing on- and offshore oil and gas activity. Viewers situated along the shoreline of the adjacent East Beaufort analysis unit may also experience views of on- and offshore oil and gas development. Developments may be long-term, such as facilities present in Deadhorse and Prudhoe Bay (Figure 3.3-14), whereas exploration structures will be temporary, such as the Mars Ice Island (Figures 3.3-15 and 3.3-16). Developments appear as compact areas of dense development with distinct vertical lines that contrast color, texture, and reflexivity to varying extents with the surrounding landscape. When viewed from the project area, the low-lying, horizontal lines of roads and pipelines blend with predominant horizontal lines of the landscape; however, when viewed from the air, the broad network of linear roads and pipelines are apparent.

In contrast, because much of the oil and gas activity occurs over 113 km (70 mi) offshore in the Chukchi Sea, these areas are not seen by viewer groups located on-land, and are rarely observed by non-industrial marine travelers.

Native Communities -- Native communities vary in size but typically have many of the same types of infrastructure. These structures and facilities include an airstrip, a landfill, and a variety of buildings and dwellings. When viewed from within the project area, communities are generally small in scale compared to the surrounding landscape.

3.3.9.9 Scenic Quality Rating

Scenic quality of seven key factors listed below was ranked for summer and winter conditions in each SQRU. Ranking was based on a scale of 0 to 5; however cultural modification also included options for ranking with negative values extending to -4. Mid-range values (i.e. 2 or 4) were permissible if that ranking most accurately portrayed existing conditions. An explanation for rating criteria is provided below (BLM 1986).

- *Landform*: A ranking of 5 is given to areas with high vertical relief as expressed in prominent cliffs, spires, or massive rock outcrops, or severe surface variation or highly eroded formations. A rating of 3 is generally assigned to steep canyons, mesas, buttes, cinder cones, and drumlins; or interesting erosional patterns or variety in size and shape of landforms; or detail features which are interesting though not dominant or exceptional. A rating of 1 is typically assigned to rolling hills, foothills, or flat valley bottoms; or few or no interesting landscape features.
- *Vegetation*: A ranking of 5 is given to areas where a variety of vegetative types are expressed in interesting forms, textures, and patterns. A ranking of 3 is given to areas where some variety of vegetation exists; however only one or two major types are present. Finally, a ranking of 1 is assigned to areas with little or no variety or contrast in vegetation.
- *Water*: A ranking of 5 is given to areas where water is clear and clean appearing, still, or cascading white water, any of which are a dominant factor in the landscape. A ranking of 3 is given to areas where water is flowing, or still, but not dominant in the landscape. Finally, a ranking of 0 is given to areas where water is absent, or present, but not noticeable.
- *Color*: A ranking of 5 is given to areas where rich color combinations, variety or vivid color exist; or where pleasing contrasts in the soil, rock, vegetation, water or snow fields is expressed. A ranking of 3 is given to areas where some intensity or variety in colors and contrast of the soil, rock and vegetation is present, but not a dominant scenic element. A ranking of 1 is given to areas with subtle color variations, contrast, or interest and/or generally mute tones.
- *Adjacent Scenery*: A ranking of 5 is given to areas where adjacent scenery greatly enhances visual quality. A ranking of 3 is given to areas where adjacent scenery moderately enhances visual quality. A ranking of 0 is given to areas where adjacent scenery has little or no influence on overall visual quality.
- *Scarcity*: A rating of 5+ is given to areas that are considered one of a kind; or unusually memorable, or very rare within region. A rating of 3 is given to areas that are distinctive, though somewhat similar to others within the region. A rating of 1 is given to areas that are interesting within its setting, but fairly common within the region.
- *Cultural Modification*: A ranking of 2 is assigned to areas where modifications add favorably to visual variety while promoting visual harmony. A ranking of 0 is given to areas where modifications add little or no visual variety to the area, and introduce no discordant elements. A ranking of -4 is given to areas where modifications add variety but are very discordant and promote strong disharmony.

The ranking of each key factor was added to derive an overall score for the unit. Based on these results, each SQRU was assigned a scenic quality rating of A, B, or C using the following convention:

Score of 19+ = Class A
Score of 12 to 18 = Class B
Score of 11 or less = Class C

Class A Scenery is thus characterized by higher scenic quality then areas classified as Class C.

All units were ranked as having Class A scenery during summer months and Class B scenic quality during the winter months. Results of the scenic quality analysis are presented below (Table 3.3-49).

Table 3.3-49 Scenic Quality Rating Summary

Key Factor	Scenic Quality Sore (Summer / Winter)				Comments
	East Beaufort Sea Unit	West Beaufort Sea Unit	North Chukchi Sea Unit	South Chukchi Sea Unit	
Landform	3 / 3	3 / 3	4 / 4	4 / 4	Views from the project area are expansive and dramatic. Landforms serve as a backdrop to the project area. Cliffs located along the shoreline of the North and South Chukchi Sea analysis units contribute visual variety in F/M distance zones through abrupt vertical relief.
Vegetation	4 /1	4 /1	4 /1	4 /1	Vegetation viewed from the project area, and serves as a backdrop. Vegetation not visible in winter. During snow-free months, vegetation contributes color and texture to landforms.
Water / Ice	5 / 5	5 / 5	5 / 5	5 / 5	Water is dynamic, striking, and dominant throughout the year.
Color	4 / 1	4 / 1	4 / 1	4/ 1	Great contrast in color exists during summer months.
Adjacent Scenery	3 / 0	3 / 0	3 / 0	3 / 0	The Brooks Range moderately enhances the visual quality of views from the project area.
Scarcity	5 / 5	5 / 5	5 / 5	5 / 5	Waters of the Beaufort and Chukchi seas are distinctive.
Cultural Modification	0 /0	-4 / -3	0 /0	0 / 0	Cultural modification most apparent in the West Beaufort Sea Unit, particularly during summer months when activity increases.
Total Score	24 / 15	20 / 12	25 / 16	25 / 16	
Scenic Quality Class	A / B	A / B	A / B	A / B	

Notes:
Class A = score of 19+
Class B = score of 12-18
Class C =- Score of 11 or less

3.3.10 Environmental Justice

EO 12898 requires federal agencies to identify and address disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on low-income populations and minority communities (1994). Agencies identify early-on when actions may have disproportional adverse environmental or health effects on minority and/or low-income communities in order to screen feasible alternatives (EPA 1998). One of the tools to identify disproportionate effects is "scoping," a public involvement process designed to identify potential areas of concern *before* the analysis of the proposed project proceeds. A detailed description of the scoping process for this project, including government-to-government consultation with Tribes, is included in the Scoping Summary Report (Appendix C).

"Minority community" and "low-income" are defined for the purposes of analyzing the effects of the agencies' actions on potentially affected populations.

- A minority is any individual self-identified as American Indian, Alaska Native, Asian or Pacific Islander, African American, or Hispanic.
- A low-income population is a community or group with a median household income at or below the U.S. Department of Health and Human Services poverty guidelines. Poverty guidelines are an administrative tool that determines financial eligibility for certain programs and are comparable to the poverty thresholds calculated by the U.S. Census Bureau for statistical purposes.
- Disproportionate high and adverse human health or environmental effects are defined when the health effects of an action are significant or above generally accepted norms (e.g. infirmity, illness or death); the risk or rate of hazard exposure is significant and exceeds the rate to the general population; or the population is exposed to cumulative or multiple adverse exposures to environmental hazards.
- Low-income populations and minority communities are defined as any readily identifiable group of minority or low-income persons who live in geographic proximity and their population percentage is meaningfully greater than the low-income/minority population percentage in an appropriate geographic unit of analysis (CEQ 1997).

Impacts to Alaska Native populations may be different from impacts on the general population due to a community's distinct cultural practices (CEQ 1997). EO 12898 recognizes the importance of research, data collection, and analysis, particularly with respect to multiple and cumulative exposures to environmental hazards and/or a disproportionately high adverse impact resulting from a federal action. Environmental justice analysis considers impacts to subsistence resources and harvest practices, sociocultural systems, and public health. Current and historic subsistence practices are described in Section 3.3.2, and Sociocultural systems are addressed in Section 3.3.1. Public Health discussions and analysis can be found in Section 3.3.3. Impacts to these resources are discussed in Chapter 4.

3.3.10.1 Definition of the Affected Populations

The area of potential affect includes the coastal communities (including critical staging areas) of the Beaufort and Chukchi seas within the NSB, NAB, and the City of Nome.

3.3.10.2 Ethnicity and Race

Each of the affected communities has a majority Iñupiat or Alaska Native population as shown in Table 3.3-50. The communities of Kaktovik, Nuiqsut, Barrow, Wainwright, Point Lay, Point Hope, Kivalina, Kotzebue, and Nome would be considered a minority community under the definition of EO 12898. Nome residents identified as 49 percent Alaska Native in the U.S. Census, but with the addition of other racial groups, a total of 68 percent of the city's population identifies as non-White. Additional demographic information and a narrative profile about each community can be found in Section 3.3.1, Socioeconomics.

3.3.10.3 Income Distribution and Poverty Status

The U.S. Census defines "income" as cash payments received on a regular basis, not including noncash benefits such as food stamps, health benefits, or subsidized housing (US Census 2011b). The U.S. Census 2006-2010 "American Community Survey" 5-Year Estimates, data found in Tables 3.3-51 and 3.3-52, are the best available estimates for household income and individual and family poverty. Estimates for affected communities from the U.S. Census 2006-2010 "American Community Survey" had extremely large margin of errors and were not used due to the data's low accuracy.

The State Department of Labor and Workforce Development (ADLWD) tracks average per capita personal income for Alaska by region (ADLWD 2010). Statewide it was $44,395 in 2008 compared to $40,673 nationwide. The highest average per capital personal income was NSB ($66,664), while Nome Census Area ($33,254) and NAB ($31,168) were less than the state average.

Per capita income data are available for 2003 in some NSB Communities from the *North Slope Borough Economic Profile and Census Report*, but are not available at the community level elsewhere. In descending order: Nuiqsut $59,907; Kaktovik $59,342; Point Hope $53,835; Point Lay $33,656; Wainwright $28,320; and data was not available for Barrow (Shepro et al. 2003). Based on data available from the 2010 Census, per capita income (based on 2011 dollars) for the NAB was $21,751 and $20,325 for the Nome Census Area (U.S. Census Bureau 2013).

The NSB fares better than the state, nation, and other affected regions in the measure of median household income (shown in Table 3.3-51). However, Alaska's higher cost of living pushes the poverty threshold about 125 percent times the U.S. level (DHHS 2011). The poverty threshold for a family of four in Alaska is an annual household income of $27,570 or less (DHHS 2009). Note that definitions of families and households are not the same although they are both included in Table 3.3-51. All three regions have higher rates of households below the poverty threshold than the state and national averages. Looking more closely at ethnic groups below the poverty level, Alaska Native people are disproportionately below the poverty threshold (Table 3.3-52). For example, the City of Kotzebue is 70 percent Alaska Native, so it would be proportionate to have 70 percent of the individuals below the poverty line to be Alaska Native. However, 85 percent of individuals living in poverty in Kotzebue are Alaska Native.

Considering the data displayed by per capita income, median household income, and poverty threshold levels, the communities of Kaktovik, Nuiqsut, Barrow, Wainwright, Point Lay, Point Hope, Kivalina, Kotzebue, and Nome would be considered low-income communities under the definition of EO 12898.

Table 3.3-50 Community Population, Race, and Ethnicity, 2010 Estimates[a]

Community	2010 Estimated Population	Race														Hispanic or Latino (of any race)[b]	
		One Race												Two or more Races			
		Percent Alaska Native or American Indian		Percent White		Asian		Black or African American		Native Hawaiian and Other Pacific Islander		Some other race

Notes:

a) Total Population, American Community Survey 2006-2010 Estimates

b) Hispanic ethnicity is calculated separately from the races of Native American/Alaskan, Asian/Pacific Islander, White, African American, and Two or More. Ethnicity is not included in the totals because it can result in double counting.

c) The City of Nome is not within an organized borough, so the regional area is known by its census geographic unit.

Table 3.3-51 Median Income and Poverty Rates Estimated for 2009[a]

Geographic Area	Median Household Income[b]	# Households	# Population[c]	# Individuals below poverty	Individual Poverty Rate (%)	# Families[d]	# Families below poverty	Family Poverty Rate (%)
Kaktovik	$44,375	81	260	27	10.4	47	3	6.4
Nuiqsut	$85,156	91	366	2	0.5	77	0	0.0

4.0 ENVIRONMENTAL CONSEQUENCES

This chapter provides the scientific and analytic basis for evaluation of the potential effects or impacts of each of the alternatives described in Chapter 2 on the physical, biological, and social environments. To complete the analysis of effects entails several steps. The first step is to examine the direct and indirect effects to a particular resource resulting from the implementation of a particular alternative. The second step focuses on cumulative effects, considering the contribution of the proposed alternatives to the effects of the past, present, and reasonably foreseeable future actions (RFFAs). These steps are described in more detail below.

This chapter also includes a separate discussion and analysis of potential environmental impacts resulting from an oil spill within the EIS project area. Oil spills are accidental or unlawful events that are evaluated according to three different size categories: small; large; and very large. A small oil spill is defined as less than 1,000 barrels (bbl). Small fuel spills could occur during G&G or exploration drilling activities. Additional information regarding small fuel spills from G&G or exploration drilling activities is discussed in Section 4.2.7 of this EIS. A large or very large oil spill is not considered part of the proposed action for any alternative because the occurrence of such a spill is a highly unlikely event. However, if a very large spill were to occur, it could result in adverse impacts on the resources discussed below. For this reason, the potential impacts of a very large oil spill are discussed and analyzed separately in Section 4.10 of this EIS.

4.1 Analysis Methods and Impact Criteria

The following terms are used throughout this document to discuss effects:

Direct Effects – caused by the action and occur at the same time and place (40 Code of Federal Regulations [CFR] § 1508.8). "Place" in this sense refers to the spatial dimension of impacts and generally, would be analyzed on the basis of the project area. The spatial dimension of direct impacts may not be the same for all resources, and will be defined on a resource by resource basis;

Indirect Effects – defined as effects which are "*caused by the action and are later in time or farther removed in distance, but are still reasonably foreseeable. Indirect effects may include growth inducing effects and other effects related to induced changes in the pattern of land use, population density or growth rate, and related effects on air and water and other natural systems, including ecosystems*" (40 CFR 1508.8). Indirect effects are caused by the project, but do not occur at the same time or place as the direct effects;

Cumulative Impacts – additive or interactive effects that would result from the incremental impact of the proposed action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (federal or non-federal) or person undertakes such other actions (40 CFR 1508.7). Interactive impacts may be either countervailing – where the net cumulative impact is less than the sum of the individual impacts; or synergistic – where the net cumulative impact is greater than the sum of the individual impacts. Focusing this EIS on reasonably foreseeable cumulative impact issues, rather than on speculative impact relationships, is critical to the success of the analysis. Direct impacts are limited to the proposed action and alternatives only, while cumulative impacts pertain to the additive or interactive effects that would result from the incremental impact of the proposed action and alternatives when added to other past, present, and reasonably foreseeable future actions. Sections 4.10.1 and 4.10.2 describe the steps involved in the cumulative impact assessment; and

Reasonably Foreseeable Future Actions – this term is used in concert with the Council on Environmental Quality (CEQ) definitions of indirect and cumulative impacts, but the term itself is

> not further defined. Most regulations that refer to "reasonably foreseeable" do not define the meaning of the words but do provide guidance on the term. For this analysis, reasonably foreseeable future actions (RFFAs) are those that are likely (or reasonably certain) to occur, and although they may be uncertain, they are not purely speculative. Typically, they are based on documents such as existing plans and permit applications.

Effects can include ecological, aesthetical, historical, cultural, economic, social, or health, whether indirect, direct, or cumulative. The terms "effects" and "impacts" are often used interchangeably in preparing these analyses. The CEQ regulations for implementing the procedural provisions of NEPA also state: "Effects and impacts as used in these regulations are synonymous" (40 CFR 1508.8).

4.1.1 EIS Project Area and Scope for Analysis

The overall spatial scope of the analysis is illustrated in Figure 1.1. It includes state and OCS waters adjacent to the North Slope of Alaska and transit areas of the Chukchi Sea north of the Bering Straits. The oceanographic area extends from Kotzebue on the west to the U.S.-Canada border on the east. The offshore boundary is the BOEM Beaufort Sea and Chukchi Sea Planning Areas, approximately 322 kilometers (km) (200 miles [mi]) offshore. Onshore locations include the communities of Kaktovik, Nuiqsut, Barrow, Wainwright, Point Lay, Point Hope, Kivalina, and Kotzebue, as well as the Prudhoe Bay area. When the overall spatial scope is not applicable to a given resource, a relevant geographic sub-area within this overall project area is defined in the analysis.

Evaluation of cumulative effects requires an analysis of the potential direct and indirect effects of the proposed alternatives, in combination with other past, present and RFFAs. Potential sources of past, present, and RFFAs may occur outside of the EIS project area, such as oil and gas activities in Canadian and Russian offshore waters. For each resource, the time frame for past/present effects is defined under the corresponding cumulative effects section. RFFAs considered in the cumulative effects analysis consist of projects, actions, or developments that can be projected, with a reasonable degree of confidence, to occur over the next five to ten years and are likely to affect the resources described.

4.1.2 Incomplete and Unavailable Information

The CEQ guidelines require that (40 CFR 1502.22):

> *When an agency is evaluating reasonably foreseeable significant adverse effects on the human environment in an environmental impact statement and there is incomplete or unavailable information, the agency shall always make clear that such information is lacking.*
>
> *(a) If the incomplete information relevant to reasonably foreseeable significant adverse impacts is essential to a reasoned choice among alternatives and the overall costs of obtaining it are not exorbitant, the agency shall include the information in the environmental impact statement.*
>
> *(b) If the information relevant to reasonably foreseeable significant adverse impacts cannot be obtained because the overall costs of obtaining it are exorbitant or the means to obtain it are not known, the agency shall include within the environmental impact statement:*
>
> *1) A statement that such information is incomplete or unavailable;*
>
> *2) A statement of the relevance of the incomplete or unavailable information to evaluating reasonably foreseeable significant adverse impacts on the human environment;*
>
> *3) A summary of existing credible scientific evidence which is relevant to evaluating the reasonably foreseeable significant adverse impacts on the human environment, and*
>
> *4) The agency's evaluation of such impacts based upon theoretical approaches or research methods generally accepted in the scientific community. For the purposes*

of this section, "reasonably foreseeable" includes impacts which have catastrophic consequences, even if their probability of occurrence is low, provided that the analysis of the impacts is supported by credible scientific evidence, is not based on pure conjecture, and is within the rule of reason.

NMFS and BOEM have relied upon the best available science to inform our consideration of the environmental impacts surrounding oil and gas exploration activities in the Beaufort Sea OCS, Chukchi Sea OCS, and in State of Alaska waters of the Beaufort Sea. However, the nature, abundance, and quality of the data often varies depending upon the action, the geographic region in which it occurs, and the environmental resources that may be affected, and all of these variables influence our understanding of how certain oil and gas exploration activities may affect environmental features. When confronted with missing information, this EIS complies with 40 CFR 1502.22 by employing the following methodology:

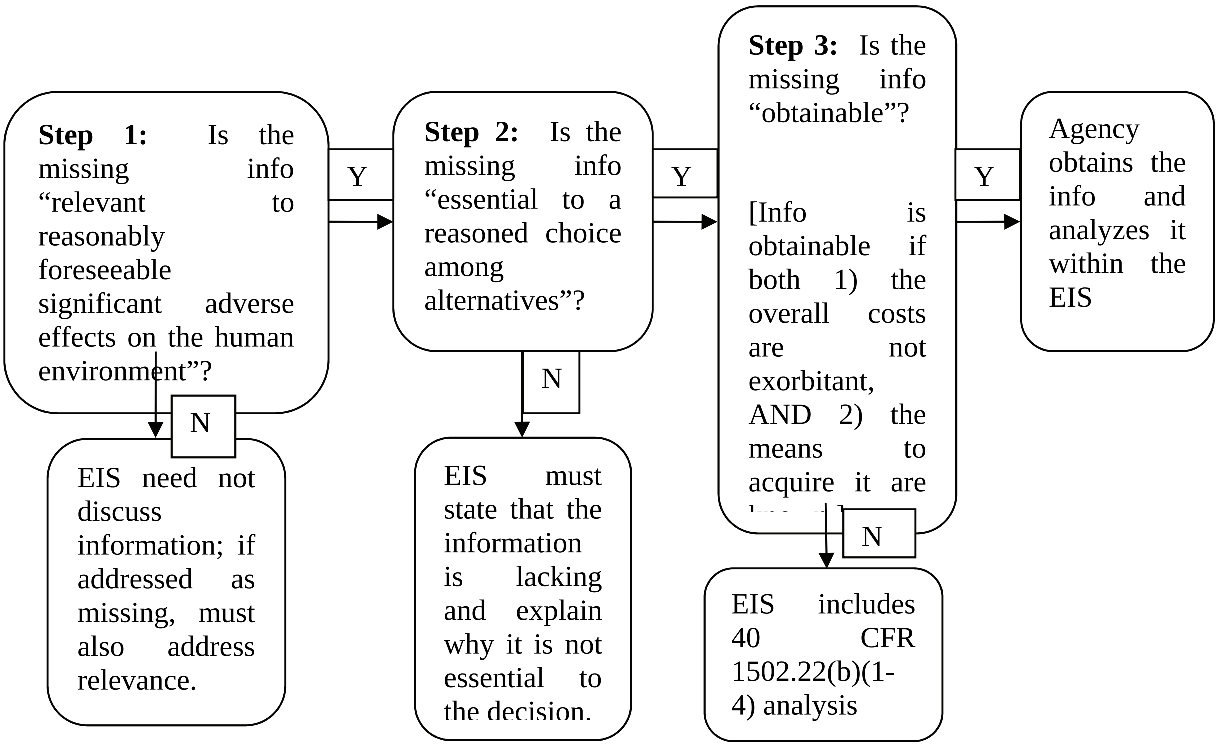

Figure 4.1-1. This diagram explains the steps utilized in this EIS for evaluating incomplete or unavailable information to comply with CEQ regulations at 40 CFR 1502.22.

4.1.3 Methods for Determining Level of Impact

4.1.3.1 Direct and Indirect Effects

Direct effects would be caused by the alternative action and would occur at the same time and place as the alternative action. Indirect effects would also be associated with the alternative but would occur later in time or at a more distant location from the action. Direct and indirect effects could be associated with seismic activities or exploratory drilling activities identified in the alternatives.

NEPA requires Federal agencies to prepare an EIS for any major federal action that significantly affects the quality of the human environment. The CEQ regulations implementing NEPA state that an EIS should discuss the significance, or level of impact, of the direct and indirect impacts of the proposed alternatives (40 CFR 1502.16). Significance is determined by considering the context in which the action will occur and the intensity of the action (40 CFR 1508.27). Actions may have both adverse and beneficial effects on a particular resource. Definitions are provided below.

4.1.3.1.1 Intensity (Magnitude)

Low: A change in a resource condition is perceptible, but it does not noticeably alter the resource's function in the ecosystem or cultural context.

Medium: A change in a resource condition is measurable or observable, and an alteration to the resource's function in the ecosystem or cultural context is detectable.

High: A change in a resource condition is measurable or observable, and an alteration to the resource's function in the ecosystem or cultural context is clearly and consistently observable.

4.1.3.1.2 Duration

Temporary: Impacts would be intermittent, infrequent, and typically last less than a month.

Interim: Impacts would be frequent or extend for longer time periods (an entire project season).

Long-term: Impacts would cause a permanent change in the resource that would perpetuate even if the actions that caused the impacts were to cease.

4.1.3.1.3 Extent

Local: Impacts would be limited geographically; impacts would not extend to a broad region or a broad sector of the population.

Regional: Impacts would extend beyond a local area, potentially affecting resources or populations throughout the EIS project area.

State-wide: Impacts would potentially affect resources or populations beyond the region or EIS project area.

4.1.3.1.4 Context

Common: The affected resource is considered usual or ordinary in the locality or region; it is not depleted in the locality and is not protected by legislation. The portion of the resource affected does not fill a distinctive ecosystem role within the locality or the region.

Important: The affected resource is protected by legislation (other than the ESA). The portion of the resource affected fills a distinctive ecosystem role (such as an important subsistence resource) within the locality or the region.

Unique: The affected resource is listed as threatened or endangered (or proposed for listing) under the ESA or is depleted either within the locality or the region. The portion of the resource affected fills a distinctive ecosystem role within the locality or the region.

4.1.3.2 Impact Criteria and Summary Impact Levels

The impact criteria tables located at the start of each resource section provide a guideline for the analysts to place the effects of the alternatives in an appropriate context and to draw conclusions about the level of impact. The criteria used to assess the effects of the alternatives vary for the different types of resources analyzed, but each resource establishes criteria to determine the level of impact based on magnitude, duration, extent, and context of occurrence. The impact criteria tables use terms and thresholds that are quantified for some components and qualitative for other components. The terms used in the qualitative thresholds are relative, necessarily requiring the analyst to make a judgment about where a particular effect falls in the continuum from "negligible" to "major". The following descriptions are intended to help the reader understand the distinctions made in the analyses.

Negligible[1]: Impacts are generally extremely low in intensity (often they cannot be measured or observed), are temporary, localized, and do not affect unique resources.

Minor: Impacts tend to be low in intensity, of short duration, and limited extent, although common resources may experience more intense, longer-term impacts.

Moderate: Impacts can be of any intensity or duration, although common resources may be affected by higher intensity, longer-term, or broader extent impacts while important and/or unique resources may be affected by medium or low intensity, shorter-duration, local or regional impacts.

Major: Impacts are generally medium or high intensity, long-term or permanent in duration, a regional or state-wide extent, and affect important or unique resources.

4.1.4 Resources Not Carried Forward for Analysis

Resources that were chosen for analysis in this EIS may be impacted by offshore oil and gas seismic exploration activities or the authorized take of marine mammals that could occur from seismic or drilling exploration activities. While the affected environment for geology is relevant to the proposed action, geological processes would not be altered by the project alternatives; this resource is not carried forward for analysis in Chapter 4.

4.2 Assumptions for Analysis

The following discussion provides potential assumptions and scenarios about how geophysical survey methods and exploratory drilling programs could be deployed in order to provide a more complete context for the analysis of effects in this EIS. These assumptions are based on recent federal and state lease planning and recent industry plans for both seismic surveys and exploratory drilling programs in the Beaufort and Chukchi seas. The purpose of developing these assumptions is to ensure a common basis for the analysis of potential environmental effects associated with these future activities.

An overriding assumption for this EIS is that activities associated with lease operations (exploratory drilling and site clearance high resolution seismic surveys) will only occur on active leases, along potential pipeline corridors, and on leases acquired in future lease sales (both federal and state). In addition, there were five pre-2003 leases in the Northstar and Liberty units which could be subject to additional seismic exploration. Seismic surveys not specifically associated with a lease (i.e. 2D and 3D surveys) would potentially occur over large areas within the EIS project area and could occur either on- or off-lease.

For federal leases, it is reasonable to analyze exploratory operations on active leases in both the Beaufort and Chukchi seas. Active federal leases include 34 leases from the Sale 186 area (15,217 hectares), 117

[1] The term negligible in this EIS does not have the same meaning as in the MMPA. The term has different meanings under the two statutes and is being used in two different contexts.

leases from Sale 195 (170,464 hectares), and 90 leases from Sale 202 (196,276 hectares) in the Beaufort Sea; and 487 leases (1,116,277 hectares) from the Sale 193 area in the Chukchi Sea (Figures 1-2 and 1-3).

Active State of Alaska leases only occur in the Beaufort Sea from the coastline out to three nautical miles (Figures 1-2 and 1-3) except in the areas of Harrison Bay and Smith Bay, which are considered historical bays thus extending the area beyond three nautical miles from the coastline. Most of the State's active leases are concentrated between Harrison Bay and Bullen Point. There are currently no State of Alaska leases in the Chukchi Sea. As of December 2012, the State has 406,408 acres (39,085 onshore acreage and 367,323 offshore acreage) on 166 leases in the Beaufort Sea. Exploratory activities (drilling and seismic surveys) could occur in any of these active state leases within the life of this EIS. The State of Alaska plans to conduct area-wide lease sales in the Beaufort Sea annually through 2017 (ADNR 2013), potentially adding new areas where exploratory activities could occur. Such sales could occur on state-owned tide and submerged lands located along the Beaufort Sea coast between the U.S./Canada border and Point Barrow. Industry activities on State of Alaska Beaufort Sea leases in the recent past have largely been concentrated offshore between Harrison Bay and Bullen Point. For this EIS, it is assumed that future activities would likely be concentrated here but could eventually expand beyond this area.

As mentioned in Chapter 2, one seismic or marine survey "program" entails however many survey areas a particular company is planning for that open water season. Each seismic or marine survey "program" would use only one source vessel (or two if the vessels are working in tandem such as with ocean-bottom cable seismic surveys) to conduct the program and would not survey multiple sites concurrently. One exploratory drilling program can entail multiple wells drilled by a single drilling platform (operated by one or multiple companies working together) working under a single approved Exploration Plan in a single season on specific leases. However, only one well would be drilled at a time for a specific program during the season.

Different combinations of seismic activity types could potentially occur under the different action alternatives within the overall limits for the three levels of activity outlined in Chapter 2. For the purposes of analysis only in this EIS, the different types and numbers of seismic and exploration drilling activity that could occur under the action alternatives will be analyzed as identified in Tables 4.2-1, 4.2-2, and 4.2-3 below. A conceptual example of temporal and spatial distributions that could occur for exploration activities is depicted for Alternative 2 (Figures 4.3-1 through 4.3-3), Alternative 3 (4.4-1 through 4.4-3), and Alternative 4 (4.5-1 through 4.5-3). These are only examples that are depicted in order to provide a conceptualization of the differences in levels of activity that could potentially occur under the different alternatives.

Two ocean-bottom cable surveys	**Five** site clearance and high resolution shallow hazards survey programs
Five site clearance and high resolution shallow hazards survey programs	**Four** exploratory drilling programs
One on-ice vibroseis seismic survey	
Four exploratory drilling programs (there is the potential for a combination up to 4 total in federal and state waters)	

4.2.1 2D and 3D Seismic Surveys

Marine 2D and 3D seismic surveys towing long streamers in OCS waters require essentially ice-free conditions to effectively maneuver the source arrays and receiver streamers, which usually begin in July or August and end in October or November depending on the onset and presence of winter ice. Marine in-ice 2D seismic surveys towing a single, long streamer and a source array can operate in up to ten tenths ice coverage by using special deployment gear to protect the equipment and following an ice breaker. In-ice surveys can be conducted in late-September into December. Marine seismic surveys could cover hundreds to a few thousand square miles depending on the survey objectives. Table 2.4 (Chapter 2) outlines specifics associated with these activities. Assumptions for analysis within this EIS for 2D and 3D marine seismic surveys, including in-ice surveys, are as follows:

- One “survey” program would be the 2D or 3D exploration conducted by a single company (or multiple companies working together) in a specific year (July to November if a traditional open water survey or late-September to December if an in-ice survey with an icebreaker for support) in either the Beaufort or Chukchi Sea.

- It is assumed that there could be one 2D/3D seismic survey in state waters of the Beaufort Sea each season. There will be no 2D/3D seismic surveys occurring in state waters of the Chukchi Sea.
- One seismic survey vessel would be deployed, supported by up to two chase/monitoring vessels or an icebreaker for surveys occurring in-ice.
- Chase/monitoring vessels would provide crew change, resupply, and acoustic and marine mammal monitoring support, and assist in ice management operations if required. These vessels will not be introducing sounds into the water beyond those associated with standard vessel operations.
- The survey source vessel, chase/monitoring vessels, and icebreaker would be self-contained, with the crew living aboard the vessels. Crew changes and resupply for open-water activities would occur at least once during each survey, involving transit to onshore support areas.
- Surveys would operate 24 hours per day and data acquisition would occur within 90 days per survey, not including downtime, such as weather delays or shutdowns for mitigation.
- For surveys in the Beaufort Sea, support operations (including crew changes and resupply) would occur out of West Dock or Oliktok Dock near Prudhoe Bay or Barrow. Air support would occur out of Prudhoe Bay or Barrow.
- For surveys in the Chukchi Sea, support operations (including crew changes and air support) would occur primarily out of Nome or Wainwright, with the possibility that these activities could be conducted out of Barrow or Wainwright as well.
- Helicopters stationed at Barrow (for operations in either the Beaufort or Chukchi Sea) or Deadhorse (for operations in the Beaufort Sea) would provide emergency or search-and-rescue (SAR) support, as needed.
- On-ice vibroseis surveys and ocean-bottom cable (OBC) surveys are also used to acquire 2D and 3D data. Vibroseis surveys occur in nearshore areas (primarily on state leases) and federal acreage in shallow water on thickened sea ice capable of supporting the equipment during the winter months. OBC surveys are conducted during open water in nearshore shallow water zones. This type of seismic survey is used to acquire seismic data in water that is too shallow for large marine-streamer vessels and/or too deep to have grounded ice in the winter. For this EIS, these two survey methods will only be analyzed for use in the Beaufort Sea.

4.2.2 Site Clearance and High Resolution Shallow Hazards Surveys

These surveys in OCS waters are conducted on active leases to evaluate for potential hazards at specific drilling locations prior to drilling or along potential pipeline routes. For analysis in this EIS, a site clearance and high resolution shallow hazards survey program may consist of several surveys conducted by a single company (or multiple companies working together) in a specific year (open water season of July to November) in either the Beaufort or Chukchi Sea. Such surveys would use the variety of methods and devices discussed in Section 2.3.2. Table 2.4 (Chapter 2) outlines specifics associated with these activities. Assumptions for analysis within this EIS for site clearance and high resolution shallow hazards surveys are as follows:

- Mobilization of a survey program would occur by mid-July and end by November 30.
- Surveys would operate 24 hours per day, and total time for data acquisition for a single program could last 45-90 days, not including downtime.

- Survey vessels are self-contained with the crew living aboard the vessel. Refueling, resupply, and crew changes would occur one time during the season.
- For surveys in the Beaufort Sea, support operations would occur out of West Dock or Oliktok Dock near Prudhoe Bay or Barrow.
- For surveys in the Chukchi Sea, support operations would occur out of Wainwright, Nome, or Barrow.
- Helicopters stationed at Barrow (for operations in either the Beaufort or Chukchi Sea) or Deadhorse (for operations in the Beaufort Sea) would provide emergency or SAR support, as needed.
- Site clearance and shallow hazards survey programs in the OCS typically also include ice gouge and strudel scour surveys. The ice gouge and strudel scour surveys do not involve the use of airguns but do involve the use of smaller, higher-frequency sound sources, such as multi-beam echosounders, and sub-bottom profilers, and side scan sonar.

4.2.3 Exploratory Drilling in the Beaufort Sea

While exploratory drilling located in offshore portions of the Beaufort Sea (as compared to directional drilling from onshore or existing offshore facilities) could occur on any active lease, as part of the assumptions for analysis in this EIS, it is assumed that exploratory drilling will likely occur initially in areas offshore of Camden Bay in the eastern portion of the Beaufort Sea during the initial year of this EIS's analysis window. There is also the potential for one or maybe two exploratory drilling programs on state leases in the Beaufort Sea. Table 2.4 (Chapter 2) outlines specifics associated with these activities. Assumptions for analysis within this EIS for exploratory drilling in the Beaufort Sea OCS are as follows:

- For each exploratory drilling program, a drillship , steel drilling caisson (SDC), or other Mobile Offshore Drilling Unit (MODU) with a fleet of support vessels (typically about 8-12 vessels) would be deployed that would be used for ice management (likely an icebreaker), anchor handling, oil spill response, capping and spill containment, refueling, resupply, and servicing the drilling operations.
- At the start of the program, the drillship, SDC, or other MODU and support vessels would transit the Bering Strait into the Chukchi Sea, and then transit further on to the Beaufort Sea drill site(s). Vessels could transit from maritime ports in the Canadian Beaufort Sea (e.g. Tuktoyaktuk) or the Russian Arctic.
- Timing of operations would commence in approximately early July and end by approximately early November. (In the future, with changing ice conditions, there is the potential that seasons could begin slightly earlier and end slightly later.)
- Drilling could occur on multiple drill sites per drilling program per year, allowing for up to four wells to be drilled per season per program depending upon weather and ice conditions. For purposes of analysis, assume up to three wells could be drilled in the season. If two programs were conducted simultaneously in the Beaufort Sea, this could result in up to six to eight wells drilled per season (with some on federal leases and others on State of Alaska leases). If up to four programs were to occur simultaneously in one season, up to 12-16 wells could be drilled in Beaufort Sea State and federal waters per year.
- Resupply vessels would operate from both Dutch Harbor and West Dock at Prudhoe Bay. Ten resupply trips per drilling program are estimated.
- Helicopters would provide support for crew change, provision resupply, and SAR operations for each drilling program. Helicopters (assume two flights per day or 12 flights per week)

used for crew change and resupply would be based in Deadhorse or Barrow and transit to/from the drill sites. Fixed winged aircraft operating daily out of Deadhorse or Barrow would support marine mammal monitoring and scientific investigations. SAR helicopters would operate as needed from Barrow.

- At the end of the drilling season, the drilling unit and associated support vessels will typically exit the area by traveling west into and through the Chukchi Sea and Bering Strait. As an alternative, the SDC, if used, could be towed to the Canadian Beaufort for the winter.

Open-water exploratory drilling currently does not occur in state waters of the Beaufort Sea. Exploratory drilling on state leases would likely occur from artificial ice islands, where the drilling is done directionally. Assumptions for analysis within this EIS for exploratory drilling in state waters of the Beaufort Sea are as follows:

- Exploratory drilling would occur within State of Alaska waters which are generally within three miles of the coastline and barrier islands in the Beaufort Sea between Point Barrow and the Canadian border; most of the state leases are concentrated between Harrison Bay and Bullen Point.
- The use of artificial ice islands requires that drilling occur during the winter months (December to April).
- Resupply and crew change support would occur through the construction of ice roads to the artificial ice island, originating from the road system at or near the Prudhoe Bay oilfield. Helicopters could also be used that would operate out of the Deadhorse airport.

4.2.4 Exploratory Drilling in the Chukchi Sea

While exploratory drilling located in offshore portions of the Chukchi Sea could occur on any active lease, as part of the assumptions for analysis in this EIS (similar to the Beaufort Sea), it is assumed that exploratory drilling in the Chukchi Sea will likely occur initially in areas on federal leases for which exploration plans have recently been submitted or are intended to be submitted during the time frame of this EIS and where there have been recent requests to approve ancillary activities. Table 2.4 (Chapter 2) outlines specifics associated with these activities. Assumptions for analysis within this EIS for exploratory drilling in the OCS portion of the Chukchi Sea are as follows:

- For each exploratory drilling program, a drillship or jackup rig (i.e. drilling unit) with approximately six to eight support vessels would be deployed. Support vessels would be used for ice management (likely an icebreaker), anchor handling, oil spill response, refueling, resupply, and servicing the drilling operations. Oil spill response vessels would be staged near the drillship or jackup rig. The icebreaker and anchor handler would be staged away from the drill site when not in use but would move closer to perform duties when needed.
- The drilling unit and support vessels would be deployed on or about July 1, traveling from the south through the Bering Sea, or from the east through the Beaufort Sea from maritime ports in the Canadian Beaufort Sea (e.g. Tuktoyaktuk) or the Russian Arctic, arriving on location in the Chukchi Sea in early July.
- Timing of drilling operations would commence soon after arriving at the drill site in early July and ending by approximately mid-November. (In the future, with changing ice conditions, there is the potential that seasons could begin slightly earlier and end slightly later.)
- Drilling could occur on multiple drill sites per drilling program per year, depending upon weather and ice conditions, allowing for up to four wells to be drilled per season. For

purposes of analysis, assume up to four wells could be drilled in the season. If two programs were conducted simultaneously in the Chukchi Sea, this could result in up to six to eight wells drilled per season. If up to four programs were to occur simultaneously in one season, up to 12-16 wells could be drilled in the Chukchi Sea per year.

- Marine resupply vessels would operate between the drill sites and Dutch Harbor or Wainwright. Ten resupply trips per drilling program are estimated.
- Aircraft operations, up to 12 flights per week, would transit from Wainwright or Barrow to each of the drilling sites. For emergencies, SAR helicopters would operate out of Barrow.
- At the end of the drilling season, the drillship or jackup rig, and associated support vessels will transit south out of the Chukchi Sea through the Bering Strait.
- There are currently no leases available in state waters in the Chukchi Sea. Exploratory drilling in state waters of the Chukchi Sea is not analyzed in this EIS.

4.2.5 Conceptual Examples

Three conceptual examples have been provided to help illustrate potential temporal and spatial arrangements of exploration activities under the action alternatives. The three conceptual examples are within the levels of activity contemplated for Alternatives 2, 3, and 4. Additionally, the examples do not exceed the level of each type of activity described in Tables 4.2-1, 4.2-2, 4.2-3 above.

For Alternative 2, Figures 4.3-1 and 4.3-2 depict conceptual examples of the spatial distribution of different activity types in the Beaufort and Chukchi seas, respectively. In order to help reviewers better visualize the impacts that could potentially result from these activities, these maps include examples of: the distances from certain sources at which sounds attenuate to below NMFS MMPA harassment threshold levels, tracklines of seismic vessels, the locations of associated support vessels for drilling platforms, and areas of particular importance for marine mammals. To avoid making the maps hard to read, subsistence areas were not included, but reviewers may cross reference to Figures 3.3-18 – 3.3-24. An associated bar graph (Figure 4.3-3) was included to depict an example of the temporal distribution of the activities in Alternative 2 illustrated in Figures 4.3-1 and 4.3-2, which provides an example of the number and types of activities that might be occurring concurrently, and for how long.

For Alternative 3, the same conceptual examples described above for Alternative 2 were also included in Figures 4.4-1, 4.4-2, and 4.4-3. These figures illustrate how for Alternative 3 (as compared to Alternative 2), which adds both seismic surveys and drilling operations, the total area over which potential impacts from the activities may occur is larger, and the amount of time that multiple activities are co-occurring (and the number of activities that are co-occurring) either within or across the Beaufort and Chukchi seas is greater. For these reasons, these figures support the general suggestion that conducting the level of activity proposed for Alternative 3 would result in both impacts to more individuals, as well as impacts of a likely more intense nature (from the combined exposure to more activities in time and space), than conducting the level of activity proposed for Alternative 2.

For Alternative 4, the same conceptual examples described above for Alternatives 2 and 3 were also included in Figures 4.5-1, 4.5-2, and 4.5-3. These figures illustrate how for Alternative 4 (as compared to Alternatives 2 and 3), which includes additional drilling operations but the same number of seismic surveys as Alternative 3, the total area over which potential impacts from the activities may occur is likely somewhat larger, and the amount of time that multiple activities are co-occurring (and the number of activities that are co-occurring) either within or across the Beaufort and Chukchi seas is somewhat greater. For these reasons, these figures support the general suggestion that conducting the level of activity proposed for Alternative 4 could result in both impacts to more individuals, as well as impacts of a likely more intense nature (from the combined exposure to more activities in time and space), than conducting the level of activity proposed for Alternatives 2 and 3. However, the difference in the level of direct impacts between Alternative 4 and Alternative 3 is not expected to be as large as the difference between Alternative 3 and Alternative 2.

4.2.6 Estimating Take of Marine Mammals

Background

The MMPA prohibits the taking of marine mammals with certain exceptions, one of which is MMPA incidental take authorizations. Incidental take authorizations allow for the take of small numbers of marine mammals if NMFS finds that the activity will have a negligible impact[2] on the affected marine mammal species and will not have an unmitigable adverse impact[3] on subsistence uses, and provided mitigation and monitoring requirements are set forth. Applicants for these authorizations are required by the MMPA implementing regulations to estimate (in advance) the number of individuals of each species that may be taken by their proposed activity [50 CFR 216.104 (a)(6)]. Take estimates are also necessary to inform the analyses that NMFS must conduct.

In order to help applicants with noise-producing activities understand when their activity might be expected to take a marine mammal (i.e., when an ITA would be needed) and to assist in the necessary quantification of likely takes, NMFS has established acoustic thresholds (discussed below). Acoustic thresholds identify received sound levels above which marine mammals would be expected to be taken (either by behavioral harassment or injury), if exposed. In short, animals predicted to be exposed to levels at or above the acoustic threshold are predicted to be taken in the specified manner (e.g., by behavioral harassment or injury).

The estimated number of animals that will be exposed at or above acoustic thresholds (and, therefore, predicted to be taken) is a valuable piece of both the “negligible impact” and “unmitigable adverse impact” analyses and directly informs whether the take numbers are “small,” however, it is only one piece of an effects analysis under the MMPA. The expected occurrence of a take or a particular *number* of estimated takes does not necessarily relate directly to the biological significance of the impacts, i.e., whether the takes will result in adverse impacts on the fitness or health of the individuals taken. The potential and likelihood of impacts on the health and fitness of individuals taken must be determined in consideration of the manner, context, duration, and intensity of those takes.

For example, some takes (such as injuries or those with significant negative energetic impacts) may have the potential to negatively affect reproductive success or survivorship, depending on the circumstances, while other takes may have no impact on the health or fitness of the affected individual. If the analysis predicts that the activity is likely to adversely affect the reproductive success or survivorship of any individual marine mammals, then additional analysis must consider how the anticipated fitness affects to those individuals would likely affect the population (e.g., rates of recruitment and survival), in consideration of the species status. Additionally, the negligible impact analysis must consider the impacts on marine mammal habitat, such as impacts on prey species or the more difficult-to-quantify acoustic

---

[2] Under the MMPA implementing regulations, a negligible impact is defined as an impact resulting from the specified activity that cannot be reasonably expected to, and is not reasonably likely to, adversely affect the species or stock through effects on annual rates of recruitment or survival (50 CFR § 216.103).

[3] An unmitigable adverse impact is defined as an impact resulting from the specified activity that is: 1) likely to reduce the availability of the species to a level insufficient for a harvest to meet subsistence needs by: causing marine mammals to abandon or avoid hunting areas; directly displacing subsistence users; or, placing physical barriers between the marine mammals and the subsistence users; AND 2) cannot be sufficiently mitigated by other measures to increase the availability of marine mammals to allow subsistence needs to be met.

habitat impacts that necessitate the consideration of the chronic effects of longer-term exposure to increased sound levels.

Finally, the need to ensure "no unmitigable adverse impacts" to the availability of subsistence uses requires consideration of far more than just take numbers, both because activities can interfere with a hunt without ever affecting a marine mammal (e.g., by blocking access of hunters to marine mammals), and because it is possible for noise to affect marine mammals in a way that would make them more difficult to hunt without always rising to the level of a take (e.g., as traditional knowledge suggests, making them "skittish.")

Current Acoustic Thresholds

When assessing impacts to marine mammals from sound sources, NMFS has historically used the following acoustic thresholds (meaning that take is predicted to occur, or assumed to have occurred, if animals are exposed at or above these levels). These thresholds have been applied to all marine mammal species under NMFS' jurisdiction.

- ***Level A Harassment (potential injury) from all non-explosive sound sources: 180 and 190 dB re 1 µPa (rms) received level for cetaceans and pinnipeds, respectively***. These received levels represent the levels above which, in the view of a panel of bioacoustics specialists convened by NMFS before additional TTS measurements for marine mammals became available, one could not be certain that there would be no injurious effects, auditory or otherwise, to marine mammals (NMFS 1995, 2000).
- ***Level B Harassment (behavioral harassment) from impulsive sources (e.g., seismic airguns): 160 dB re 1 µPa (rms) received level for all species.*** This sub-injurious threshold was based on measured avoidance responses observed in whales in the wild. Specifically, the 160 dB rms re: 1µPa threshold was derived from data for mother-calf pairs of migrating gray whales (Malme et al. 1983, 1984) and bowhead whales (Richardson et al. 1985; Richardson et al. 1986) responding when exposed to seismic airguns.
- ***Level B Harassment (behavioral harassment) from continuous sources (e.g., drilling): 120 dB re 1 µPa (rms) received level for all species.*** This threshold originates from research on baleen whales, specifically migrating gray whales (Malme et al.1984; predicted 50% probability of avoidance) and bowhead whales reacting when exposed to industrial (i.e., drilling and dredging) activities (non-impulsive sound source) (Richardson et al. 1990).

Revision of Acoustic Thresholds[4]

NMFS is currently in the process of revising and updating our acoustic thresholds to incorporate newer science and utilize improved methods. NMFS is using a phased approach to conduct these update. The thresholds currently being revised include: 1) the injury (Level A Harassment) thresholds to be applied to all sound sources and; 2) the behavioral (Level B Harassment) thresholds to be applied only to seismic activities and seismic-like sound sources (e.g., primarily mobile and impulsive sources). In addition to ensuring that NMFS is using the appropriate acoustic thresholds in its decision-making processes, the development of these revised acoustic thresholds will create a single document/ reference that clearly articulates the thresholds, how they were scientifically derived, and how NMFS plans to apply them pursuant to the multiple NOAA authorities that address noise impacts (e.g., MMPA, ESA).

The process for revising the acoustic thresholds is separate from this NEPA process for Arctic Oil and Gas Exploration. The acoustic threshold revision process will include extensive internal (NOAA) review,

[4] This information is distributed solely for the purpose of predissemination peer review, including public review and comment, under applicable Information Quality Guidelines. It has not been formally disseminated by NOAA. It does not represent and should not be construed to represent any agency determination or policy.

an external peer review, and public review. Currently, NMFS is in the internal review part of this process and we expect the other steps (peer and public review) to occur generally in parallel with the development of the Final EIS for Arctic Oil and Gas Exploration. This means that we expect final or near-final acoustic threshold revisions for inclusion in this Final EIS. However, importantly, the revised acoustic thresholds specifically referenced here will not be used in any final management decisions pursuant to the MMPA or ESA until they have undergone both public and peer review and have been officially finalized by NMFS. Until then, NMFS will continue to use the current thresholds referenced above.

Government agencies must make decisions every day based on the best available science. NEPA requires agencies to conduct environmental impact analyses, some of which span multiple years during which science and policy related to the actions being considered are constantly evolving. As noted above, NMFS is currently in the internal review phase of our revision of the acoustic thresholds and some facets of the revisions are not yet ripe for consideration by the public. Additionally, both peer review and public review will create opportunities for any draft thresholds available now to change, potentially significantly. However, enough basic information about the likely nature of the revisions to the thresholds is available to provide valuable input into the environmental analysis contained in this Supplemental DEIS, and not including an introduction to these anticipated changes here and (in fuller form) in the Final EIS would lessen the value of the Final EIS to inform NMFS decision-making. As noted above, a full draft of the revised acoustic thresholds will be made available to the public for review in a separate process (anticipated later in 2013) and the input from that process will inform both the final acoustic thresholds that are ultimately adopted, as well as NMFS' effects analysis in the Final EIS for Arctic Oil and Gas Exploration.

Below, we include an introduction to the revision of the acoustic thresholds (including actual preliminary draft thresholds for injury), along with a summary of the ways in which changes of the nature discussed might be expected to shape the analysis of effects contained elsewhere in the document (and informed by the current acoustic criteria). As discussed in more detail above and below, acoustic thresholds are only one part of the analysis of marine mammal and subsistence impacts and the analysis contained elsewhere in this document (informed by current acoustic criteria) creates a solid analytical foundation upon which considerations of acoustic threshold revisions can be layered for a fuller understanding of how the anticipated changes may inform future decision-making.

Behavioral Harassment Thresholds

As noted above, NMFS is currently in the process of revising the acoustic thresholds for behavioral harassment for seismic activities, including airguns and similar sources (e.g., primarily mobile and impulsive sources). Although new numerical thresholds are not presented here (for behavioral harassment), an introduction to the anticipated change in methodology and a preview of the quantitative adjustments that could result from the inclusion of newer data are included.

The current acoustic threshold for behavioral harassment from impulsive sounds, a 160-dB rms step function, predicts that all animals exposed to levels above 160 dB would be taken, and that no animals exposed to levels below 160 dB would be taken. Both data and logic suggest that this method may oversimplify the relationship between sound exposure and behavioral harassment, and there are other methods available that can better characterize this relationship, given the available data, while also incorporating consideration of variability in individual responses to sound. Dose-response-type curves, or risk functions (see Figure 4.6-1), when supported by data and with an appropriate cut-off, can be used to more fully describe how exposures to different received levels can result in different outcomes (e.g., number of animals responding in a certain way, probability of individual responses). For example, given a specifically defined response, a risk function could describe how a higher percentage of animals exposed to higher received levels might demonstrate that response, while a lower percentage of animals exposed to lower received levels might demonstrate that response (see example used for Navy mid-frequency sources below). NMFS' preliminarily plans include exploring the use of dose-response or risk function-like curves to characterize the relationship between received sound level and behavioral responses. Further, while other metrics have been explored, based on the available data NMFS' believes that dB rms (the metrics used in the current acoustic thresholds) is still the most appropriate metric to characterize the relationship between received level and behavioral response.

Additionally, as has become increasingly evident and more highlighted in publications (e.g., Ellison et al., 2011), the context of an exposure of marine mammals to sound (e.g., the behavioral state of the animal, whether a sound source is approaching and how fast, etc.) can affect both how an animal initially responds to a sound and the ultimate impacts of the sound exposure on that individual. NMFS is also exploring additional methods of augmenting the use of a dose-response-like curve to address contextual factors beyond received level (such as distance from the sound or behavioral state of the animal), as well as the more chronic effects of sound sources operated over longer periods of time.

Currently, based on the limited data available and what it suggests is appropriate, NMFS plans to have different basic acoustic thresholds for mysticetes, odontocetes, and pinnipeds, with the recognition that sometimes there may be sufficient data to suggest that a species within one of those groups is "sensitive" and should have different (lower) acoustic threshold. Although draft curves will not be presented here, a look at some of the data that will be used to derive the curves will help us understand how the results of using a curve may differ from the results of using the current 160-dB step function. Because data indicate that not all mysticetes exposed to received levels of 160 dB or above would be expected to be taken (Miller 2005, Malme et al. 1983, 1984, 1985), a dose-response approach for mysticetes would likely result in estimates that show fewer takes resulting from exposures to received levels above 160 dB (than when the current step function is used). However, there are also data showing that some portion of mysticetes (including, and perhaps especially, bowheads) exposed to seismic signals at received levels below 160 dB, and potentially down to around 120 dB, may respond in a manner that NMFS would categorize as a Level B behavioral take, especially in certain contexts, such as within a migratory corridor or if the activity were expected to be continuous over multiple days (Di Iorio and Clark 2009, Richardson et al. 1985/1986, Richardson et al. 1999). A dose-response-like approach incorporating these data would result in some number of animals exposed at levels below 160 dB being predicted to be taken.

Fewer data exist showing how odontocetes and pinnipeds (as compared to mysticietes) behaviorally respond to seismic airguns and similar sources. However, what data are available suggest that some percentage of odonotcetes exposed to received levels above 160dB would not be taken and that some percentage exposed to levels below 160 dB may respond in a manner that NMFS would consider Level B harassment (Miller et al. 2005). Alternately, data suggest that not all pinnipeds will be taken at received levels of 160 dB (or higher), and there are no data (with measured received levels) indicating how they would respond to levels below 160 or 165 dB.

In consideration of the acoustic threshold revisions being conducted, NMFS qualitatively considers how changes of the nature described above could potentially shape our further analyses of the alternatives in this Supplemental DEIS. As described above, much of the impact analysis occurs subsequent and in addition to the initial estimate of the number exposures that are predicted to result in a take. This additional analysis determines whether the anticipated exposures with the potential to injure or disturb marine mammals (counted as takes) would be likely to affect the health or fitness of any individuals (in a manner that would affect survivorship or reproductive success), whether altered health or fitness of the expected number of individuals would adversely affect rates of recruitment or survival, and whether any of the expected effects on individuals would have an unmitigable adverse impact on subsistence uses.

When estimating the potential number of take from a particular activity, NMFS has typically multiplied the anticipated area to be ensonified by the appropriate threshold (noted above) by the expected species density. For some activities occurring in the Beaufort Sea during the fall bowhead migration, additional factors were taken into consideration in the take estimates, such as the proportion of whales migrating past in certain water depths and how that falls within the applicable sound thresholds. When sound propagation is considered (and the larger areas ensonified at lower levels), if the acoustic thresholds were revised in the form of dose-response curves reflecting the data referenced above (after input from the public and peer reviewers), it is likely that it would result in a change in the estimated number of takes that would result from the operation of seismic airguns (as compared to the numbers predicted using the current criteria). This change would likely be in the direction of a moderate to large increase in the number of predicted mysticete behavioral harassment takes, a small to moderate increase in the number of odontocete takes, and little change or a slight decrease in the number of pinniped takes.

Any increase in numbers of estimated take would entirely be the result of adding behavioral harassment takes that would be predicted to result from lower level exposures, which are also typically associated with lower potential severity, or lower likelihood of affecting the health and fitness of any individual marine mammals. As discussed above, the quantification of anticipated takes is only part of the larger marine mammal impact analysis and is separate from the analysis of the severity of any single one of those takes, which must consider the biological and operational context in which those takes occur. So, while these revisions could notably change predicted take numbers in some cases, we would not *necessarily* change our analyses (i.e., the analysis contained elsewhere in this Supplemental DEIS) of the biological significance of the increased total takes on the individuals or populations. The analysis of the potential health and fitness impacts of the expected take, or the population level impacts, includes consideration of the life history of the affected species, their behavioral patterns and distribution within the action area, the duration, season, geographic scope, and operational parameters of the expected activities, along with the potential implementation of multiple mitigation measures intended to minimize the intensity of the affects – and these analyses are not notably changed by the likely modification of predicted harassment take numbers.

Separately, any revisions to the acoustic thresholds also result in changes to the distances from sound sources within which we quantify impacts. NMFS has previously qualitatively acknowledged our concerns regarding the more chronic, longer-term effects of increasing noise levels (at levels below 160 dB) in potentially interfering with marine mammal's ability to detect and interpret important environmental cues (especially for low frequency specialists and low frequency sounds). For example, we outlined the 120-dB isopleths around seismic airgun operations in the original DEIS (even though the current acoustic threshold for behavioral harassment is 160 dB) to give a sense of the geographic scope of these chronic noise concerns. Revised acoustic thresholds, with which we may include methods to address the contextual and chronic concerns of noise exposure, may allow us to quantitatively augment the existing qualitative analysis of these concerns.

Injury

NMFS is also currently in the process of revising the acoustic criteria for determining at what received levels a marine mammal is likely to incur injury (i.e., PTS onset) from seismic activities, including use of airguns. Southall et al. (2007) identified dual criteria (using peak pressure and sound energy level) for assessing PTS from multiple pulse sounds. Using those proposed levels as a starting point, NMFS is proposing to modify them using more recent data, which suggest: 1) that phocids should be separated from otariids when estimating TTS or PTS (because of their inner ear anatomy) and likely incur hearing impairment at lower received levels based on the data currently available (Kastak and Schusterman 1998; Hemilä et al. 2006; Mulsow et al. 2011), and; 2) that cetaceans are more likely to incur TTS and subsequent PTS within the frequency ranges of their best hearing sensitivity (,Finneran and Schlundt 2010; Finneran and Jenkins 2012). An overview of these NMFS draft acoustic exposure criteria is included below. Finneran and Jenkins (2012), which describes the new weighting functions, is included here as Appendix B, and Figure 4.6-2 summarizes the weighting. Additional information regarding the derivation of these draft thresholds may be found in Southall et al. (2007) and section 3.4 of the Navy's Atlantic Fleet Training and Testing DEIS (aftteis.com). NMFS will provide our own full description of the derivation of the revised acoustic thresholds once the internal review is complete and NMFS' revised acoustic thresholds are released for public comment through the separate process referenced above.

Table 4.2-4 NOAA Draft Proposed Injury (PTS) Criteria for Marine Mammals

Draft Proposed Injury Criteria		
	PTS Onset (Received Level)	
Hearing Group	**Impulsive**	**Non-impulsive**
Low-Frequency Cetaceans	*Cell 1* *230 dB_{peak}* **&** *187 dB cSEL***	*Cell 2* *230 dB_{peak}* **&** *198 dB cSEL***
Mid-Frequency Cetaceans	*Cell 3* *230 dB_{peak}* **&** *187 dB cSEL***	*Cell 4* *230 dB_{peak}* **&** *198 dB cSEL***
High-Frequency Cetaceans	*Cell 5* *201 dB_{peak}* **&** *161 dB cSEL***	*Cell 6* *201 dB_{peak}* **&** *171 dB cSEL***
Phocid Pinnipeds (Underwater)	*Cell 7* *224 dB_{peak}* **&** *181 dB cSEL***	*Cell 8* *224 dB_{peak}* **&** *186 dB cSEL***
Otariid Pinnipeds (Underwater)	*Cell 9* *230 dB_{peak}* **&** *215 dB cSEL***	*Cell 10* *230 dB_{peak}* **&** *220 dB cSEL***

* Dual criteria: Use on one [dB_{peak} or dB cSEL] exceeded first.

** NOTE – When comparing these thresholds to existing 180/190-dB rms thresholds, two important differences must be kept in mind: 1) these thresholds are based on the frequency of highest sensitivity for each taxa and are intended to be used in conjunction with frequency weighting, and 2) the metric of these thresholds are SEL instead of SPL.

When considering how revised acoustic thresholds for injury similar to those outlined above might compare (adopted in this form after public and peer review and finalized) to the current 180/190-dB rms thresholds, it is important to note three important differences in what the two sets of thresholds (current and revised) represent. First, dual criteria are utilized, meaning that whichever is exceeded first is the one that should be used for assessing injury (in almost all cases, the cSEL metric will be exceeded first). Second, the thresholds outlined above use the cSEL metric (which allows for the consideration of how the sound accumulates over time), not the SPL rms metric of the current thresholds (which does not directly take into account the duration of exposure). This means, for example, that one 100-ms pulse with a received SPL rms level of 161 dB would only have an SEL of 151 dB. However, multiple pulses must be taken into consideration, and, if a receiver were in a position to receive 10 of those same pulses within that same distance, the cSEL would accumulate up to 161 dB (e.g, cSEL equals SPL rms levels when the total duration of exposure to the same level is 1 second). Last, the cSEL thresholds outlined above take into account the frequency range of highest sensitivity for each functional hearing group and are intended to be used in conjunction with frequency weighting functions that are depicted below (Figures 4.6-2 and 4.6-3) and outlined in more detail in Finneran and Jenkins (2012) technical memo (Appendix B). In short, applying frequency weighting functions puts the sound produced by the source in question through a functional hearing group-specific and frequency-specific filter and for any part of the signal that is not in the area of highest sensitivity for that functional hearing group, i.e., more energy is needed to reach the threshold (e.g., range to isopleth decreases). Of note, the values of highest sensitivity for mysticete hearing specialists depicted below are extrapolated from mid-frequency hearing specialists and NMFS expects that these values may be more likely to significantly change than other groups.

NMFS has conducted some simple calculations, with underlying assumptions (e.g., spherical spreading, airgun shot lasts 100 ms, accumulate 20 shots, animal not avoid source). If thes revised thresholds were adopted in this form, it is likely that the distances from the source within which we would expect animals to potentially be exposed to injurious levels (e.g., within these cSEL thresholds) would primarily fall within the distances to the current 180-dB SPL rms threshold for cetaceans. However, for phocids, the distances within which received levels may exceed the new thresholds could be somewhat larger than the distances to the current 190-dB threshold. However, as noted, these calculations do not take into account the likely avoidance of higher sound levels by some portion of marine mammals or the potential success of mitigation measures in avoiding exposures to those animals that approach more closely. This Supplemental DEIS analysis currently suggests that while marine mammal injury resulting from airgun exposure is unlikely, it cannot be ruled out – and that analysis is anticipated to remain accurate in consideration of revised acoustic thresholds.

Tables 4.2-5, 4.2-6, and 4.2-7 contain a representative summary of takes that were predicted to occur in the Beaufort and Chukchi seas based on previously issued IHAs for the different types of activities analyzed in this EIS.

Table 4.2-5 Examples of estimated takes for different types of oil and gas exploration activities in the Beaufort Sea using the current acoustic criteria, followed by estimated takes if those examples are used to total maximum activity levels for each alternative.

BEAUFORT	Bowhead Whale	Beluga Whale	Gray Whale	Minke Whale	Humpback Whale	Harbor Porpoise	Ringed Seal	Bearded Seal	Spotted Seal	Ribbon Seal

4.2.7 Accidental Exploration Spills

An accidental hydrocarbon spill or release is an event of concern because it has the potential to result in environmental impacts. A hydrocarbon spill can affect environmental, social, and economic resources. For these reasons, it is important to understand the frequency of occurrence and fate for impact assessment purposes. To this end, the frequency of varying sizes of hydrocarbon spills have been estimated using historical data from the U.S. OCS and other offshore oil and gas development regions, and the trajectories of large and very large spill scenarios have been modeled (MMS 2003, 2007, 2008, BOEMRE 2010 a, b; 2011 a, b, c).

For the purposes of the environmental assessment, two types of accidental events during exploration operations are considered – small spills and very large spills. Small spills are likely to occur over the life of exploration activities and are generally 50 bbls or less. Approximately 99% of OCS spills are less than 50 bbl (BOEM 2012). Very large spills are very unlikely to occur during exploration activities and are greater than or equal to 150,000 bbl. Although very large spills are not estimated to occur during exploration activities, Section 4.10 addresses very large spills to inform the decision maker of the impacts of a very unlikely but not impossible very large oil spill.

Small fuel spills associated with the vessels used for G&G activities could occur, especially during fuel transfer. However, there are no reported historical fuel spills from geological or geophysical operations on the Chukchi and Beaufort OCS. Small spills could also occur during exploration drilling operations. A ≤50 bbl spill was estimated to occur during exploration drilling operations from refueling (MMS 2009a, b; BOEMRE 2011a.c). Historical Beaufort Sea and Chukchi Sea OCS exploration spill data suggest that a small spill is likely to occur. Thirty five exploration wells were drilled in the Arctic OCS from 1981-2003. During that time period 35 small spills have occurred spilling a total of 26.7 bbl (of which 24 bbl was recovered). The largest Arctic OCS exploration spill was less than 20 bbl. The most likely cause of a small oil spill during exploration is operational, such as a hose rupture. Estimated ranges for small fuel spill volumes with respect to G&G activities and exploration activities are discussed below and summarized in Table 4.2-8.

Table 4.2-8 Number of respective activities for each activity level and the estimated small spill volume range used for purposes of analysis.

Alternative	Activity	Activity Number Beaufort	Activity Number Chukchi	Small Spill Volume Range (bbl)
2	Seismic or CSEM surveys	4	3	0–<7*
	Exploratory Drilling	1	1	0–100*
3	Seismic or CSEM surveys	6	5	0–<11*
	Exploratory Drilling	2	2	0–200*
4	Seismic or CSEM surveys	6	5	0–<11*
	Exploratory Drilling	4	4	0–400*

*A single small exploratory drilling spill would be ≤50 bbl, and a single seismic or CSEM survey spill would be <1 bbl.

G&G Small Fuel Spill. For purposes of analysis, a seismic vessel transfer spill was estimated to range from <1-13 bb (BOEMRE 2010a, b). The <1 bbl minimum volume represents a spill where dry quick disconnect and positive pressure hoses function properly. The 13 bbl maximum spill volume represents a spill where spill prevention measures fail or fuel lines rupture. For purposes of analysis the lesser volume is used to estimate cumulative spill volumes. Using the maximum volume would overestimate the likely volume spilled at the upper end of the range. Should one fuel hose rupture occur the fate and effects would be similar to the upper range volume.

Refueling spills could range from no fuel spills to one per activity. The estimated fuel spills from maximum anticipated annual levels of geophysical or geological activities for Alternative 2 could range from zero bbl if no fuel spills occur to <7 bbl if every operation refuels, every refueling operation has a fuel spill, and spill prevention equipment functions properly. For Alternatives 3, 4, 5 and 6, small spills could range from zero if no fuel spills occur to <11 bbl if every operation refuels, every refueling operation has a fuel spill, and spill prevention equipment functions properly. Refueling operations for Beaufort Sea operations likely would occur at Prudhoe Bay's West Dock facility, in Tuktoyuktok, Canada, or at sea with the use of fuel supply vessels. Refueling operations in the Chukchi Sea likely would occur at sea with the use of fuel supply vessels.

Exploration Small Fuel Spill. For purposes of analysis, a ≤50 bbl spill was estimated to occur during exploration drilling operations from refueling (MMS 2009a, b; BOEMRE 2011a, b). For Alternative 2 the estimated fuel spills that could occur during exploratory drilling could range from zero if no fuel spills occur to 100 bbl if both exploratory drilling operations have a spill. For alternatives 3, 5 and 6 estimated fuel spills could range from zero to 200 bbl and for Alternative 4 could range from zero to 400 bbl.

Summary. Previous NEPA analyses, such as those for Shell's 2010 and 2012 Exploration Plans (MMS 2009a, b; BOEMRE 2011 a, c), concluded any effects from a 48 bbl spill would be localized and temporary (persisting up to 3 days). At the high end of the range, exploration spills would not overlap temporally or spatially, such that any single spill would likely be ≤50 bbl. Likewise the effects of seven spills <1 bbl (each) or 11 spills <1 bbl (each) cannot reasonably be expected to exceed those of a 48 bbl spill as was analyzed in Shell's 2010 and 2012 Exploration Plan (MMS 2009a, b; BOEMRE, 2011 a, c). Therefore the effects of seven spills <1 bbl (each) or 11 spills <1 bbl (each) would most likely be localized, persisting less than three days.

Given that small spills are low in intensity, temporary in duration, and local in extent, and that small spills would not overlap in time or space, they are analyzed only once for each resource under Alternative 2. Subsequent alternatives 3, 4, 5 and 6 reflect the same level of effect for small spills.

4.3 Mitigation Measures

Mitigation measures associated with this EIS (Appendix A) are placed into two categories for analysis:

Standard Mitigation Measures – These measures, which are required in all five of the action alternatives, are those that NMFS deemed appropriate to *require* in MMPA authorizations. These measures (e.g. shutdown zones, time/area closures to protect known subsistence uses) have been used consistently in past permits and authorizations.

Additional Mitigation Measures – These measures, which are evaluated *but not required* in all five action alternatives, may or may not be implemented in current and future activities depending on the outcome of the MMPA authorization processes (or other environmental compliance processes) associated with current and future actions. These measures are intended to include other reasonable potential mitigation measures, such as those that have been required or considered in the past or recommended by the public, which may or may not have been required or considered in the past.

The suite of standard and additional mitigation measures that are analyzed in this EIS are designed specifically to reduce adverse impacts to marine mammals and to subsistence uses of marine mammals. Therefore, the discussion and full analysis of the standard and additional mitigation measures, the degree to which the measures are expected to lessen impacts to the resource, their likely effectiveness, and their practicability for implementation are contained in the marine mammal and subsistence sections of Alternative 2 (Sections 4.5.2.4.15, 4.5.2.4.16, 4.5.3.2.3, and 4.5.3.2.5). As each measure is analyzed independently in this EIS, the additive evaluation and implementation of measures will occur at the MMPA authorization stage. Even though the measures are specifically designed to mitigate impacts to marine mammals and to ensure the availability of marine mammals for subsistence uses, there is the potential for some measures to mitigate impacts to other resources described in this EIS. Sections 4.5.1.7, 4.5.2.7, and 4.5.3.10 contain brief summaries regarding the mitigation measures for the Physical, Biological, and Social Environments.

As discussed in Chapter 2 (Section 2.4.2), NMFS' evaluation of the standard and additional mitigation measures is needed in order to better assess the programmatic appropriateness of each measure (i.e., based on the generalized expectations for a given year of projected activities) and to inform decisions of whether the measure should:

a) Be considered a Standard Mitigation Measure (i.e., required in every ITA for a given activity type);

b) Never be required; or

c) Be included in the Additional Mitigation Measure category, which means that the measure will be considered for inclusion as a requirement through future regulatory processes during which more specific information is known.

All Additional Mitigation Measures ultimately identified in the Final EIS for a particular activity type will be further evaluated for potential required inclusion for any specific proposed activity through the MMPA process (and potentially other environmental compliance processes) using the additional detail that will be available once applicants have determined the specific activities that they propose to conduct in a given year and submitted their applications. These measures will be further evaluated using this more specific information to determine the degree to which the measure is likely to reduce impacts to marine mammals or subsistence uses based on the proposed specified activity, the likely effectiveness of the measure, and the practicability of the measure. Some of the types of more specific information that will be used to make the decision of whether to require a given measure include:

- The timeframe, duration, and location of the proposed activity and the spatiotemporal overlap with marine mammal distribution and subsistence hunts of marine mammals;
- The specific characteristics of the sound sources used in the proposed activity;
- The availability and cost of the resources needed to carry out the measure;
- The timeframe, duration, and locations of other activities expected in the same season; and
- New information related to the likely success of the measure (from reports from previous years).

4.4 Direct and Indirect Effects for Alternative 1 – No Action

Under Alternative 1, NMFS would not issue any ITAs under the MMPA for seismic surveys or exploratory drilling in the Beaufort and Chukchi seas, and BOEM would not issue G&G permits or authorize ancillary activities in the Beaufort and Chukchi seas. There would be no direct or indirect effects to resources as a result of Alternative 1, other than to socioeconomics and land and water use, management, and ownership. Therefore, only these two resources are discussed under Alternative 1.

Over the past several years, there has been a certain level of oil and gas exploration activity permitted by BOEM in the Beaufort and Chukchi seas, with associated MMPA ITAs issued by NMFS. This level of activity is greater than what is associated with Alternative 1 (no activity permitted) but less than what is associated with Alternative 2. The impacts analyzed for Alternative 1 would be less than the status quo for oil and gas exploration activities in the Beaufort and Chukchi seas.

4.4.1 Social Environment

4.4.1.1 Socioeconomics

Offshore seismic activity and exploration drilling is conducted to locate potential commercially recoverable sources of oil and gas. Offshore exploratory drilling is a precursor to oil and gas development and production if potentially commercial quantities of oil are found in a prospect. Alaska OCS development is anticipated to be a significant driver in "the next generation of economic activity by extending the duration of the petroleum industry in the state" (ISER 2009). The Institute of Social and Economic Research (ISER) at the University of Alaska, Anchorage conducted a study for Shell Exploration and Production to estimate the economic impacts of exploration, development, and production in three Alaska OCS areas (Beaufort Sea, Chukchi Sea, and North Aleutian Basin). Based on certain assumptions and production scenarios, ISER concluded that OCS development could offset the decline of petroleum production on state lands on the North Slope.

A number of issues associated with economic development and potential socioeconomic effects were raised during the scoping process. Because of the potential importance of offshore oil and gas development to Alaska's economy, there was interest in the potential for this EIS to result in greater predictability in the issuance of MMPA ITAs. New natural gas production from the Alaska OCS was also perceived to enhance the economic viability of the proposed natural gas pipeline from Alaska to the Lower 48. Also voiced during scoping was the concern that the personal incomes of whaling crews could be negatively impacted because greater deflection of marine mammals could make subsistence activities more expensive.

The following discussion of direct and indirect effects of the Alternatives (which were presented in Chapter 2) describes the nature of the socioeconomic contribution of offshore (including on-ice) seismic and exploratory drilling activities in the Beaufort and Chukchi seas. Based on the nature of these activities, this section describes effects on public revenues and expenditures, employment and personal income, demographic characteristics, and demand on social organizations and institutions.

The analysis of impacts is general in nature because publicly available economic information has not disaggregated the impact of exploration activities from the larger process of development and production nor estimated contributions at a community level. Section 3.3.1.2 provides the best available detailed information regarding employment and personal income in the NSB and NAB.

The level of impacts will be based on levels of intensity, duration, geographic extent, and context, as shown in Table 4.4-1.

Table 4.4-1 Impact Levels for Effects on Socioeconomics

Impact Component	Effects Summary		
Magnitude or Intensity	**Low**: <5% increase or decrease in social indicators	**Medium**: 5% to 10% increase or decrease in social indicators	**High**: >10% increase or decrease in social indicators (such as employment, population, or tourism levels)
Duration	**Temporary**: Changes in social indicators last less than one year	**Long-term**: Changes in social indicators extend up to several years	**Permanent**: Changes in social indicators persist after actions that caused the impacts cease
Geographic Extent	**Local**: Affects a sector of a single community; may alter but does not impair functions of that sector	**Regional**: Affects two or more communities in the region or multiple sectors of a single community	**State-wide**: Affects multiple sectors of multiple communities in the region and/or a single sector of a community outside the region
Context	**Common**: Affects communities that are not minority or low-income	**Important**: Not Applicable	**Unique**: Affects minority or low-income communities

4.4.1.1.1 Direct and Indirect Effects

Public Revenue & Expenditures

Under Alternative 1, there would be no new (or there would be delayed) public revenue sources associated with offshore exploration activities and any subsequent production. There would be no change of expenditures to the public sector from federal, state, or local governments. If Alternative 1 results in no issuance of authorizations or permits by NMFS and BOEM, respectively, then exploratory drilling and new leasing could be delayed or may not occur. Furthermore, if there is no prelease seismic surveying or issuance of MMPA ITAs, potential lessees might not participate in the OCS lease sales as scheduled under the 2012-2017 Program; as a result, revenue from bids and rentals might not be generated.

There is potential corresponding loss in State revenue from foregone taxes, and to the NSB from foregone facility improvements to handle produced petroleum. Because NMFS and BOEM have assumed that no staging activities would occur out of Kivalina or Kotzebue, as such activities have not occurred from those communities in the past, there would be no change to municipal tax revenue for the NAB. Potential production foregone associated with Alternative 1 could result in a decline in domestic production and an increase in the import of fossil fuels from other countries, which would not have the same revenue benefits as production from federal and state waters in the Beaufort and Chukchi seas. Further, potential offshore production would not occur or would be delayed.

Although the likelihood of exploration resulting in production cannot be predicted, and the magnitude is unknown, any production from a successful oil discovery would likely be transported through the Trans Alaska Pipeline System (TAPS). Current TAPS throughput has fallen to one-third its peak flow, and any OCS contribution would extend its commercial life. This would continue state and local royalty oil revenue that otherwise would end immediately upon closure of TAPS. If the inability of NMFS and BOEM to issue authorizations and permits delays offshore leasing and exploration, OCS production could occur too late to contribute to TAPS throughput.

Employment & Personal Income

Alternative 1 would result in lost opportunities for employment and personal income in areas providing support activities in the NSB, NAB, Nome, and Dutch Harbor. This includes lost employment to NSB and NAB residents as PSOs, subsistence advisors, Com Center staff, and spill response personnel. There could also be lost employment and personal income to oil and gas professionals in Anchorage, other parts of the state, and nation as a result of Alternative 1. An example of the number of unrealized jobs can be found in Tables 4.5-23 and 4.5-24.

Demographic Characteristics

Under Alternative 1, the potential for new local jobs associated with exploration activities would be unrealized. However, the small number of local hire positions and short term nature of the work is not enough to cause any outmigration, therefore there would be no change to coastal communities' populations in the Beaufort and Chukchi seas.

Social Organizations & Institutions

Under Alternative 1, there would be no impact on social organizations and institutions because there would be no new revenue moving throughout municipalities, native villages or corporations, and there would be no additional demand for non-governmental organization (NGO) response.

4.4.1.1.2 Conclusion

The general direction of the socioeconomic direct and indirect impacts under Alternative 1 is generally negative, due to unrealized local employment and tax revenue to local, state, and federal governments and the strong probability that at a minimum the federal government would return several billion dollars to the current leaseholders. In terms of local employment and sales tax, the potential impact is low in magnitude because total personal income and local employment rates are not increased by more than five percent. The duration of the local socioeconomic impacts are temporary because it is not year-round. However, the activity is scheduled to occur over a fixed number of years. With regard to potential unrealized revenue for state and federal governments, the likelihood of exploration resulting in production cannot be predicted, and the magnitude is unknown but is likely to be medium to high as only a large discovery would be developed. However, these potential negative economic impacts of the activity are statewide and even nationwide. The context of the socioeconomic impacts, the people that would experience the flow of workers and research vessels, are considered unique Iñupiat communities. Therefore, the summary impact level for socioeconomics is moderate.

4.4.1.2 Land and Water Ownership, Use, and Management

Section 4.1.3 describes the basic significance criteria used to assess direct and indirect impacts throughout this document. For land and water ownership, use and management, impact levels would be derived primarily from the response needed by owners or managers, and whether or not the impacts were perceived as positive or negative. A major adverse impact would be one associated with a forced change in ownership or management that is inconsistent with existing plans and management regulations. It is assumed that, for all action alternatives, existing land use and management is in compliance with current federal and state regulations and existing management plans and is consistent with other land uses. Currently, the BOEM manages oil and gas activities in federal waters, and these activities comply with federal management guidelines. Similarly, ADNR manages oil and gas activities in state waters, and permitted exploration activities comply with state management guidelines. Offshore activities are subject to voluntary compliance with the NSB and the NAB management guidelines. For this section, the basic significance criteria are further refined as described in Table 4.4-2.

Table 4.4-2 Impact Criteria for Land and Water Ownership, Use, and Management

Impact Category	Intensity Type	Definition
Intensity (Magnitude)	Low	Land/water ownership/use or development rights do not change and/or owner need not respond to action in any substantive way; action is substantially consistent with existing land use and management plans.
	Medium	Changes in land/water ownership/use or development rights are minor and/or owner must respond to the action, but response is minor or routine. Action is neither wholly consistent nor wholly inconsistent with existing uses and management plans.
	High	Changes in land/water ownership/use are major and/or owner must respond in substantial ways to the action—change in ownership (condemnation) or substantial change in management– major inconsistency with land management plan that forces amendment of plan.
Duration	Temporary	Land/water use, ownership or management changes do not occur, are expected to be infrequent, or last only a single season.
	Long term	Land/water use, ownership, or management changes may reasonably be expected to convert (or revert) to another use frequently, or extend up to several years.
	Permanent	Land/water use, ownership, or management changes are expected to have a permanent change that would last beyond the life of the plan even if the actions that caused the change were to cease.
Extent	Local	Impacts would be limited geographically; impacts would not extend to a broad region or a broad sector of the population.
	Regional	Impacts would extend beyond a local area, potentially affecting resources or populations throughout the EIS project area.
	State-wide	Impacts would potentially affect resources or populations beyond the region or EIS project area.
Context	Common	The supply of land or water for an affected use or management category is extensively available, serves no specialized function and is not identified as having special, rare, protected or unique characteristics in an adopted management plan.
	Important	The supply of land or water for an affected use or management category is moderately available, serves a specialized function but is not identified as having special, rare, protected, or unique characteristics in an adopted management plan.
	Unique	The supply of land or water for an affected use or management category is constrained and is identified as having special, rare, protected, or unique characteristics in an adopted management plan.

Under Alternative 1, NMFS would not issue ITAs under the MMPA for seismic surveys or exploratory drilling in the Beaufort and Chukchi seas. From a land ownership and use perspective, this is characterized as the inability to issue permits and authorizations, as compared to the denial of a permit/authorization based on regulatory review. Alternative 1 would result in leaseholders not being able to drill, and would affect the leaseholders' ability to pursue exploration and discovery of hydrocarbons. This would run contrary to current federal and state management of offshore waters. It would cause some change in activity levels or procedures and affect management plans for land and water in the EIS project area.

4.4.1.2.1 Direct and Indirect Effects on Land and Water Ownership

Federal Ownership

Because BOEM has awarded leases in the Beaufort and Chukchi seas for the purpose of exploring for and developing petroleum resources in the federal OCS, the non-issuance of G&G permits and authorizing ancillary activity by BOEM would prevent leaseholders from pursuing exploration activities in compliance with federal regulations. This would indirectly affect BOEM mandate to manage development of offshore energy and balance economic development, energy indepdence, and environmental protection by constraining activities on leases awarded and represents a high intensity, long-term adverse effect of regional extent. There would be no indirect effect to federal ownership by constraining activities on leases. The federal ownership would be maintained.

State Ownership

The ADNR has awarded leases in the Beaufort Sea for the purpose of exploring for and developing petroleum resources. ADNR could continue to permit activities on leases awarded, but the inability to obtain ITAs from NMFS would prevent leaseholders from pursuing exploration activities if there is the potential for take of marine mammals, as non-compliance with federal regulations could constrain their ability to utilize their leases. This would indirectly affect state ownership by constraining activities on leases awarded and represents a high intensity, long-term adverse effect of regional extent. There would be no indirect effect to state ownership by constraining activities on leases. The state ownership would be maintained.

Private Ownership

The award of oil and gas leases to a private entity is a right to use property and is characterized as a form of private ownership for the purposes of this EIS. The Supreme Court has recognized that "[u]nder OCS Lands Act's plain language, the purchase of a lease entails no right to proceed with full exploration, development, or production…; the lessee acquires only a priority in submitting plans to conduct these activities" (Secretary of the Interior v. California, 464 U.S. 312, 339 [1984]. The inability of BOEM and NMFS to issue permits and authorizations, as compared to the denial of a permit/authorization based on regulatory review, would prevent leaseholders from pursuing exploration activities on awarded federal and state offshore oil and gas leases in compliance with federal regulations and would constrain their ability to utilize their leases. This represents a high intensity, long-term adverse effect of regional extent on lease awarded to private parties and their exploration rights.

There would be no direct or indirect effects on Alaska Native land ownership from the inability of BOEM and NMFS to issue permits and authorizations.

Borough and Other Municipal Lands

There would be no direct or indirect effects on borough and other municipal land ownership from the inability of BOEM and NMFS to issue permits and authorizations.

4.4.1.2.2 Conclusion

Based on Table 4.4-2 and the analysis provided above, the impacts on land and water ownership under Alternative 1 are described as follows. The magnitude of ownership impacts on federal and state waters is high because major changes in the ability to conduct activities on leases on federal and state waters will result from this action. The duration of impact would be long-term because leaseholders will not be able to utilize leases for exploration of oil and gas resources. The extent of impacts would be regional, covering federal and state leases in the Beaufort and Chukchi seas. The context of impact would be important because the affected federal and state waters are currently available for leasing, and no additional waters would be available for exploration under the characteristics of this alternative. In total, the direct and indirect impacts on land ownership are considered to be major; they are high intensity, long-term, regional, and result in changes of federal, state, and private development rights by effectively preventing exploration for oil and gas resources in compliance with federal regulations.

4.4.1.2.3 Direct and Indirect Effects on Land and Water Use

Recreation

There would be no direct or indirect effects on recreation use from the inability of BOEM and NMFS to issue permits and authorizations.

Subsistence

The inability of BOEM and NMFS to issue permits and authorizations could reduce or eliminate potential conflicts between oil and gas exploration activities and subsistence uses. These conflicts can be mitigated to some degree through plans of cooperation and other measures. For more detail, see Section 4.7.3.2, Subsistence.

Industrial

The inability of BOEM and NMFS to issue permits and authorizations could reduce or eliminate oil and gas exploration activities on existing leases in federal and state waters. This would lead to an overall reduction in ship traffic and the potential for a decrease in or elimination of support activities like crew change and survey preparations in areas such as Prudhoe Bay, Barrow, Wainwright, Nome, and Dutch Harbor. These activities require facilities and structures (e.g. warehouses, repair and maintenance shops) in areas generally zoned for industrial use. A reduction in support activities could create decreased demand for industrial facilities resulting in higher vacancy rates and building underutilization when compared to current levels.

Residential

There would be no direct or indirect effects on residential use from the inability of BOEM and NMFS to issue permits and authorizations.

Mining

There would be no direct or indirect effects on mining from the inability of BOEM and NMFS to issue permits and authorizations.

Protected Natural Lands

There would be no direct or indirect effects on protected land use from the inability of BOEM and NMFS to issue permits and authorizations.

Transportation

The inability of BOEM and NMFS to issue permits and authorizations could reduce or eliminate transportation activities supporting oil and gas exploration activities on existing leases in federal and state waters. This would be reflected in lower numbers of ships, aircraft, and surface vehicles and a reduction in use of affiliated docks, airstrips, and roads. Initially, lower usage would place less maintenance demand on these facilities. However, chronically low usage can have a long term detrimental effect on maintenance and funding priorities resulting in accelerated infrastructure deterioration. Deteriorating infrastructure then impacts the viability of surrounding land uses that rely on it. Transportation uses most likely to be affected would occur primarily in Prudhoe Bay, Barrow, Wainwright, Nome, and Dutch Harbor.

Commercial

The inability of BOEM and NMFS to issue permits and authorizations could reduce or eliminate commercial uses supporting oil and gas exploration activities on existing leases in federal and state waters. This could indirectly affect commercial land use if demand is reduced for the sale of goods and services to support exploration activities. This would reduce the amount of crew and resupply activity in port communities and could impact retail stores, maintenance equipment suppliers, restaurants, taxi services, and similar commercial businesses. A reduction in demand would be reflected in reduced sales and could result in struggling businesses, business closures, and the rezoning of land to other uses. Commercial uses most likely to be affected would occur primarily in Prudhoe Bay, Barrow, Wainwright, Nome, and Dutch Harbor.

4.4.1.2.4 Conclusion

Based on Table 4.4-2 and the analysis provided above, the impacts on land and water use under Alternative 1 are described as follows. The magnitude of use impacts on federal and state waters is high because major changes in the ability to conduct activities on leases in federal and state waters will result from this action, also affecting transportation and commercial uses that support these activities. The duration of impact would be long-term because leaseholders will not be able to utilize leases for exploration of oil and gas resources. The extent of impacts would generally be regional, covering federal and state leases in the Beaufort and Chukchi seas. However, supporting transportation and commercial uses would be affected out of region, in areas that provide support services such as Nome and Dutch Harbor. The context of impact would be important because the affected federal and state waters are currently available for leasing, and no existing or additional waters would be available for exploration under the characteristics of this alternative. In total, the direct and indirect impacts on land use are considered to be major; they are high intensity, long-term, regional, and result in changes of federal, state, and private development rights by effectively preventing exploration for oil and gas resources in compliance with federal regulations. This would be offset to some degree by the potential reduction/elimination in conflicts with subsistence uses in the EIS proposed project area.

4.4.1.2.5 Direct and Indirect Effects on Land and Water Management

Federal Land and Water Management

Because BOEM has awarded leases in the Beaufort and Chukchi seas for the purpose of exploring for and developing petroleum resources in the federal OCS, the inability to issue ITAs and G&G permits and authorizing ancillary activities would prevent leaseholders from pursuing exploration activities in compliance with federal regulations and constrain their ability to utilize their leases. This would indirectly affect federal management by constraining activities on leases and conflicting with the BOEM mandate to manage development of offshore energy and balance economic development, energy indepdence, and environmental protection. This represents a high intensity, long-term adverse effect of national extent.

State Land and Water Management

The ADNR has awarded leases in the Beaufort Sea for the purpose of exploring for and developing petroleum resources. ADNR could continue to permit activities on leases awarded, but the inability to obtain ITAs from NMFS would prevent leaseholders from pursuing exploration activities in compliance with federal regulations and constrain their ability to utilize their leases. This would indirectly affect state management of offshore waters by constraining activities on leases awarded and conflicting with the management objective of allowing oil and gas exploration and development of state waters. Preventing oil and gas exploration and development of the federal OCS would eliminate any oil production that could extend the commercial life of TAPS. This represents a high intensity, long-term adverse effect of statewide extent.

Private Land Management

The inability of BOEM and NMFS to issue permits and authorizations for offshore oil and gas exploration activities could have an adverse effect on management of Alaska Native corporation lands that would provide support for offshore oil and gas activities. This would apply to lands intended to provide support activities primarily in Wainwright, where there has been discussion of developing marine support facilities, and potentially in Barrow.

Borough Land and Water Management

The inability of BOEM and NMFS to issue permits and authorizations for offshore oil and gas exploration activities would reduce or eliminate potential conflicts of exploration activities with NSB and NAB comprehensive plans and Land Management Regulations coastal management policies. However, compliance with Borough Land Management Regulations is undertaken on a voluntary basis for activities occurring on state and federal waters. The Alaska Coastal Management program was not reauthorized by the State legislature in 2011 and is no longer in effect.

4.4.1.2.6 Conclusion

Based on Table 4.4-2 and the analysis provided above, the impacts on land and water management under Alternative 1 are described as follows. The magnitude of management impacts on federal and state waters is high because major changes in the ability to conduct activities on leases on federal and state waters will result from this action and conflict with management objectives. The duration of impact would be long-term because leaseholders will not be able to utilize leases for exploration of oil and gas resources. The extent of impacts would generally be regional, covering federal and state leases in the Beaufort and Chukchi seas, although some changes in land use could occur in support areas out of the region. The context of impact would be important because the affected federal and state waters are currently available for leasing, and no additional waters would be available for exploration under the characteristics of this alternative. In total, the direct and indirect impacts on land and water management are considered to be major; they would be high intensity, long-term, regional, and result in changes of federal and state land and water management by effectively preventing exploration for oil and gas resources.

4.4.2 Mitigation Measures Under Alternative 1

No standard mitigation measures associated with socioeconomics would be implemented under Alternative 1 as no oil and gas exploration activities would occur. Additionally, there would be no additional mitigation measures employed under Alternative 1 as no oil and gas exploration activities would occur.

4.5 Direct and Indirect Effects for Alternative 2 – Authorization for Level 1 Exploration Activity

4.5.1 Physical Environment

4.5.1.1 Physical Oceanography

Physical characteristics of the ocean in the EIS project area are discussed in Section 3.1.1 of this EIS. The discussion in Section 3.1.1 is divided into several sections, with each section focusing on particular physical characteristics of the ocean:

- Water Depth and General Circulation;
- Currents, Upwellings, and Eddies;
- Tides and Water Levels;
- Stream and River Discharge; and
- Sea Ice.

The analysis below discusses the effects of the proposed activities on the physical characteristics of the ocean and potential hazards that may be caused by physical characteristics of the ocean on the proposed activities (i.e. risks to human safety). The analysis of alternatives is structured in a fashion parallel to the discussion of physical oceanography in Section 3.1.1. The level of impacts on physical oceanography will be based on levels of intensity, duration, geographic extent, and context, as shown in Table 4.5-1.

Table 4.5-1 Impact Levels for Effects on Physical Oceanography

Impact Component	Effects Summary		
Magnitude or Intensity	**Low**: Changes in physical characteristics of the ocean may not be measurable or noticeable	**Medium**: Noticeable changes in physical characteristics of the ocean	**High**: Acute or obvious changes in the physical characteristics of the ocean including waves, currents, tides, sea ice
Duration	**Temporary**: Physical characteristics of the ocean would be impacted infrequently but not longer than the span of the project season and would be expected to return to pre-activity states at the completion of the activity	**Long-term**: Physical characteristics of the ocean would be impacted through the life of the project and would return to pre-activity states at some time after completion of the project	**Permanent**: Chronic effects; physical characteristics of the ocean would not be anticipated to return to previous state
Geographic Extent	**Local**: Impacts limited geographically; <10% of EIS project area affected	**Regional**: Affects physical characteristics of the ocean beyond a local area, potentially throughout the EIS project area	**State-wide**: Affects physical characteristics of the ocean beyond the region or EIS project area
Context	**Common**: Affects usual or ordinary physical characteristics of the ocean	**Important**: Affects semi-unique physical characteristics of the ocean	**Unique**: Affects unique physical characteristics of the ocean

4.5.1.1.1 Direct and Indirect Effects

Water Depth and General Circulation

Effects on water depth and general circulation resulting from the activities described under Alternative 2 would be restricted to changes in bathymetry that would result from deposition of material discharged to the seafloor during exploratory drilling programs. Certain permitted materials, including drill cuttings and drilling fluids, would be discharged to the water in the vicinity of the drilling activity (see Section 2.3.3 - Exploratory Drilling Activity Discharges and Emissions). The discharged cuttings and drilling fluids would be composed of a slurry of particles with wide ranges of grain sizes and densities, ranging from liquids and neutrally-buoyant colloids to gravel (Neff 2005). Most cuttings solids would have densities between 2.30 to 2.65 g cm^{-3}, whereas barite (a common component of drilling muds) has a density of 4.3 g cm^{-3} (Neff 2005). As a result of the physical and chemical heterogeneity of typical drill cuttings and drilling fluids, the mixture would undergo rapid fractionation (separate into various components) as it is discharged to the ocean. The larger particles, which represent about 90 percent of the mass of drilling mud solids, would settle rapidly out of solution, whereas the remaining 10 percent of the mass of the mud solids consisting of fine-grained particles would drift with prevailing currents away from the drilling site (NRC 1983, Neff 2005). The fine-grained particles would disperse into the water column and settle slowly over a large area of the seafloor, whereas coarser and denser particles would be deposited on the seafloor within several hundred meters of the point of discharge, forming a mud/cuttings pile that would affect water depths near the drilling site (Figure 4.5-1) (Neff 2005, NRC 1983).

A working definition of a cuttings pile is taken to be “a discrete accumulation of material clearly identifiable as resulting from material discharged from drilling activities, and forming a topographic feature distinct from the surrounding seabed” (adapted from Gerrard et al. 1999).

The distance traveled by discharged particles, and thus, the spatial extent and depth of the cuttings pile would depend not only upon the attributes of the discharged material but also upon the rate and duration of the discharge, the distance between the discharge point and the seafloor, lateral transport of discharged material in the water, turbulence, and local current speeds (MMS 2002, Neff 2005). Modeled distribution and loading of material on the seafloor following discharges of drill cuttings to offshore waters suggests that maximum loading of the seafloor from drilling waste solids would be 64 kg m^{-2}, equating to a depth of about 4 cm (1.6 inches), in an area adjacent to a platform (Smith et al. 2004, Neff 2005). However, cuttings pile heights measured in the North Sea under conditions different from those used in the model are 15 to 19 m (49 to 62ft) for cuttings piles with volumes of 40,000 to 45,000 m^3 (251,592 to 283,041 bbl) (Gerrard et al. 1999, Koh and Teh 2011). Exploratory wells are estimated to discharge about 1,000 m^3 (6290 bbl) of dry solids over the life of the well (NRC 1983). In 2012, the EPA released information regarding the deposition of open water drilling fluid solids in the Beaufort and Chukchi Seas in relation to Shell’s exploration drilling programs on leases in both OCS regions (EPA 2012c, d). In the Beaufort Sea, the maximum deposition for a slower current speed of 0.1 m/s (0.32 ft/sec) occurs from 100 to 500 m (328 to 1,640 ft) from the discharge point while the maximum deposition occurs 800 to 1,400 m (2,624 to 4,600 ft) from the discharge point for a higher current speed of 0.3 m/s (1 ft/sec) (EPA 2012c, d). Current speeds in the Beaufort and Chukchi seas can exceed 0.3 m/s. Additional information can be found in the EPA’s evaluations (2012c, d).

The overall effect of material discharged from exploration wells on water depth in the proposed action area would depend on the characteristics of the discharged material, the rate and duration of the discharge, the distance between the discharge point and the seafloor, lateral transport of discharged material in the water, turbulence, and local current speeds (MMS 2002, Neff 2005). Changes in water depth from discharged material would have only minor effects on the physical resource character of the proposed action area. Those effects would be low-intensity, permanent, and would affect a common resource as defined in the impact criteria in Section 4.1 of this EIS.

Currents, Upwellings, and Eddies

Seismic surveys, site clearance and shallow hazards surveys, and on-ice seismic surveys would have only negligible effects on currents, upwellings, and eddies within the proposed action area.

Construction of artificial islands, which could occur in nearshore state waters of the Beaufort Sea at a rate of one island per year under Alternative 2, would result in medium-intensity, permanent, localized effects on nearshore currents in the waters adjacent to the artificial islands. Over the life of this EIS, those effects would be minor and would occur only if artificial islands are constructed to support exploratory drilling activities. Use of drillships or jackup rigs in deeper state and federal waters would be temporary in nature and have only a seasonal presence of extremely limited size and geographic distribution, and would have negligible effect on currents, upwellings, and eddies within the proposed action area.

Tides and Water Levels

The activities described under Alternative 2 would be temporary in nature and would have only a seasonal presence of extremely limited size and geographic distribution, and would not affect tides or water levels within the proposed action area.

However, wind, waves and storm surge would potentially impact seismic and exploratory drilling activities, and could influence human safety as a result of the activities described under Alternative 2.

Stream and River Discharge

The activities described under Alternative 2 would occur in marine waters and would generally not affect stream and river discharge within the proposed action area. Exploratory drilling in state waters on grounded ice could occur from manmade reinforced ice "islands," but would have negligible effects on stream and river discharge within the nearshore portion of the proposed action area.

Sea Ice

Seismic surveys and site clearance and shallow hazards surveys conducted during the open water period would not affect sea ice in the proposed action area.

Icebreaking activities and thermal inputs associated with in-ice seismic surveys and exploratory drilling activities in the Beaufort and Chukchi seas would result in noticeable changes in the character of the sea ice in the vicinity of the icebreaking activity. However, the effects of icebreaking activities would be temporary as seawater exposed to the air as a result of icebreaking activities would freeze within hours of the activity, effectively replacing the broken ice. Repeated icebreaking within a given channel may lead to formation of 'brash ice' and an overall thickening of ice within the channel (Ettema and Huang 1990). Icebreaking activity would have medium-intensity, temporary, and local effects on sea ice. These effects would be minor and would affect a common resource.

On-ice seismic surveys involving truck-mounted vibrators would have minor effects on sea ice within the proposed action area. On-ice vibroseis operations would require stable sea ice at least 1.2 m (3.9 ft) thick. Such surveys would generally occur only between January and May over landfast ice or stable pack ice near the shore. Noticeable changes to the character of the ice would result from marking the ice in order to designate source receiver locations and from construction of snow ramps to smooth rough ice within the survey area. The effects of these activities on sea ice would be medium-intensity, local, temporary, and would affect a resource that is common in the proposed action area.

Construction of ice islands, which could occur in nearshore state waters of the Beaufort Sea under Alternative 2, would result in medium intensity, temporary, localized effects on sea ice in state waters of the Beaufort Sea. These effects would be minor, and would occur only if artificial islands are constructed to support exploratory drilling activities.

The presence of sea ice in lease and non-lease areas targeted for open water seismic exploration and exploratory drilling could result in changes to the schedule, location and duration of exploratory activities. The presence of ice also represents a potential hazard to vessels and exploratory drilling platforms. Industry operators in offshore areas have developed procedures for managing sea ice, including changes to schedule, vessels dedicated to ice management, and procedures for taking drilling platforms off location until potential hazards subside.

In-ice and on-ice seismic exploration activities could experience similar and additional hazards from sea ice, including the potential for ice override events. On-ice exploration activities have established protocols for response to potential ice hazards. Moving ice is not expected to impact drilling on artificial ice islands, but storm surge and ice override events could have potential effects. Within the Beaufort Sea, where drilling on artificial ice islands could occur in state waters, much of the area is protected from ice override by barrier islands. Individual drilling operations would need to assess the potential for ice related hazards and develop appropriate design and operation protocols. In-ice exploration activities would use an ice breaker for the purpose of ice management and have established protocols for response to potential ice hazards.

<u>4.5.1.1.2 Conclusion</u>

The overall effects of Alternative 2 on physical ocean resources would be of medium intensity, temporary, local, and would affect common resources as defined in the impact criteria in Section 4.1 of this EIS. The overall direct and indirect effects of the proposed level of activity described in Alternative 2 on physical ocean resources in the EIS project area would be minor.

4.5.1.2 Climate

The Intergovernmental Panel on Climate Change (IPCC) (2007) reports the Alaskan Arctic has reacted to changes in climate over the past century. Emissions of greenhouse gases (GHGs) around the world are believed to be one of several factors driving the changes, which are attributed to atmospheric warming of the Earth's climate and referred to as the greenhouse effect. As a result, the Council on Environmental Quality (CEQ) has provided draft guidance for consideration of climate change when proposed federal actions are evaluated under NEPA (CEQ 2010). Following this guidance, NMFS finds the proposed action and alternatives have the potential to emit GHGs into the atmosphere in quantities that may be meaningful to an evaluation of climate change. Consequently, GHG emissions due to the proposed action and alternatives are quantified and discussed with respect to the potential contribution to climate change. Greenhouse gas emissions are also discussed relative to the relationship to (or affect on) the proposed action and alternatives.

The GHGs that EPA regulates under the Clean Air Act are, carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6). The combustion of fossil fuels, such as diesel and gasoline, is responsible for the majority of GHGs. For example, when burned, a gallon of regular diesel fuel produces 22.4 pounds of CO_2, and burning a gallon of regular gasoline (with 10 percent ethanol) produces 17.7 pounds of CO_2 (BP, 2005; EIA, 2012). Because the overwhelming majority of GHG emissions from the combustion of fossil fuels are CO_2, emissions, the other GHGs are typically reported in terms of equivalency to the global warming potential (GWP) of CO_2. As such, total GHG emissions are referred to collectively as "CO_2 equivalent" emissions, or CO_2e.

Refer to Section 3.1.4.4 (*Climate Change in the Arctic*) for a thorough discussion of climate systems.

<u>4.5.1.2.1 Direct and Indirect Effects</u>

Direct effects contributing to climate change would occur as a result of CO_2e emissions caused by the drilling and seismic vessels proposed to be used under this alternative. Indirect effects occur due to the operation of vessels and aircraft in support of the proposed activities but are separated from the original project in either time or space. In addition, the sources identified as causing indirect effects are those that remain under practical control and responsibility of the operator, assuming the effects can be quantified.

Direct Effects

Direct effects contributing to climate change under this alternative would occur from CO_2e emissions occurring during operation of engines used to power the drillships, drilling units, seismic vessels, and all other onboard engines and generators necessary to operate the vessels and equipment. The engines are powered by diesel oil, a fuel produced from a fossil source of carbon that when burned adds CO_2e emissions to the biosphere contributing to climate change.

Indirect Effects

Indirect effects to resources under this alternative that have the potential to contribute to climate change are emissions of CO_2e from the operation of crew boats, supply vessels, icebreaker vessels, aircraft, and other support vessels needed to complete and protect the activities and programs proposed under this alternative. The owner or operator would have an oversight role in these activities and would have the authority to limit or otherwise control operations of the vessels and hence the emissions. The activities proposed under this alternative, which include EPs and seismic surveys, do not include removal or extraction of any product of drilling. Therefore, potential emissions from the transport of raw materials, refining the oil and gas product, usage of oil and related products, or the manufacturing of plastic products and asphalt from crude oil is not considered under this or any other alternative in this EIS.

Regulatory Reporting and Permitting

The EPA established the portion of the Greenhouse Gas Reporting Rule that applies to petroleum and natural gas systems in 2010 (75 FR 74458, November 30, 2010). Established at 40 CFR Part 98, Subpart W, the EPA requires the owner or operator of certain stationary facilities to report potential emissions of CO_2e that is expected to equal or exceed 25,000 metric tons per year (metric tpy). The EPA finalized the last step to the phase-in approach to permitting emissions of CO_2e under the Clean Air Act effective on August 13, 2012 (77 FR 41051, Jul. 12, 2012). Under the last step, certain new and existing stationary industrial facilities identified by the EPA with CO_2e emissions that equal or exceed 100,000 metric tpy must obtain an operating permit under Title V of the Clean Air Act. The data are used by EPA to implement the Clean Air Act Section 103(g) regarding improvements in strategies and technologies for preventing or reducing air pollutants, and to inform policy-makers on possible regulatory actions to address and reduce CO_2e emissions. The rule, as it applies to the oil and gas industry, pertains only to the extraction of crude petroleum and natural gas, the transportation by pipeline of natural gas, and natural gas distribution facilities. Consequently, the activities and programs proposed under this alternative are not subject to the EPA Greenhouse Gas Reporting Rule and a permit is not required. However, reporting the total potential emissions of CO_2e should be disclosed in any environmental review under the NEPA..

CO_2e Emissions Inventory

Under this alternative several programs and activities are proposed including exploration plans, multiple seismic surveys (some including an icebreaker vessel), shallow hazards surveys, and on-ice seismic surveys plans within the U.S. Chukchi and Beaufort seas. The specific description and number of each of these programs and activities proposed for the U.S. Chukchi and Beaufort seas, on an annual basis, were summarized earlier in Table 2.4 (*Activity Definitions*) and Section 2.4.5 (*Alternative 2 – Authorization for Level 1 Exploration Activity*). The estimated potential annual emissions of CO_2e for each type of activity and program proposed under this alternative are provided in **Table 4.5-2**. The data in this table assume no controls to reduce emissions.

Effects of this Alternative on Climate Change

Existing climate models are not refined enough to accurately predict changes in the climate within the timeframe considered under this EIS. This is because climate change resulting from CO_2e emissions occurs many years, often decades, after the emissions are generated and in locations far from the point of emission. Given the uncertainty of existing climate change models, it is not feasible to determine the effect of this alternative to such a degree that measurable consequences can be defined over a relatively short period of time (120-day drilling season or 76-day survey). Nonetheless, the potential impact of contributions to the CO_2e emission budget, particularly in the Arctic, is recognized as a concern by the EPA. Therefore, total annual CO_2e emissions will be reported for activities and programs once specific project details are proposed and available under this alternative.

Table 4.5-2 Estimated CO_2e Emissions by Activity and Program Type for the Arctic OCS

Activity/Program Types	Chukchi Sea OCS Annual CO_2e Emissions (metric tons per year)
2D/3D Seismic Survey (including one survey using an ice breaker vessel)	44,761
Site Clearance and High Resolution Shallow Hazards Survey Program	7,435
Exploration Plan	93,007
Total	**145,203**
Activity/Program Types	**Beaufort Sea OCS Annual CO_2e Emissions** (metric tons per year)
2D/3D Seismic Survey (including one survey using an ice breaker vessel)	58,405
Site Clearance and High Resolution Shallow Hazards Survey Program	7,435
On-Ice Seismic Survey	25
Exploration Plan	93,007
Total	**158,872**

---

Effects of Climate Change on Resources under this Alternative

Warming of permafrost could affect the ability and timeframe for moving large, heavy equipment over frozen tundra to the EIS project area. Keeping in mind that warming in the Arctic that could potentially impact environmental resources within the next five years would not be the result of the alternative, but from emissions worldwide within recent decades. The decrease in sea ice thickness and extent could affect timing and location of in-ice seismic and on-ice vibroseis surveys, as well as extend the season for drilling activities requiring ice-free conditions. The types of conditions that could affect activities under this alternative may require unique planning and engineering but are not expected to adversely affect the implementation of this alternative.

4.5.1.2.2 Conclusion

Direct and indirect impacts associated with climate are associated mainly with potential emissions of CO_2e that could, decades from now, contribute to changes in the environmental conditions already occurring in the Arctic and throughout the world. As such, the impacts to climate change cannot be measured on a project-level basis and instead are global in scope. However, data provided in Table 4.5-2 should be disclosed in NEPA documentation.

While there is no mandatory reporting or permitting required for CO_2e emissions that could potentially occur under this alternative, the contribution of CO_2e emissions should be reported in the environmental review to disclose potential contributions to climate change.

To control the degree of climate change taking place around the world, federal agencies, owners, and operators of CO_2e emission sources may use alternative fuels or after-market emission-reduction devices. Emissions of CO_2e and sulfur dioxide are reduced to some extent by the use of ultra-low sulfur diesel fuel, which is mandatory in Alaska for both on-road and non-road (including marine) diesel engines (71 FR 32450, June 6, 2006). Ultra-low sulfur diesel (ULSD) is diesel fuel containing a maximum of 15 parts per million (ppm) of sulfur; whereas regular diesel fuel had sulfur levels up to 3,000 ppm (EPA, 2012). In addition to sulfur emissions, using ULSD fuel would reduce fine particle emissions ($PM_{2.5}$), nitrogen oxides (NO_x), hydrocarbons (HC), and carbon monoxide (CO) emissions in diesel exhaust; the greatest emission reduction would occur in a 2007 or newer model-year engine. However, most of the engines used to power the ships for drilling and surveys under this alternative are likely to be pre-2007 models. Using ULSD fuel in older engines will not harm the engines and the degree of emission reduction would be less, nevertheless there would still be some reduction in emissions.

To increase emission reductions in older engines while using ULSD fuel, operators may invest in diesel retrofits, which are control devices that can be installed after-market on older engines. These devices can reduce emissions of criteria pollutants and VOCs. Use of the emission reduction devices that lead to improved engine performance and fuel economy, such as the Selective Catalytic Reduction device that reduces emissions of NO_2, also reduces emissions of CO_2e.

4.5.1.3 Air Quality

Activities associated with oil and gas exploration work that have the potential to affect air quality include: seismic surveys, site clearance and shallow hazards surveys, other various surveys (e.g. on-ice vibroesis and electromagnetic surveys), and exploratory drilling. A list of typical equipment used for these activities is provided in Table 2.2 *Summary of Typical Support Operations for Exploration Activities*, and includes survey vessels, diesel-fired power generating equipment needed for drilling and miscellaneous support activities, and various other vessels used in support of these survey and drilling activities (e.g., tugboats, supply boats, icebreakers, crew boats, oil spill response vessels, and aircraft). The majority of air emissions from these activities are due to fuel combustion used to power vessel propulsion and power generation. The federal and state regulated air pollutants that are associated with this alternative are summarized in Table 3.1-4 *Federal and State Ambient Air Quality Standards*, which is based on the National Ambient Air Quality Standards (NAAQS). The criteria pollutants mainly associated with combustion of diesel fuel include:

- CO – carbon monoxide,
- PM_{10} – coarse particulate matter,
- $PM_{2.5}$ – fine particulate matter,
- SO_2 – sulfur dioxide,
- NO_2 – nitrogen dioxide, and
- Pb – lead.

Also under consideration are emissions of volatile organic compounds (VOCs), not a criteria pollutant, but a precursor to the development of O_3; therefore, VOC is a regulated pollutant under other rules rather than the NAAQS. Fuel combustion releases lesser amounts of ammonia (NH_3) and reduced sulfur compounds (RSC) depending on fuel characteristics and applied control technologies, if any are used. While not specifically evaluated, the activities proposed under this alternative may release a limited amount of fugitive emissions from storage tanks (i.e. VOCs) and potential associated onshore activities (i.e. emissions of PM).

4.5.1.3.1 BOEM Air Quality Regulatory Program (AQRP)

Jurisdiction to authorize air emissions on the Arctic OCS was the responsibility of the EPA beginning in 1990 until amendments to the Clean Air Act Section 328 were enacted on December 23, 2011, through the Consolidated Appropriations Act, 2012 (Public Law [Pub. L.] 112-74). The signing of Pub. L. 112-74 transferred the jurisdiction for emission source control from the EPA to the Department of Interior, BOEM Alaska OCS Region (AOCSR), for the U.S. Beaufort Sea and Chukchi Sea OCS Planning Areas adjacent to the Alaska North Slope Borough (Arctic OCS) (Consolidated Appropriations Act, 2012). The authority supporting the restored jurisdiction is granted under Section 5(a)(8) of the OCS Lands Act, and the control procedures are structured under the BOEM Pollution Prevention and Control regulations (30 CFR Part 550 Subpart C). The other Alaska OCS Planning Areas remain under EPA jurisdiction by authority granted under the Clean Air Act Section 328 and regulated pursuant to 40 CFR Part 55. However, Pub. L. 112-74 did not change the jurisdiction of the State of Alaska Department of Environmental Conservation (ADEC). All actions within three miles of Alaska's coast remain within the jurisdiction of the ADEC and may require state air quality operating permits.

The BOEM Air Quality Regulatory Program (BOEM AQRP), which now applies to the Arctic OCS, requires a unique evaluation of emissions generated by individual stationary facilities on the OCS. The BOEM AQRP applies only while facilities are securely attached to the sea floor, regardless of whether the sources are permanent or temporary. The objective of the BOEM AQRP is to ensure that onshore effects from offshore drilling activities will be inconsequential (i.e. negligible) (47 FR 15128, March 7, 1980). To achieve this objective, the BOEM AQRP requires control of stationary-source emissions on the OCS only when the emissions are shown to have significant effects on the air quality of an onshore area. Emission controls refer to mechanical devices such as selective catalytic reduction (SCR) devices. Emission reduction strategies include operational modifications such as limiting operational hours or fuel use. The BOEM AQRP is not applicable to geophysical seismic surveys, shallow hazards surveys, and on-ice seismic surveys, as all emission sources for these surveys are mobile marine vessels. The BOEM AQRP applies only to stationary sources on the OCS, meaning drilling units that are securely attached to the sea floor (including drillships, drill rigs, and platforms).

Under the BOEM AQRP, the AOCSR requires emission control strategies only for stationary sources on the Arctic OCS under specific conditions. Referred to as "facilities," the stationary sources would include drill rigs, drillships, and platforms only while securely attached to the seafloor. Facilities with annual emission rates (tons per year) that do not exceed the calculated emission exemption thresholds are excused from further review and possible additional analysis under the BOEM AQRP (30 CFR 550.303(d)). The calculations for the emission exemption thresholds are based on the distance of the facility from the nearest onshore area. The exemption thresholds serve as a screening tool to eliminate from further review those facilities which will have no significant effect on the air quality of any onshore area. The BOEM AQRP does not assign exemption rates for emissions of CO_2e. The emission exemption threshold equations are in the form:

$$E = k * (d^{n})$$

where, E is the annual emission exemption threshold rate expressed in tons per year, and *d* is the distance between the facility and the nearest onshore area of the State, expressed in statute miles, and measured from the facility to the mean high water mark onshore; *n* is the pollutant-specific exponent, and k is the pollutant-specific constant, such that:

$E = 3400(d^{2/3})$ for CO emissions

$E = 33.3d$ for emissions of each, TSP, SO_2, NO_x, and VOC

Source: 30 CFR §550.303(d).

If not exempt, lessees would be required to conduct an air quality impact analysis (i.e. dispersion analysis) to compare facility-specific pollutant concentrations predicted to occur on the nearest onshore area to the EPA Significance Impact Levels (EPA SILs) published at 40 CFR 51.165(b)(2) and adopted under the BOEM AQRP at 30 CFR 550.303(e) as the "Significance Levels: Air Pollutant Concentrations" (SLs). Projects that exceed any of the EPA SILs on the shore are considered to cause, or contribute to, a violation of a national ambient air quality standard and thus generate a potentially significant air quality effect onshore. Conversely, onshore concentrations from a facility that are equal to or less than the EPA SILs are considered to be *de minimis* by the EPA and BOEM (i.e. negligible impact). Should the air quality impact analysis demonstrate that the onshore effects would exceed one or more of the EPA SILs, the application of BACT would be required to reduce emissions of the relevant pollutant(s). Note that significant effects from emissions of VOCs cannot be discerned through a dispersion analysis. When VOC emissions are not exempt, control technology and other strategies would be applied in lieu of a dispersion analysis.

No air quality permit is issued or required under the BOEM AQRP; rather, the AOCSR, Office of Environment, would conduct a critical appraisal of the air quality information provided in an EP, or other drilling plan, for compliance with the BOEM AQRP. None of the exemption thresholds may be exceeded if the emissions from the facility are to be considered exempt from further review under the BOEM AQRP. Should the appraisal result in such an affirmative finding of compliance with the BOEM AQRP, the AOCSR, Office of Leasing and Plans, would be notified that emissions from the facility are compliant, and the emissions would be authorized upon approval of the overall plan. Should the appraisal result in an affirmative finding of compliance only when BACT or other emission controls are applied, the use of control strategies for the sources and pollutants exceeding the thresholds would be enforced by BSEE AOCSR, and the emissions would be authorized upon approval of the overall plan by the AOSCR, Office of Leasing and Plans.

When a drillship is anchored at a position where any one or more of the exemption thresholds (excluding VOC) is exceeded, the lessee must perform computer dispersion analysis to disclose the air quality impact of that pollutant on the nearest onshore area. The results of the dispersion analysis would be compared to the EPA SILs to determine whether emissions from the facility would likely have a significant air quality effect onshore (40 CFR 51.165(b)(2) and 30 CFR §550.303(e)). The EPA SILs are provided in Table 4.5-3.

A finding that emissions from the facility would not exceed the exemption thresholds indicates the facility would not likely produce onshore ambient air pollutant concentrations above the EPA SILs, no emission controls or control strategies would be required, and the projected emissions would not have the potential to cause or contribute to a significant air quality effect onshore. If dispersion modeling indicates the project would generate emissions that exceed any of the EPA SILs, the lessee must apply BACT to reduce the emissions from the facility. When drilling operations proposed in an EP are not expected to continue in the same location for more than three years, the emissions from the facility are considered temporary, and no further analysis beyond the application of BACT is required under the BOEM AQRP for a temporary facility. Exploratory drilling on the Arctic OCS is conducted only during a summer ice-free season of approximately 120 days (30 CFR Part 550.302).

Table 4.5-3. EPA Significance Impact Levels

Air Pollutants and Averaging Periods	Pollutant Concentrations (μg/m^3)
SO_2	
Annual	1
24-hour	5
3-hour	25
1-hour [1/]	7.80
$PM_{2.5}$ [2/]	
Annual	0.3
24-hour	1.2
PM_{10} [3/]	
24-hour	5
NO_2	
Annual	1
1-hour [4/]	7.53
CO	
8-hour	500
1-hour	2,000

Note: Data in this table is valid for EPA significant impact levels (SILs) at 40 CFR 51.165(b)(2), including the interim values (*see* 1/ and 4/ below), which are not exactly the same as the data for significance levels published under BOEM's 30 CFR 550.303(e) in the early 1980s. Should the BOEM adopt or require the updated EPA SILs, the data in this table would apply.
μg/m^3 is micrograms of pollutants per cubic meter of air.
SO_2 is sulfur dioxide.
PM_{10} and $PM_{2.5}$ are coarse and fine particles, respectively.
NO_2 is nitrogen dioxide.
VOC is volatile organic compounds.
CO is carbon monoxide.

1/ EPA Office of Air Quality Planning and Standards. Aug. 23, 2010. Memorandum to Regional Air Division Directors, from Stephen D. Page, Director, Office of Air Quality Planning and Standards, stating interim 1-hour average SO_2 "significant impact level" (SIL) for 40 CFR 51.166 and 40 CFR 52.21 is 4 percent of the 1-hour average concentration of SO_2 NAAQS (ie. 75 ppb) or 7.80 μg/m^3. An air quality effect at or below the SIL is *de minimis* in nature and would not cause a violation nof the NAAQS.

2/ Table published at 30 CFR Part 550, Subpart C [30 CFR 550.303(e)] provides "total suspended particles" (TSP) instead of the updated PM_{10} and $PM_{2.5}$ standards.

3/ 71 Federal Register 61144, Oct. 17, 2006; effective Dec. 18, 2006. Revoke annual PM_{10} standard.

4/ EPA Office of Air Quality Planning and Standards. Jun. 28, 2010. Memorandum to Regional Air Division Directors, from Anna Marie Wood, Acting Director, Air Quaity Policy Division, stating interim 1-hour average NO_2 "significant impact level" (SIL) for 40 CFR 51.166 and 40 CFR 52.21 is 4 percent of the 1-hour average concentration of NO_2 NAAQS (ie. 100 ppb) or 7.53 μg/m^3. An air quality effect at or below the SIL is *de minimis* in nature and would not cause a violation nof the NAAQS.

4.5.1.3.2 Direct and Indirect Effects

The assessment of direct and indirect air quality effects that may potentially occur as a result of implementation of an OCS EP or to conduct seismic surveys requires consideration of provisions under NEPA, the Clean Air Act, and the OCS Lands Act. Under NEPA, an inventory is created to disclose total emissions likely to occur as a result of the proposed alternative. The total emission inventory would include an accounting of emissions from all reasonably foreseeable sources, including mobile and stationary, land, sea, and air, and temporary and permanent emissions—all emissions that would occur only through the implementation of the proposed alternative. Based on the annual emission rate (expressed in tons per year), the inventory may be translated into pollutant concentrations (expressed as micrograms per cubic meter, $\mu g/m^3$) using an EPA-approved computer dispersion model to discern the onshore effect of the proposed alternative. The results of the computer dispersion modeling would be compared to the NAAQS, together with the background concentrations, as required under the Clean Air Act.

Emission Inventory

Emission inventories measure the total rate of direct and indirect emissions from a proposed action and are the first step in identifying potential air quality effects of a proposed alternative. The emission inventory is also the basis for dispersion analysis, when needed, that measures the actual air quality effect on the nearest onshore areas, including potentially affected communities on the North Slope. Regulated pollutants that are considered in the emission inventory include:

- CO,
- PM_{10},
- $PM_{2.5}$,
- SOx – sulfur oxides that include emissions of SO_2,
- NO_x – nitrogen oxides that include emissions of NO_2,
- VOC, and
- CO_2e – carbon dioxide equivalent emissions.

Preparing an inclusive emission inventory for each proposed alternative requires operational information for all the marine engines and equipment sources of the pollutants listed above. As no specific project or plan is proposed under the alternatives of this EIS, the inventories provided in this section reflect emissions from sources likely to be engaged in an EP or seismic survey plan. Likely sources include the drilling unit for the EP (i.e. drillship), survey vessels, and support vessels for monitoring, crew change, ice-management, oil-spill-response equipment, fuel barges, and aircraft (helicopter and fixed-wing). The varied use of these sources will be specific to actual operations proposed for an action, and the operational specifics will modify the emission inventory presented in an EIS or EA. Operational specifics include vessel transit speeds, which are highly variable, and range from 8 knots to 20 knots depending on the operational need, vessel's design, the sea state, ice conditions, local meteorology, length of the operation, and choice and design of drilling units and survey vessels.

Exploration Plan Emission Inventory. An inventory of emissions likely to occur from the implementation of the EP under the proposed alternative was prepared using information available for recent EPs submitted to BOEM AOCSR by lessees proposing similar activities. A summer drilling season on the Arctic OCS for an EP was assumed to be 120 days throughout the ice-free period from July through the end of October. The inventory methodology conservatively assumes operation of the drilling unit for 24 hours each day for the entire 120 days.

The emission rates likely to occur as a result of implementation of one EP, where one EP is proposed for the U.S. Chukchi Sea OCS and one EP for the U.S. Beaufort Sea OCS are presented in **Table 4.5-4**.

The inventory assumes no application of BACT or the use of ultra-low-sulfur diesel (ULSD) fuel and so would be considered a conservative estimate of projected emissions for one EP occurring during one drilling season of 120 days. The emission inventory presented in Table 4.5-4 assumes the lessee proposes each EP would use a drillship with a maximum horsepower of 61,800 (157.2 MMBTU/hr), estimated using the BOEM Maximum Emissions Estimates for Rig and Drillship Types provided by BOEM Gulf of Mexico Region (GOMR). The emissions from the drillship and support vessels were calculated using the Form BOEM-0138 as provided by the GOMR (BOEM, 2011). Aircraft emissions includes both helicopter and fixed-wing aircraft. Emissions from aircraft were estimated using the Federal Aviation Administration (FAA) Emissions and Dispersion Modeling System (EDMS v 5.1.3) (FAA 2010).

Table 4.5-4. Estimated Annual Emission Inventory of an Exploration Plan

Pollutant Sources	One (1) Exploratory Drilling Program and Annual Emissions for One Drilling Season (tons per year)					
	PM	**NO_X**	**SO_2**	**CO**	**VOC**	**CO_2e***
Drill Rig	62.73	2,156.20	1.08	470.40	64.69	18,184
Ice Breakers (2 vessels each EP)	48.20	1,659.40	0.84	362.00	49.78	36,369
Anchor Handler	11.20	156.10	0.06	33.80	12.50	455
Oil Spill response Barge	24.10	829.70	0.42	181.00	24.89	18,184
Oil spill Response Tug	11.20	156.10	0.06	33.80	12.50	455
Tank Vessel for Spill Storage	24.10	829.70	0.42	181.00	24.89	18,184
Support Vessels (3 vessels each EP)	33.60	468.30	0.18	101.40	37.50	1,176
Aircraft	0.001	0.05	0.21	8.06	3.28	**
Total	**215.1**	**6,255.6**	**3.3**	**1,371.5**	**230.0**	**93,007**

Notes: SO_x (sulfur oxides) includes emissions of sulfur dioxide (SO_2).
NO_x (nitrogen oxides) includes emissions of nitrogen dioxide (NO_2).
PM (particulate matter) includes emissions of coarse and fine particulate matter (PM_{10} and $PM_{2.5}$).
VOC is volatile organic compounds.
CO is carbon monoxide.
CO_2e (carbon dioxide equivalent) is a combination of emissions of the six most common greenhouse gases expressed as a rate in relation to the global warming potential of CO_2.
*CO_2e is expressed in metric tons; all other data are given in units of short tons.
** No information on CO_2e emissions is available from EPA for aircraft.
Sources: BOEM, Alaska OCS Region. 2012.

Survey Emission Inventory. An inventory of emissions likely to occur from operations throughout seismic, on-ice, and shallow hazards surveys was prepared using information developed for the 2012 ION Seismic Survey EA (USDOI, BOEM, 2012), which for each survey assumed a research survey vessel with gross tonnage of approximately 3,500 tons. The survey was conservatively assumed to occur over a period of 76 days, operating 24 hours each day. The annual emission rates likely to reflect the multiple surveys proposed under this alternative for the Arctic OCS are presented in **Table 4.5-5** and **Table 4.5-6**.

Greenhouse Gases and Hazardous Air Pollutants

In addition to the pollutants regulated under the BOEM AQRP, emissions of greenhouse gases (GHGs) and hazardous air pollutants (HAPs) occur as a result of the operation of diesel-powered vessels supporting oil and gas activities on the OCS. Because of the change in jurisdiction under Pub. L. 112-74, GHG and HAP emissions are no longer reported to the EPA through the Clean Air Act Title V or Prevention of Significant Deterioration (PSD) permitting processes. The BOEM does not require reporting these emissions as a condition of EP approval. It is, therefore, the independent responsibility of the lessee to coordinate with the appropriate EPA office to arrange and comply with mandatory reporting of GHG and HAP emissions, including any permits for GHG emissions that exceed 100,000 tons per year under the Prevention of Significant Deterioration (PSD) Tailoring Rule (77 FR 41051, Jul. 12, 2012) or for HAPs under Section 112 of the Clean Air Act. Should a State of Alaska air permit be required, which would only occur if a lessee proposed a drilling location within the three-mile State boundary, an accounting of ammonia (NH_3) emissions and reduced sulfur compounds (RSC) may be required. The BOEM does not regulate emissions of NH_3 or RSC. Therefore, the lessees would be expected to coordinate independently with the ADEC to arrange and comply with mandatory reporting of NH_3 and RSC emissions.

Applications for State air quality permits, if required, are not included as part of this EIS. State air quality permits on the Arctic OCS are only required when a lessee proposes a drilling location within three miles of shore, which are considered State jurisdictional waters. Details regarding air permit actions (type and schedule), along with specific source/equipment applicability, will be determined once a project alternative has been selected and specific project details are known.

Fugitive Emissions and Oil Spills

Potential fugitive emissions from fuel storage tanks on vessels are not included in this EIS assessment and would be expected to have a minor impact at the facility and an even lower impact onshore. However, fugitive emissions may need to be inventoried in connection with a State of Alaska air permit, if one is required.

There are no regular activities associated with the proposed alternative that would generate fugitive dust, as most activities would occur over open water. In the event of temporary onshore activities that may generate dust, measures would be taken to reduce fugitive dust. Neither of these localized or onshore occurrences is expected to vary with the proposed alternatives; therefore, no evaluation of these pollutant sources is provided in this analysis.

There is the potential for oil spills from drilling failure or equipment leaks under the proposed alternative. Although these emissions are unplanned, oil spills have the potential to impact air quality due to the hydrocarbon volatilization, in-situ burning of spilled fuel, and the operation of additional vessels and equipment for clean up and restoration. The use of oil spill response vessels as a precaution is included in the emissions estimates for the proposed alternative. Fugitive emissions from oil spills are addressed in Section 4.10, and are not used as a criterion for comparing effects on air quality between alternatives.

Table 4.5-5. Estimated Annual Emission Inventory of Multiple Surveys on the Chukchi Sea OCS

Vessels	**Chukchi Sea OCS Three (3) - 2D/3D Seismic Surveys Annual Emissions** (tons per year)					
	PM	**NO_X**	**SO_2**	**CO**	**VOC**	**CO_2e***
Seismic Vessel	17.2	477.1	70.5	106.8	18.1	22,122

4.5.1.3.3 Air Quality Impact Analysis

Whether or not emissions from a proposed plan are exempt from the BOEM AQRP requirements for dispersion analysis depends on the distance of the proposed alternative from the shore. In any case, exempt status under the BOEM AQRP does not preclude the requirement for disclosure of the air quality impact of total project emissions under NEPA. The BOEM AOCSR requires lessees proposing operations on the Alaska OCS to perform dispersion analyses for any EP with a rate of total emissions greater than 250 tons per year for any regulated pollutant. Total emissions include the drillship or rig together with emissions from all support vessels, aircraft, and construction, thus the inventory is not limited to the stationary facility as under the BOEM AQRP. Emissions from seismic and other surveys would not likely require dispersion analysis because movement of the ships prevents transport and build-up of pollutants to occur continually over the same onshore area. However, proposed EPs generally generate emissions that exceed 250 tons per year if BACT is not provided for in the operational plan. Emissions of NO_x and CO will likely be the pollutants that exceed the 250-ton threshold. In most cases, the application of BACT will lower the emissions of NO_x and CO to a level below 250 tons per year for all pollutants and no dispersion analysis under NEPA would be required. Thus, an air quality impact analysis may be required under two conditions. First, a dispersion analysis is required under the BOEM AQRP when the emission rate caused by the stationary facility exceeds the calculated emission exemption thresholds (30 CFR 550.303(d)). Second, a dispersion analysis is required to discern the potential pollutant concentrations onshore resulting from the total project emissions disclosed under the NEPA process, which is not limited to emissions from the stationary facility evaluated under the BOEM AQRP or limited to sources evaluated for purposes of an Alaska air permit.

When an air quality impact analysis is required, the lessee will use a computer dispersion model approved by the EPA to predict the onshore concentration of pollutants and report potential adverse air quality impacts. The analysis would be conducted using the methods, and a preferred model, recommended in the EPA *Guideline on Air Quality Models* (40 CFR Part 51 Appendix W). A meteorological data set of sufficient length will be used to ensure that worst-case meteorological conditions are adequately represented in the model results.

Results of the dispersion analysis of total emissions would be used to determine the project's air quality level of effect onshore. The dispersion analysis, if required, would provide at a minimum, predicted pollutant concentrations on the nearest shore (under BOEM AQRP) and in the nearest community (under NEPA) for all the primary and secondary standards (except ozone) regulated by the Clean Air Act (i.e. the NAAQS). For NEPA purposes only, and in lieu of dispersion modeling of total emissions, the onshore air quality effect may be satisfied by a lessee who provides documentation of a previous oil and gas air quality impact analysis conducted for a project or plan of similar size and scope. The similar project would not be farther from shore than the proposed plan and the similar project would also be located on the Arctic OCS. Substitution of results from a similar analysis requires the approval of the BOEM Office of Environment. Otherwise, a dispersion analysis would be required.

Air Quality Related Values (AQRV) Analysis

In addition to human health, air pollutants can have an effect on visibility and vegetation, which is a particular concern for a project proposed near an EPA Class I wilderness area and national parks. The nearest Class I area to the proposed action is the Denali National Park, located approximately 650 kilometers (400 statute miles) distance from the project area. There would be no impact to Denali National Park from the activities proposed under this alternative and an Air Quality Related Values (AQRV) analysis is not required.

Emission Controls and Reduction Strategies

There would be no emission controls or pollution reduction strategies required for a stationary facility under the BOEM AQRP unless there is a potential for significant air quality impacts onshore. No controls or strategies are likely to be required for mobile sources operated for a seismic survey plan. When emissions from a stationary facility are not exempt, and dispersion analysis is conducted, a significant impact occurs when the predicted pollutant concentrations exceed one or more of the EPA SILs (40 CFR 51.165(b)(2) and 30 CFR 550.303(e)). Under NEPA, controls on emission-source engines may be required, particularly if sources generate emissions that cause "design concentrations" onshore to exceed the NAAQS; design concentrations are the sum of project-related pollutant concentrations together with background concentrations. The use of ultra low-sulfur diesel (ULSD) fuel to reduce emissions is discussed in Section 4.5.1.2 *Climate*.

4.5.1.3.4 Level of Effect

The annual rate of air emissions and onshore pollutant concentrations are the two basic measurements for assessing a proposal's level of effect on air quality. The emission inventory provided in this section discloses the rate of emissions likely to reflect a proposal under this alternative, expressed in short tpy. When necessary, an emission inventory is translated into pollutant concentrations expressed in micrograms per cubic meter ($\mu g/m^3$), a value that can be measured against the NAAQS, allowing the level of effect to be categorized relative to the conditions summarized in Table 4.5-7 Impact Levels for Effects on Air Quality.

The calculations for dispersion emission indicate the greater the rate of emissions offshore, the greater the impact onshore; however, many factors combine to affect the transport of air pollutants, including meteorological conditions, the temporary nature of the activities, the location on the OCS of any stationary sources of emissions, and whether the entire proposal includes only mobile sources and no stationary sources.

Generally, implementation of an EP would be expected to have a greater impact onshore compared to a geophysical seismic survey because of the stationary nature of the drillship that continuously streams air pollutants downwind and over the same onshore area each day of operation. Impacts would be reduced the farther the drilling location is from shore. The transient nature of survey vessels would impact an onshore area only momentarily as the vessels cruise past shore areas and move further out to sea and away from the shore. Thus, survey activities would likely have impacts of a lesser extent. Until a proposal is put forward under this alternative, the actual extent of air quality effects cannot be determined.

Due to the variability of exploration activities, potential effects of emissions from an EP at unique or sensitive locations are expected to be only a temporary occurrence. Therefore, the context of air quality effects is expected to be the same for any of the alternatives.

Table 4.5-7 Impact Levels for Effects on Air Quality

Impact Component	Effects Summary		
Magnitude or Intensity	**Low**: Effects are below air quality regulatory limits	**Medium**: Effects are equal to air quality regulatory limits	**High**: Effects are sufficient to exceed air quality regulatory limits
Duration	**Temporary**: Air quality would be reduced infrequently but not longer than the span of the project season and would be expected to return to pre-activity levels at the completion of the activity	**Long-term**: Air quality would be reduced throughout the life of the project and would return to pre-activity levels at some time after completion of the project	**Permanent**: Air quality would be reduced and would not be anticipated to return to previous level
Geographic Extent	**Local**: Affects air quality only locally	**Regional**: Affects air quality on a regional scale	**State-wide**: Affects air quality beyond a regional scale
Context	**Common**: Affects areas of common air quality or unclassified airsheds	**Important**: Affects unclassified airsheds with local air quality standards	**Unique**: Affects areas of very high or very low quality air: Class I airshed or EPA non-attainment area

4.5.1.3.5 Conclusion

Emissions from the drillship, proposed under Alternative 2 and shown in Table 4.5-4 (2,156.2 tons per year of NO_x), would be exempt under the BOEM AQRP only when drilling would occur at a distance greater than 65 statute miles from shore [30 CFR 550.303(d)]. Some lease areas within the U.S. Chukchi Sea OCS Planning Area are closer than 65 statute miles from shore and all the leases on the U.S. Beaufort Sea OCS Planing Area are closer than 65 statute miles. Thus, without emission reduction controls on the drillship engines, potential exists for one or more of the EPA SILs to be exceeded onshore, which must be determined by dispersion modeling. Should emission reduction strategies be used that reduce onshore effects so that levels do not exceed the EPA SILs, the air quality effect onshore would be minor. In addition, a dispersion analysis would be conducted to assess the onshore effect of the remaining mobile sources of emissions as compared to the NAAQS. Otherwise, there may be a moderate air quality effect onshore due to the drillship alone.

Emissions from the survey vessels are much lower when compared to an EP, and because of the transient nature of the activity and the distance from shore for the majority of the surveying time, emissions from surveys would have little chance of exceeding the NAAQS on the nearest onshore area. The need for a dispersion impact analysis would be unlikely, given the expected lack of potential for seismic survey operations to cause significant air quality impacts onshore; thus a negligible to minor level of effect on air quality is expected. Cumulatively, the total estimated emissions for each Arctic OCS planning area, when considering all plans and activities described under this alternative, are summarized in Table 4.5-8.

Control of oil and gas emission sources on the OCS, and levels of effect, are considered on a project-by-project basis, as each individual operator would have the responsibility to engage any engine emission controls required by BOEM AOCSR. Emission reduction strategies have the potential to reduce at least some emissions of all pollutant types, including CO_2e. Therefore, the data provided in Table 4.5-8 would represent a worst-case scenario for each Arctic OCS planning area.

Table 4.5-8. Estimated Annual Emission Inventory for Arctic OCS – Level 1 Activity

Plan/Activity	Chukchi Sea OCS Annual Emissions (tons per year)

4.5.1.4 Acoustics

The term acoustics for purposes of this EIS refers to the state of ensonification of the environments of the EIS project area by anthropogenic noise resulting from activities of the alternatives. The acoustic environment is an important habitat component for multiple species. For example, sound is critical to marine mammals for communication, prey and predator detection, and for detecting and interpreting other important environmental clues (e.g., navigation). The presence of increased sound levels from anthropogenic activity and consequent exposures of marine wildlife to these conditions could potentially cause effects. This section considers levels of ensonification (intensity), duration and spatial extent of anthropogenic noise produced by Alternative 2 to inform the wildlife effects assessments elsewhere in this EIS. Alternative 2 is the first alternative that introduces anthropogenic noise sources associated with oil and gas exploration. The acoustic characteristics of these sources are compiled and discussed in this section specifically for Alternative 2 but the same sources are used in other alternatives and the information presented here is also relevant for those.

The evaluations of acoustics effects in this section consider three criteria: intensity, duration, and extent, as defined in Table 4.5-9 below. The criteria are based on sound levels that have been associated with possible disturbance of marine mammals, although specific impacts are not considered here. Intensity considers the magnitude of the broadband acoustic source levels associated with the activity. Duration considers the time period over which sound sources operate. Extent considers the spatial area over which sound levels exceed the lowest marine mammal disturbance level relative to the Chukchi Sea and the EIS project areas; the impact category of context is not applicable to acoustics, as it is not a resource that can be classified as common, important, or unique (although context in a more general sense is critical to an assessment of acoustic impacts and is therefore discussed in relation to its importance to certain biological resources in those individual sections).

Table 4.5-9 Impact Criteria for Acoustics

Impact Category	Intensity Type	Definition
Intensity (Magnitude)	Low	Broadband acoustic source levels from anthropogenic sources are below 160 dB re 1 uPa @ 1 m (either continuous SPL or 90% rms SPL for impulsive sources).
	Medium	Broadband acoustic source levels from anthropogenic sources reach or exceed 160 and are below 200 dB re 1 µPa @ 1 m.
	High	Broadband acoustic source levels from anthropogencic sources reach or exceed 200 dB re 1 uPa @ 1 m.
Duration	Temporary	Acoustic levels are modified for one season or less.
	Long term	Acoustic levels are modified for multiple years, perhaps due to multi-year exploration in preparation for production.
	Permanent	Acoustic levels are increased for many years such as could occur with installation of a permanent structure such as CGBS production facilities.
Extent	Local	Anthropogenic noise levels are increased above 120 dB re 1 uPa over less than 10% of the EIS project areas.
	Regional	Anthropogenic noise levels exceed 120 dB re 1 uPa over at least 10% and less than 50% of the EIS project areas.
	State-wide	Anthropogenic noise levels exceed 120 dB re 1 uPa over 50% or more of the EIS project area.

Alternative 2 includes exploration activities that would likely require an ITA for possible harassment of marine mammals from noise produced by seismic survey sources, drill rigs and vessels. Other than the No Action Alternative, Alternative 2 contemplates the lowest level of activity.

Noise sources included in Alternative 2 include deep-penetration seismic airgun arrays, seismic survey vessels, including in-ice seismic vessels for winter programs, small airgun arrays for site clearance and high resolution shallow hazards surveys or for use during VSP surveys in conjunction with exploration drilling activities, vibroseis systems for on-ice surveys, and drilling rigs. With the exception of exploratory drilling rigs, all of the source types have operated in the EIS project area environments for commercial oil and gas exploration projects between 2006 and 2010. Most of these projects operated under IHAs that required acoustic measurements of underwater noise sources, and the results are cataloged in a series of monitoring reports submitted to NMFS (see references in Table 4.5-9). The reports dating back to 2006 are publicly available on NMFS' ITA website: http://www.nmfs.noaa.gov/pr/permits/incidental.htm.

Table 4.5-10 lists the specific programs conducted in the EIS project area and the sources included in the reported acoustic measurements that are relevant to understanding sound levels produced by airgun arrays and vessels as included in activities under the alternatives.

Table 4.5-10 O&G Exploration Projects in the EIS Project Area, 2006 to 2010, that have reported measurements of sound levels produced by their activities.

Notes:

2D = 2-Dimensional seismic survey using airgun array sources

3D = 3-Dimensional seismic survey using airgun array sources

OBC = Ocean Bottom Cable survey using airgun array sources

SH = Site Clearance and high resolution shallow hazards surveys using small airgun arrays, sparkers or boomers or bubble pulsers.

GT = Geotechnical survey using sidescan, multibeam, single beam sonars

GC = Geotechnical Coring

4.5.1.4.1 Acoustic Propagation Environments

The Alternative 2 noise sources generate acoustic footprints that depend on the source type and location of operation. For this discussion, the overall EIS project area is divided into three primary acoustic environments introduced in Section 3.1.6.1. These environments are the Chukchi shelf, the Beaufort shelf, and Beaufort coastal area. Though the sediment type and water column features may vary across these environments, the primary distinguishing factor for influencing sound propagation in each environment is water depth. The EIS project area on the Chukchi Shelf is comprised of spatially-uniform water depths between approximately 25 m (82 ft) and 50 m (164 ft) in the areas of oil and gas activities. Bottom relief over the extent of individual seismic or site clearance survey areas is generally small, typically within 10 percent of the nominal location depth, but spatially-extended 2D surveys can cover larger depth intervals. The Beaufort shelf areas have a larger depth range, from approximately 15 m (50 ft) to a few hundred meters near the shelf edge; however, most recent exploration activity has occurred in less than 35 m (115 ft) water depth. The lower depth range limit of 15 m (50 ft) is due mainly to difficulties towing seismic streamers in shallower water. Surveys in shallower water are performed using OBC systems with hydrophones deployed on the seabed. OBC surveys were performed by Eni/PGS and BP in 2008 inside the barrier islands of the Beaufort Sea, in water depths less than 5 m (16 ft), to a few kilometers outside the islands in water depths to approximately 15 m (50 ft).

4.5.1.4.2 Relevant Acoustic Thresholds

Acoustic footprints will be considered in terms of areal extents and source-receiver distances to specific noise thresholds that are pertinent for assessing marine mammal acoustic impacts. NMFS currently consider thresholds of 190 and 180 dB re 1 µPa (rms) to be representative of the levels below which we can be confident that PTS (or injury) will not occur, based on TTS data in pinnipeds and cetaceans respectively. Thresholds for marine mammal disturbance are 120 dB and 160 dB re 1 µPa for continuous and pulsed noises, respectively. However, as discussed in Section 4.2.6 of this EIS, NMFS is considering revisions to its acoustic criteria. NMFS notes that marine mammals may respond to pulsed noise at levels below 160 dB re 1 µPa (potentially down to 120 dB) in a manner with the potential to impact subsistence uses of those animals, and, therefore, distances to the 120 dB re 1 µPa isopleths are typically identified for both continuous and pulsed sources. Richardson (1995) noted bowhead deflections at 35 km (21 mi) distance from a seismic survey airgun array source in the Alaskan Beaufort Sea, and estimated the corresponding exposure SPL between 125 and 133 dB re 1 µPa. Additionally, as noted earlier (Section 4.2.6), other studies also suggest that some portion of mysticetes may respond to seismic sources at received levels lower than 160 dB (potentially down to 120 dB) in a manner that NMFS would consider harassment, and therefore, we are currently considering revisions to the acoustic criteria. Therefore, acoustic information will be presented pertaining to the occurrence of sound levels at threshold values of 190 dB, 180 dB, 160 dB and 120 dB re 1 µPa.

4.5.1.4.3 Acoustic Footprints of Airgun Sources

Airgun array sources generate impulsive sound with source levels typically exceeding 200 dB re 1 µPa @ 1m. The SSV measurements for the oil and gas programs listed in Table 4.5-9 have determined the distances at which certain sound level isopleths from airgun sources are reached. The common approach to determine threshold distances has been to fit smooth curves through broadband rms SPL measurements and then to select the distances at which the curves cross the thresholds (Warner et al. 2008). Conservative estimates of the distances are obtained by shifting the best-fit curves upward in level so they exceed 90 percent of the measurement data values. The distances determined from the shifted curves are referred to as 90th percentile distances. Most of the measurements of airgun array sources have sampled sound levels in both the endfire direction (parallel to airgun array tow direction) and broadside direction (perpendicular to tow direction) to quantify direction-dependent sound emissions. Table 4.5-11 provides a summary of the airgun array measurements that have been performed for the programs listed in Table 4.5-10. Measured distances for sound, including seismic survey sound, change depending upon ambient conditions (i.e. wind, waves, salinity, temperature, etc.). Therefore, Table 4.5-11 provides a snapshot of one set of measurements taken at these sites rather than a static threshold.

Table 4.5-11 Measured distances for seismic survey sounds to reach threshold levels of 190, 180, 160 and 120 dB re 1 µPa (*rms*) at sites in the Beaufort and Chukchi seas

*Empirical distance was based on an extrapolation of the fitted curve beyond the range of the measured data

The results in Table 4.5-11 exhibit variability of the measured levels, even when considering similar sources in the same primary acoustic environment. This can arise due to differences of the sediment type or of the structure of the sound speed profile, both factors that influence sound propagation. For example, severe weather and surface waves can increase mixing in the water column and reduce the effect of a surface sound channel that can support strong sound propagation in calm conditions. Or, the sediment type may be more reflective in one measurement site enhancing the sound propagation. At present, there is not sufficient geoacoustic information available to quantify these differences and allow the primary acoustic environments to be further subdivided. Instead the measurements have been averaged to provide representative propagation ranges for each environment by size of source.

Representative distances to sound level thresholds of 190, 180, 160 and 120 dB re 1 µPa (rms) for airgun sources were obtained by averaging the Table 4.5-11 results for offshore and coastal surveys, and are presented in Table 4.5-12. The averages are based on the 90th percentile distances and the maxima of broadside and endfire measurements where both directions are sampled. These distances were used to assess the direct and indirect acoustic impacts from airgun sources for each action alternative.

Table 4.5-12 Average distances to sound level thresholds from measurements listed in Table 4.5-11 for several airgun survey systems.

The averages are based on 90th percentile distances, where available, and the maxima of broadside and endfire measurements are used where both directions were sampled.

4.5.1.4.4 Acoustic Footprints of Non-Airgun Sources

The non-airgun sources of Alternative 2 include seismic vessels, support vessels, drill rigs (drillships and jack-up rigs) and on-ice surveys using vibroseis. Site clearance surveys also employ high-resolution acoustic sources including multibeam and sidescan sonars, echosounders and sub-bottom profilers. The majority of these sources do not ensonify significant areas where sound levels exceed NMFS' injury criteria thresholds. However, they may produce sound levels that exceed NMFS' continuous and/or pulsed noise thresholds for marine mammal disturbance (i.e. Level B harassment). Sound source noise emissions are discussed here, and representative distances to the 120 dB re 1 µPa threshold are summarized in Table 4.5-13. This table only presents a representative sample, and other vessels will likely have different sound propagation characteristics.

Support vessel operations in the Chukchi and Beaufort Shelf environments may, depending on the type of vessels employed, generate 120 dB re 1 µPa zones extending approximately 1 km to 5.4 km (0.6 to 4 mi) (Chorney et al. 2010). For reference, open water ambient noise levels in the Chukchi Sea in the 10 Hz to 24 kHz frequency band can fall below 100 dB re 1 µPa (Fig 3.19 in O'Neill et al. 2010). Noise generated by research vessel *Mt. Mitchell*, transiting at 10 knots over the Burger prospect during Shell's 2010 Geotechnical Survey, reached 120 dB re 1 µPa at 1.6 km distance. Its sound emission levels increased when operating in dynamic positioning (DP) mode, and the estimated distance to 120 dB re 1 µPa increased to 5.6 km (Chorney et al. 2010).

Vessel operations in the shallower coastal areas of the Beaufort Sea produce smaller noise footprints due to reduced low frequency sound propagation in shallower water. Acoustic measurements of nine vessels, including two source vessels, three cable lay vessels, and two crew-change/support vessels were made in 9 m water depth during the Eni/PGS 2008 OBC project (Warner et al. 2008). Their 120 dB re 1 µPa threshold distances ranged from 280 m, for a cable lay vessel to 1,300 m (0.8 mi) for a crew change vessel. The average distance was 718 m (0.43 mi), and that value is considered as representative for support vessels in coastal operations.

Drillship sound levels are discussed in Section 2.3.3. For the purpose of this evaluation, the 120 dB re 1 µPa threshold distance is based on the source level measurements of the Shell drillship *Noble Discoverer* made in 2009 in the South China Sea (Austin and Warner 2010). Those measurements indicated drilling source levels from 178.5 to 185.4 dB re 1 µPa@1m (10 Hz to 24 kHz). Based on this information, the estimated 120 dB re 1 µPa threshold distance is likely between 1.5 and 2 km (0.9 and 1.2 mi).

Jack-up drill rigs produce lower level of sounds than vessels as the support legs do not effectively transmit vibrations from on-rig equipment into the water. For the purpose of this evaluation, the 120 dB re 1 µPa threshold distance is based on the source level measurements made by JASCO using the Marine Operations Noise Model in support of a 2014 exploration drilling program contemplated by ConocoPhillips' (O'Neill et al. 2012). The modeling efforts indicated a broadband source level of 167 dB re 1 µPa. Based on this information, the estimated 120 dB re 1 µPa threshold distance is estimated to be 210 m (689 ft).

Sounds from on-ice vibroseis systems are discussed in Section 2.3.2. Vibroseis source pressure waveforms are typically frequency sweeps below 100 Hz, though strong harmonics may exist to 1.5 kHz, and with signal durations of 5 to 20 seconds. They are presently categorized as continuous-type sounds (Richardson et al. 1995). The measurement of on-ice vibroseis source levels in shallow water is complicated by interference from bottom and surface reflections, and as a consequence there is considerable variability in the published source levels. Holliday measured an on-ice vibroseis source level of 187 dB re 1 µPa@1m, with bandwidth 10 to 70 Hz (Holliday et al. 1984 as discussed in Richardson et al. 1995), and that source level will be used for the present analysis. While the source level is several decibels higher than those of vessels, the low operating frequency will lead to shorter horizontal propagation distances. It is expected the maximum levels will be similar to or less than those from the larger vessels. The largest 120 dB re 1 µPa threshold distance for vessels in the Eni/PGS 2008 OBC study was 1,300 m (0.8 mi). That distance will be assumed also for the vibroseis in this analysis.

The measurements referenced in the preceding discussion are summarized in Table 4.5-13, providing the expected distances to the 120 dB disturbance criteria for each non-airgun source. These values are used in the impact assessments that follow for each alternative.

Table 4.5-13 Examples of empirically measured distances to 120 dB re 1 µPa for non-airgun sources, from discussion above.

Source Type	Distance to 120 dB re 1 µPa
Drillship	2 km (1.2 mi)
Jack-up rig	210 m (689 ft)
Support Vessel in Offshore Operation	1.6 km (1 mi)
Support Vessel in Coastal Operation	0.72 km (0.43 mi)
On-ice vibroseis	1.3 km (0.78 mi)

4.5.1.4.5 Direct and Indirect Effects

Under Alternative 2, underwater noise levels will increase in the vicinity of seismic survey and support vessels, drill rigs, and airgun sources. The effects considered here are based on the current NMFS rms sound level thresholds for PTS (injury) and disturbance that were discussed above.

Estimates of Total Surface Areas of Ensonification at Threshold Levels

Table 4.5-14 contains estimates of surface areas ensonified above given threshold levels under Alternative 2 based on the ranges provided in Table 4.5-11. For the purpose of computing these notional areas, the seismic survey activities listed in Table 4.2-1 for Activity Level 1 are distributed among the three environments considered in this EIS. The three exploration surveys and three site clearance or high resolution shallow hazards surveys in the Chukchi Sea are all assumed to be in the mid-depth shelf region; the four exploration surveys and three site clearance or high resolution shallow hazards surveys in the Beaufort Sea are divided between the mid-depth shelf and the shallow-depth coastal regions in the proportions of 3:1 and 2:1 respectively (giving greater representation to the shelf region makes the estimates more precautionary). The source array sizes in the three zones reflect the prevailing configurations for seismic surveys conducted in each region. The percentages are based on nominal surface areas of 263,500 km^2 for the Chukchi Sea portion of the EIS project area and 255,350 km^2 for the Beaufort portion. Of note, the total surface areas do not subtract out either overlap with other isopleths of concurrent source operation or land area where activities are closer to shore. For that reason, the area ensonified over 120 dB is likely a significant overestimate (see figures 4.3-1 through 4.5-3 illustrating conceptual examples to get a sense of this).

Table 4.5-14 Total Surface Areas Ensonified Above Sound Level Thresholds Under Alternative 2, From Averages Listed in Table 4.5-12.

		Total Surface Areas (km^2) to sound level (90% rms SPL (dB re 1 µPa

vessels. Indicated area is within 120-dB radius, included in 160-dB column for assessment.					

<u>4.5.1.4.6 Conclusion</u>

Alternative 2 presents the lowest activity of the alternatives, but it represents an increase in activity above current levels. The distances to PTS thresholds are given in Table 4.5-11 (summarized in Table 4.5-12) for deep penetration airgun array sources and shallow hazards sources. The 180 dB re 1 µPa distance for deep penetration seismic sources extends out to 2,570 m for 2D and 3D surveys on the Beaufort Shelf based on measurements of 3147 in^3 arrays. All of the sound sources associated with Alternative 2 will ensonify nearby areas above the current marine mammal disturbance threshold of 120 dB re 1 µPa for continuous noise and 160 dB re 1 µPa (90 percent rms) for impulsive noise. Estimated distances to these thresholds for seismic airgun sources are given in Table 4.5-12 and for all other sources in Table 4.5-14. The largest expected distance to the 160 dB re 1 µPa disturbance threshold for airgun sources is 11.4 km (6.8 mi), and to the 120 dB re 1 µPa continuous SPL for non-airgun sources it is the drillship at 10 km (6 mi). The maximum measured 120 dB re 1 µPa radius from airgun sources is 167 km (104 mi) (Austin and Laurinolli, 2007), but the average distance for recent 3-D surveys in the Beaufort and Chukchi Sea is 95 km (59 mi) (Table 4.5-12). The relevance of these disturbance zones to specific marine mammal species is discussed in Sections 4.5.2.4.

The intensity rating of this alternative is high, as additional exploration activities will introduce sources with source sound levels that exceed 200 dB re 1 µPa. Because the exploration activities could continue for several years, the duration is considered as long term. The spatial extent of these activities is regional, since the distribution of exploration activities over the EIS project areas will lead to 25 percent of the EIS project area being exposed to sound levels in excess of 120 dB re 1 µPa. Therefore, the overall impact rating for direct and indirect effects to the acoustic environment under Alternative 2 would be moderate.

4.5.1.5 Water Quality

The EPA has the authority to regulate industrial discharges of pollutants to the surface waters of the Beaufort and Chukchi seas under the National Pollution Discharge Elimination Systems (NPDES) program. Wastes generated from activities within the EIS project area would be discharged in accordance with the conditions of the NPDES general permit. The Arctic NPDES General Permit for wastewater discharges from Arctic oil and gas exploration expired on June 26, 2011. On October 29, 2012, the EPA issued final Clean Water Act NPDES general permits for wastewater discharges from oil and gas exploration on the Beaufort Sea OCS and Contiguous State Waters (AKG 28-2100) and on the Chukchi Sea OCS (AKG 28-8100). ADEC issued a Clean Water Act Section 401 Certification for the Beaufort Sea general permit on October 9, 2012.

The water quality parameters most likely to be affected by the activities described in the alternatives fall into four categories: temperature and salinity; turbidity and total suspended solids; dissolved metals; and hydrocarbons and other organic contaminants. There are many additional metrics for water quality that could be applied to the EIS project area (e.g. pH, fecal coliform counts, residual chlorine concentrations), but considering the nature of the activities described in the alternatives, these four categories encompass the water quality parameters most likely to reflect the potential effects of the alternatives on long-term productivity and sustainability of valued ecosystem components.

The actions proposed in Alternatives 2, 3, 4, and 5 are defined by four action components and various combinations of mitigation measures. The action components are: seismic surveys, site clearance and shallow hazards surveys, on-ice seismic surveys, and exploratory drilling programs, which are described in detail in Chapter 2 of this EIS. The water quality effects of each action component are analyzed separately for each alternative. Overall, seismic surveys, site clearance and shallow hazards surveys, and on-ice seismic surveys are expected to have negligible impacts on water quality. Effects of exploratory drilling on water quality would depend upon the specific techniques used for exploratory drilling, the location of the activity, and mitigation measures implemented, such as reduced discharge. For example, construction of gravel artificial islands in nearshore waters would result in different impacts to water quality than would drilling from a floating vessel or a jackup rig in offshore waters (see Section 2.3.3).

In any case, exploratory drilling programs would involve discharges to the marine environment that could result in adverse impacts to water quality. The transport, dispersion, and persistence of materials discharged into the marine environment from exploratory drilling operations have been previously evaluated for several areas of the Alaska Arctic OCS. The general conclusions reached in these studies regarding the transport, dispersion, and persistence of drilling discharges are discussed below (from EPA 2006b):

> *The drilling mud discharge separates into an upper and lower plume. Physical descriptions of effluent dynamics and particle transport differ substantially for the two plumes. Drill cuttings (parent material from the drill hole) are generally coarse materials that are deposited rapidly following discharge and settle within the 100-m radius mixing zone. Discharged drilling materials typically settle in the immediate vicinity of the discharge area. However, deposition patterns are extremely variable and are strongly influenced by several factors, including the type and quantity of mud discharged, hydrographic conditions at the time of discharge, and height above the seafloor at which discharges are made.*
>
> *Although metals were enriched in the sediment, enrichment factors were generally low to moderate, seldom exceeding a factor of 10. The spatial extent of this enrichment also was limited. These considerations suggest that exploratory activities will not result in environmentally significant levels of trace metal contamination. However, other factors, such as the intensity of exploratory activities, normal sediment loading, and proximity either to commercial shell fisheries or to subsistence populations, could alter this conclusion. Analyses of sediment barium and trace metal concentrations have been used to examine nearfield fate of drilling fluids on the seafloor (e.g. the rate of dispersion of sedimented material). If high concentrations of barium are persistently found near a well site, this finding suggests it is in a lower energy area, which favors deposition. If elevated levels cannot be found, even soon after drilling, then this finding suggests a higher energy environment, where resuspension and sediment transport were promoted.*
>
> *Data from exploratory drilling operations have been used to examine deposition of metals resulting from drilling operations. These indicate that several metals are deposited, in a distance-dependent manner, around platforms, including cadmium, chromium, lead, mercury, nickel, vanadium, and zinc. At present, the area-wide large-scale distribution of drilling discharges is difficult to predict. However, it can be surmised that drilling discharges associated with short-term exploration operations will have little effect on the environment due to deposition of drilling-related materials on the seafloor.*

In October 2012, the EPA released updated analyses in conjunction with the new NPDES permits for the Beaufort and Chukchi seas (EPA 2012c, d). At that time, the EPA also released a technical memorandum on the "Results from Chukchi/Beaufort Seas Permit Dilution Modeling Scenarios" (EPA 2012h). This memorandum documents the simulation of mixing and dispersion of pollutant discharges authorized by the Beaufort and Chukchi general permits. The primary discharge type of interest is drilling fluid (mud) with dispersal in the water column and deposits on the sea bed producing smothering impacts and potentially exposing water column and benthic organisms to contaminants in the drilling fluid. The evaluation considered a range of expected discharge rates and physical configurations for the range of ambient environmental conditions including water depth, stratification, and tidal and non-tidal currents characterizing the areas. Mixing, dispersion, and deposition are simulated using version 2.5 of the Offshore Operators Committee Mud and Produced Water Discharge Model (OOC Model). Additional information can be found in the memorandum issued by the EPA and is incorporated herein by reference.

The level of impacts to water quality will be based on levels of intensity, duration, geographic extent, and context, as shown in Table 4.5-15.

Table 4.5-15 Impact Levels for Effects on Water Quality

Impact Component	Effects Summary		
Magnitude or Intensity	**Low**: Effects are below water quality regulatory limits	**Medium**: Effects are equal to water quality regulatory limits	**High**: Effects are sufficient to exceed water quality regulatory limits
Duration	**Temporary**: Water quality would be reduced infrequently but not longer than the span of the project season and would be expected to return to pre-activity levels at the completion of the activity	**Long-term**: Water quality would be reduced throughout the life of the project and would return to pre-activity levels at some time after completion of the project	**Permanent**: Water quality would be reduced and would not be anticipated to return to previous level
Geographic Extent	**Local**: Affects water quality only locally	**Regional**: Affects water quality on a regional scale	**State-wide**: Affects water quality beyond a regional scale
Context	**Common**: Affects areas of common water quality or where there is an abundance of water sources	**Important**: Affects areas with high water quality or water sources that are considered important in the region	**Unique**: Affects areas of high water quality that are protected by legislation

4.5.1.5.1 Direct and Indirect Effects

Water Temperature and Salinity

Seismic Surveys

Seismic surveys conducted from ships are not expected to have any measureable impact on water temperature or salinity in the proposed action area. Thermal inputs to the water from seismic survey activities would be extremely local in nature, and any effects on water quality resulting from such inputs are expected to be negligible. If there is coolant water withdrawn or water for desalination withdrawn, there would be negligible temperature and salinity effects in surface waters, as permitted and regulated under current NPDES general permits.

Site Clearance and Shallow Hazards Surveys

Site clearance and shallow hazards surveys are not expected to have any measureable impact on water temperature or salinity in the proposed action area. Thermal inputs to the water from site clearance and shallow hazards survey vessels would be local in nature, and any effects on water quality resulting from such inputs are expected to be negligible. If there is coolant water withdrawn or water for desalination withdrawn, there would be negligible temperature and salinity effects in surface waters, as permitted and regulated under current NPDES general permits.

On-ice Seismic Surveys

On-ice seismic surveys are not expected to have any measureable impact on water temperature or salinity in the proposed action area. Thermal inputs to the water from on-ice seismic surveys vehicles would cause some ice melt but would be extremely local in nature, and any effects on water quality resulting from such inputs are expected to be negligible. Likewise, on-ice seismic surveys are not expected to affect the salinity of waters within the proposed action area.

Exploratory Drilling Programs

Exploratory drilling programs can be conducted from a variety of different platforms (see Chapter 2). The choice of platform affects the type and magnitude of impacts on water temperature and salinity.

Certain discharges from oil and gas exploratory drilling programs in the Beaufort and Chukchi seas would be considered by the EPA under the Clean Water Act (CWA) Section 402, National Pollutant Discharge Elimination System (NPDES) permitting authority. Prior to issuance of NPDES discharge permits for these actions, EPA is required to comply with the Ocean Discharge Criteria (40 CFR 125 Subpart M) for preventing unreasonable degradation of ocean waters.

In addition to muds and cuttings, NPDES-permitted discharge streams may include deck drainage, sanitary wastes, domestic wastes, desalination unit wastes, blowout preventer fluid, boiler blowdown, fire control system test water, non-contact cooling water, uncontaminated ballast water, bilge water, excess cement slurry, and test fluids (EPA 2006).

Non-contact cooling water is comprised of seawater that would be pumped continuously to provide cooling for certain pieces of machinery associated with exploratory drilling activities. Heat transferred from the machinery to the water is expected to raise the temperature of the seawater in the system by about 1.5 degree Celsius (EPA 2012h). Chlorine, as calcium hypochlorite, or a similar biocide, would be added to the non-contact cooling water to reduce biofouling and would contribute to the overall salinity of the waste stream. Before discharge, water from the cooling system would generally be mixed with other discharges. After mixing, sodium metabisulfate may be added to the effluent to reduce total residual chlorine concentration to comply with regulatory limits (MMS 2002, EPA 2006b). Discharged waters would be slightly warmer and would contain higher concentrations of dissolved salts relative to the ambient waters of the Beaufort and Chukchi seas. Therefore, discharged waters would increase the temperature and salinity of the seawater in the immediate vicinity of the discharge. Effects on water quality resulting from increased temperature and salinity from exploratory drilling activities under Alternative 2 are expected to be low-intensity, temporary, local, and would affect a common resource as defined in the impact criteria in Section 4.1 of this EIS.

Turbidity and Total Suspended Solids

Seismic Surveys

Seismic surveys conducted using shipboard acoustic instruments generally do not involve chemical inputs, discharges to the marine environment, or contact with the seafloor. Therefore, in most instances, seismic survey activities would not be expected to affect turbidity or concentrations of total suspended solids within the proposed action area. If any of the vessels involved in seismic survey activities were to set an anchor within the action area, then suspension of seafloor sediments could result in localized increases in turbidity around the area where the anchor is set and retrieved. Ocean-bottom cable seismic surveys would result in localized, temporary increases in turbidity in the immediate vicinity of the survey area as the cables are laid on and retrieved from the seafloor. There is also the potential for the cables to affect turbidity if the cables move while on the seafloor. Effects on water quality resulting from increases in turbidity and/or total suspended solids as a result of conducting seismic surveys, if any, would be low-intensity, temporary, local, and would affect a common resource.

Site Clearance and Shallow Hazards Surveys

Site clearance and shallow hazards surveys are conducted using echosounders and various subbottom profiling instruments, as well as other acoustic sources, which would not affect turbidity or concentrations of total suspended solids in the proposed action area. If any of the vessels involved in site clearance or shallow hazard survey activity were to set an anchor within the action area, then suspension of seafloor sediments could result in localized increases in turbidity around the area where the anchor is set and retrieved. Effects on water quality resulting from potential increases in turbidity and/or total suspended solids as a result of conducting site clearance and shallow hazard surveys, if any, are expected to be low-intensity, temporary, local, and would affect a common resource.

On-ice Seismic Surveys

On-ice seismic surveys would not affect turbidity or concentrations of total suspended solids in the proposed action area, as they occur on the ice and not in the open-water environment. No contact is made with the seafloor during these types of surveys.

Exploratory Drilling Programs

Construction and maintenance of gravel islands for exploratory drilling would result in additional turbidity caused by increases in suspended particles and sediments in the water column. The release of sediments and drilling muds associated with exploratory drilling activity would also result in increased turbidity and concentrations of suspended solids in the water column. Increased turbidity and suspended solids resulting from artificial island construction or exploratory drilling discharges could have adverse impacts on water quality if increases persisted for extended periods of time. Direct toxicity from suspended sediments is not considered to be a regulatory issue, and neither state nor federal water quality standards have been established with regard to toxicity of suspended sediments in the marine environment. Expected toxicity for suspended sediments resulting from discharges of drill cuttings and water based drilling fluids is expected to be somewhere between that of a clay such as bentonite, and that of calcium carbonate (NRC 1983, MMS 2002). The LC_{50} (i.e. the concentration that is lethal to half of the organisms in a test population after a 96-hour exposure period) for bentonite is 7,500 parts per million (ppm) (test organism, eastern oyster (Daugherty 1951)), and because surface seawater is saturated with calcium carbonate (Chester 2003), it can be considered nontoxic.

For this analysis, 7,500 ppm suspended solids is used as an unofficial acute toxicity criterion for water quality. This value is the lowest (most toxic) LC_{50} for a clay or calcium carbonate reported in the National Research Council (1983) assessment of drilling fluids in the marine environment, and adoption of this unofficial criterion is consistent with previous analyses of the environmental effects of oil and gas activities in the proposed action area (MMS 2001, MMS 2002).

Increases in suspended solids resulting from construction of artificial islands are generally expected to be less than the 7,500 ppm suspended solids used in this analysis as an unofficial criterion for water quality (MMS 2002). The intensity, duration, and extent of the effects on water quality resulting from increased suspended sediment concentrations and turbidity levels depend on the grain-size distribution of the material being introduced to the water, the rate and duration of the activity, lateral transport and turbulence in the water column, local current speeds, and where applicable, the ice regime in the potentially affected area (MMS 2002). Data from site-specific studies in the Beaufort Sea indicate that concentrations of suspended sediments introduced as a result of construction activities decrease to well below the threshold values within 30 m (98 ft) of the activity (MMS 2002).

The release of drill cuttings and drilling muds associated with exploratory drilling activity would also result in increased turbidity and concentrations of total suspended solids in the water column. Drill cuttings and water-based drilling fluids are comprised of a slurry of particles with a wide range of grain sizes and densities, and various fluid additives may be water soluble, colloidal, or particulate in nature (Neff 1981, Neff 2005). Drill cuttings are particles of sediment and rock extracted from the bore hole as the drill bit penetrates the earth. Water-based drilling fluids consist of water mixed with a weighting agent (usually barium sulfate [$BaSO_4$]) and various additives to modify the properties of the mud (Neff 2005).

As a result of the physical and chemical heterogeneity of typical drill cuttings and drilling fluids, the mixture would undergo fractionation (separate into various components) as it is discharged to the ocean. The larger particles, which represent about 90 percent of the mass of drilling mud solids, would settle rapidly out of solution, whereas the remaining 10 percent of the mass of the mud solids consists of fine-grained particles that would drift with prevailing currents away from the drilling site (NRC 1983, Neff 2005). The fine-grained particles would disperse into the water column and settle slowly over a large area of the seafloor. Models, lab-scale simulations, and field studies suggest that discharged drilling muds and cuttings would be rapidly diluted to very low concentrations, and that suspended particulate matter concentrations would drop below effluent limitation guidelines within several meters of the discharge (Nedwed et al. 2004, Smith et al. 2004, Neff 2005). In well-mixed waters, particles discharged to the ocean from drilling activities are typically diluted by 100-fold within 10 m (33 ft) of the discharge and by 1,000-fold after a transport time of about 10 minutes at a distance of about 100 m (328 ft) from the platform (Neff 2005). Therefore, effects on water quality resulting from turbidity from discharged drill cuttings and drilling fluids are expected to be temporary, localized to the vicinity of the discharge, and would be low-intensity with regard to the overall water quality in the proposed action area.

Turbidity above ambient levels caused by increases in suspended particles in the water column would affect water quality in the proposed action area. Turbidity levels are generally expected to remain considerably below 7,500 ppm suspended solids, which is used as an acute toxicity criterion for water quality in this analysis (NRC 1983, MMS 2002). In the immediate vicinity of exploratory drilling and anchor handling activities, turbidity may locally exceed the 7,500 ppm threshold. Local effects on water quality may be high-intensity but would dissipate quickly with distance from the activity. Effects resulting from increased turbidity would be temporary and expected to end within a few days after drilling or anchor handling activity stops. Effects on water quality resulting from increased turbidity would be local and would generally be restricted to the areas within 100 m (328 ft) of the drilling or anchor handling activity (NRC 1983, Neff 2005).

Material discharged at the seafloor would be similar in composition to naturally-occurring seafloor sediments, and its contribution to turbidity from waves and currents would be about the same as the sediments existing at the seafloor surface before drilling activities (MMS 2002).

If floating vessels or jackup rigs were used for exploratory drilling, overall effects on water quality from normal operations would be low-intensity, temporary, local, and would affect a common resource. Construction of gravel artificial islands to support exploratory drilling activities could result in effects on water quality that are medium-intensity, long-term, local and would affect a common resource as defined in the impact criteria in Section 4.1 of this EIS. If oil and gas industry operators comply with EPA CWA requirements, then elevations in turbidity and concentrations of total suspended solids resulting from exploratory drilling activity would not result in unreasonable degradation of the marine environment.

Proposed mitigation measures intended to reduce/ lessen non-acoustic impacts on marine mammals (see Section 2.4.7(c)) have the potential to further reduce adverse impacts to water quality by reducing discharge of drill cuttings and drilling muds.

Metals

Seismic Surveys

Seismic surveys conducted from ships would not be expected to have any measureable impact on total or dissolved metal concentrations in the EIS project area. Inputs to the water from ship-based seismic survey activities would be local in nature, and any effects on water quality resulting from such inputs are expected to be negligible.

Site Clearance and Shallow Hazards Surveys

Site clearance and shallow hazards surveys conducted from ships would not be expected to have any measureable impact on total or dissolved metal concentrations in the EIS project area. Inputs to the water from ship-based site clearance and shallow hazards surveys would be local in nature, and any effects on water quality resulting from such inputs are expected to be negligible.

On-ice Seismic Surveys

On-ice seismic surveys would not be expected to have any measurable impact on total or dissolved metal concentrations in the EIS project area. Inputs to the water from on-ice seismic survey activities would be local in nature, and any effects on water quality resulting from such inputs are expected to be negligible.

Exploratory Drilling Programs

Discharge of drill cuttings and drilling fluids from exploratory drilling programs could result in elevated levels of metals in the water (Neff 1981, NRC 1983). Chromium, copper, mercury, lead, and zinc are the metals of greatest concern resulting from the discharge of drill cuttings and drilling fluids (Neff 1981). The EPA marine water quality criteria concentrations for these metals are given in Table 3.1-7 (EPA 2009b). Arsenic, nickel, vanadium, and manganese may also be present at elevated concentrations in some drill cuttings and drilling fluids. Barium, as $BaSO_4$, is usually present at high concentrations in drilling fluids, but due to its low solubility in seawater and low reactivity, barium sulfate would settle to the seafloor as it is discharged, and would not be expected to have any effects on water quality (DHHS 2007). Some metals are present in additives that may be mixed with the drilling mud to improve the physical and chemical properties of the mud, while other metals may be contaminants of major mud ingredients or may be present in drill cuttings (Neff 1981). Additives such as drill pipe dope, which contains 15 percent copper and seven percent lead, and drill collar dope, which can contain 35 percent zinc, 20 percent lead, and seven percent copper, may also contribute trace metals to discharges of drill cuttings and drilling fluids (EPA 2006b). Lignosulfonate compounds that are commonly added to drilling fluids as deflocculants and thinners are another source of metals in discharges from exploratory drilling programs. The concentrations of some metals commonly found in drill cuttings are given in Table 3.1-9.

A detailed discussion related to the environmental distribution of trace metals from exploratory drilling activities is available in the *Ocean Discharge Criteria Evaluation for Oil and Gas Exploration Facilities on the Outer Continental Shelf and Contiguous State Waters in the Beaufort Sea, Alaska (NPDES Permit No.: AKG-28-2100)* (EPA 2012c) and *Ocean Discharge Criteria Evaluation for Oil and Gas Exploration Facilities on the Outer Continental Shelf in the Chukchi Sea, Alaska (NPDES Permit No.: AKG-28-8100)* (EPA 2012d) and is incorporated here by reference.

As discussed in the section about turbidity and suspended solids, the discharge plume would undergo rapid fractionation as it is discharged to the ocean. Most of the discharged drill cuttings and drilling fluids would rapidly sink to the bottom near the discharge location (Neff 2005). The actual distance traveled by the discharge would depend on the water depth, lateral transport, particle size and the density of the discharged material (NRC 2003). A smaller fraction of the discharge plume, consisting of soluble components and fine-grained particles, is likely to remain in the water column longer, and may be transported considerable distances from the discharge site. Depending on the composition of the discharged drill cuttings and drilling fluids, as well as the rate of discharge, lateral transport, and dilution rates, concentrations of soluble metals may exceed EPA marine water quality criteria for dissolved metals within a small area around the site of discharge. Effects on water quality would be local and would generally be restricted to the areas within 100 m (328 ft) of the activity (NRC 1983, Neff 2005). Direct effects on water quality resulting from increased dissolved metal concentrations from exploratory drilling activities under Alternative 2 are expected to be low-intensity, temporary, local, and would affect a common resource as defined in the impact criteria in Section 4.1 of this EIS.

Indirect effects could result from resuspension of deposited sediments with elevated concentrations of trace metals. Metals from resuspended sediments could contribute to elevated concentrations of metals dissolved in the water. The magnitude of effects on water quality resulting from elevation of metal concentrations would depend on the composition of the sediments, concentrations of certain metal ions in the water column, and the uses of the affected water. As discussed in the previous paragraphs, concentrations of certain dissolved metals above the established threshold values would result in adverse effects on water quality within the proposed action area (Table 3.1-7, EPA 2009b). These effects could occur indirectly (i.e. at a later time than the proposed action) if deposited sediments with elevated concentrations of soluble metals were resuspended by tides, waves, or other natural or unnatural events. The magnitude of such indirect effects on water quality would depend on the composition of the deposited sediments, as well as other factors. Based on analysis of sediments discharged from oil and gas operations (NRC 1983) and chemical assessment of sediments in the Sivulliq Prospect around

Hammerhead drillsite (Trefry and Trocine 2009), concentrations of metals dissolved from resuspended sediments are unlikely to exceed the EPA Water Quality Criteria (EPA 2009b). If such indirect effects were to occur, the effects on water quality in the proposed action area under Alternative 2 are expected to be low-intensity, temporary, local, and would affect a common resource.

Hydrocarbons and Organic Contaminants

Seismic Surveys

Seismic surveys conducted from ships, as described in Section 2.3.2 of this EIS, would have negligible impacts on concentrations of hydrocarbons and organic contaminants in the waters of the proposed action area. Inputs to the water from seismic survey activities would be extremely local in nature, and effects on water quality resulting from such inputs, if any, are expected to be negligible.

Site Clearance and Shallow Hazards Surveys

Site clearance and shallow hazards surveys would have negligible impacts on concentrations of hydrocarbons and organic contaminants in the waters of the proposed action area. Inputs to the water from site clearance and shallow hazards survey activities would be extremely local in nature, and effects on water quality resulting from such inputs, if any, are expected to be negligible.

On-ice Seismic Surveys

On-ice seismic surveys would have minor impacts on concentrations of hydrocarbons and organic contaminants in the waters of the proposed action area. Contaminants from fluids entrained in the ice roads would be discharged every spring during breakup. Entrained hydrocarbons and other organic contaminants from vehicle exhaust, oil, grease, and other vehicle-related fluids would pass into the Beaufort Sea system at each breakup as a result of on-ice seismic surveys. The effects of these discharges on water quality would be temporary and local in nature, and overall impacts to water quality from on-ice seismic surveys are expected to be minor as defined in the impact criteria in Section 4.1 of this EIS.

Exploratory Drilling Programs

Inputs of hydrocarbons and other organic contaminants resulting from construction activities related to exploratory drilling programs are expected to be negligible. Other activities associated with exploratory drilling activities are addressed below.

Discharge of drill cuttings and drilling fluids from exploratory drilling programs would result in increased concentrations of hydrocarbons and other organic contaminants in the water (Neff 1981, NRC 1983, EPA 2012d). Although only water based drilling fluids would be used in the drilling of exploration wells within the proposed action area, organic additives are often used to modify the properties of the water based fluid (Neff 2005). These additives serve a variety of purposes. Petroleum products may be added to drilling fluid as lubricants and fluid loss agents, and blends of organic compounds, synthetic polymers, and salts may be added to the fluid as heat-stable dispersants and thinning agents (Neff 1981). In most cases, discharges of spent drilling fluids and cuttings coated by those fluids contain considerable amounts of relatively stable and potentially toxic hydrocarbon compounds (Patin 1999). Example concentrations of several organic compounds in drill cuttings are provided in Table 3.1-9 (Chapter 3).

Like metals and suspended sediments discharged as components of drilling fluid mixtures, the dispersion, distribution, and fate of discharged hydrocarbons and other organic contaminants would depend upon the chemical attributes of the compounds being discharged, as well as the rate of discharge, lateral transport, and dilution rates of the discharge plume in the environment. Also, because of the lack of applicable water quality criteria for some of the organic compounds present in drilling fluids, determination of potential exceedances resulting from drilling fluid organics in marine water is problematic.

Impacts to water quality resulting from hydrocarbons and other organic contaminants would be temporary and would dissipate soon after the discharge is stopped. Such impacts would be local in nature due to rapid dilution of discharged compounds into the ocean. It seems probable that inputs of hydrocarbons and other organic contaminants from exploratory drilling programs under Alternative 2 would have minor to moderate effects on water quality outside of the discharge plume area.

There is the potential that a small, accidental fuel spill of less than 50 bbl could occur (see Section 4.2.7). A fuel spill would introduce hydrocarbons and temporary toxicity to the surface water. The effects of a fuel spill would be limited by required deployment of booming equipment during fuel transfers and automatic shutdown of fuel lines triggered by decreased pressure. The effects are anticipated to be localized and short-term.

4.5.1.5.2 Conclusion

The effects of Alternative 2 on water quality are expected to be low-intensity, temporary, local, and would affect a common resource. The overall effects of the proposed activity described in Alternative 2 on water quality in the proposed action area are expected to be negligible.

4.5.1.6 Environmental Contaminants and Ecosystem Functions

"Ecosystem functions" refer to the capacity of natural components and processes to provide goods and services that satisfy human needs, directly or indirectly (De Groot et al. 2002). Ecosystem goods (such as subsistence foods) and services (such as waste assimilation) represent the benefits that human populations derive, directly or indirectly, from ecosystem functions (Costanza et al. 1997). A large number of Alaska Arctic Region OCS ecosystem functions can be identified, and many of the goods and services that depend on those functions are discussed in the other resource-specific sections of this document (e.g. subsistence, recreation, cultural resources). Some examples of relevant ecosystem goods and services from the Alaska Arctic region OCS and the functions from which they are derived are summarized in Section 3.1.8.1 of this EIS.

The values of ecosystem goods and services in the Alaska Arctic Region OCS are usually derived from interplay among various ecosystem components — the physical environment, chemical environment, and biological communities. Ecosystem goods and services are only rarely the product of a single species or component. Therefore, the interactions of various ecosystem components must be considered as important aspects of the affected environment. Environmental contaminants resulting from activities described in the alternatives have the potential to impact ecosystem goods and services by upsetting the synergies that exist between different components of the ecosystem and disrupting the ecosystem functions from which humans derive value. These contaminants of concern would be introduced to the environment through various pathways associated with the alternatives, as well as from sources outside of the action area via transport and deposition processes (Woodgate and Aagaard 2005). Many contaminants of concern are discussed in the resource specific sections of this document (e.g. water quality, air quality), and this section does not aim to repeat those discussions. Rather, in response to comments received during the scoping process, this analysis takes an integrated approach by assessing the effects of contaminants on ecosystem functions, which are derived from connectivity and interplay between ecosystem components. Comments from Scoping Report (Appendix C):

COR 11 *"The EIS should follow an ecosystem approach in its evaluation of impacts to biological resources and their habitats…"*

RME 1 *"The EIS needs to consider that the Arctic contains some of the world's last remaining intact marine ecosystems and impacts to this baseline from climate change, ocean acidification, and increasing industrial activities."*

Traditional Knowledge also suggests that an ecosystem approach is needed for assessment of effects of oil and gas activities in the Arctic. On March 11, 2010 at the Nuiqsut Scoping Meeting for this EIS, Rosemary Ahtuangaruak of the Iñupiat Community of the Arctic Slope stated:

> *The process with the issues related to the water quality, you know, I don't know how the process is still presented to us in the plan, dumping the muds into the water. I mean, where is the level of understanding of the importance of the biological diversity of the area, the increased risk factors we have because of our continued living in this area and the increased concentration in these animals because of the decades of lives that they live and the reactions that occur to us.*

Taking an "ecosystem approach", this section presents qualitative analyses of potential impacts under each alternative related to the influence of contaminants of concern on ecosystem functions. These analyses identify contaminants of concern, explore potential exposure pathways for habitat and biological resources, and assess the effects of contaminants on selected ecosystem functions.

Although a wide range of ecosystem functions have been described, they can generally be grouped into four basic categories based on definitions provided by DeGroot et al. (2002). **Regulation functions** relate to the capacity of natural systems to maintain essential ecological processes (such as nutrient cycles) and life support systems (such as provision of clean water). **Habitat functions** relate to provision of refuge and reproduction habitats and therefore contribute to the (*in situ*) conservation of biological diversity and evolutionary processes. **Production functions** relate to conversion of energy and nutrients into biomass by primary producers, as well as subsequent trophic transfers and biogeochemical processes, which create a diversity of living biomass, as well as non-living resources, from which a wide range of ecosystem goods and services are provided. **Information functions** contribute to the maintenance of human health by providing opportunities for spiritual enrichment, cognitive development, recreation, and aesthetic experience (DeGroot et al. 2002).

The level of impacts to environmental contaminants will be based on levels of intensity, duration, geographic extent, and context, as shown in Table 4.5-16.

Table 4.5-16 Impact Levels for Effects on Environmental Contaminants

Impact Component	Effects Summary		
Magnitude or Intensity	**Low**: Changes in ecosystem functions may not be measurable or noticeable	**Medium**: Noticeable changes in ecosystem functions	**High**: Acute or obvious changes in ecosystem functions
Duration	**Temporary**: ecosystem functions would be reduced infrequently but not longer than the span of the project season and would be expected to return to pre-activity levels at the completion of the activity	**Long-term**: ecosystem functions would be reduced through the life of the project and would return to pre-activity levels at some time after completion of the project	**Permanent**: Chronic effects; ecosystem functions would not be anticipated to return to previous levels
Geographic Extent	**Local**: Impacts limited geographically; <10% of EIS project area affected	**Regional**: Affects ecosystem functions beyond a local area, potentially throughout the EIS project area	**State-wide**: Affects ecosystem functions beyond the region or EIS project area
Context	**Common**: Affects usual or ordinary ecosystem functions; not impacted	**Important**: Affects impacted ecosystem functions within the	**Unique**: Affects unique ecosystem functions

Impact Component	Effects Summary		
		locality or region	

4.5.1.6.1 Direct and Indirect Effects

Contaminants of Concern

Organochlorines

Organochlorine contaminants, such as dichlorodiphenyltrichloroethane (DDT), polychlorinated biphenyl compounds (PCBs), chlorinated benzene isomers (ClBz), and hexachlorocyclohexane isomers (HCHs), would not be introduced into the EIS project area in substantial quantities as a result of the activities proposed under Alternative 2. The impacts of Alternative 2 on organochlorine contaminants in the EIS project area are expected to be negligible.

Petroleum hydrocarbons and polycyclic aromatic hydrocarbons (PAHs)

Petroleum hydrocarbons and PAHs would be introduced into the EIS project area in measureable quantities as a result of the actions proposed under Alternative 2. Petroleum hydrocarbons and PAHs would be discharged as a result of activities associated with exploration drilling, and would also be present in fuel and exhausts from vehicles and machinery associated with all components of Alternative 2. Due to their hydrophobic properties and persistence in the environment PAHs would partition into sediments and lipids in the marine environment, and their concentrations would increase at higher trophic levels as a result of persistence in biological systems and efficient transfer of lipids between trophic levels.

PAHs and petroleum hydrocarbons resulting from past oil and gas exploration activities have been measured in sediments in the vicinity of Prudhoe Bay (Neff 2010), and the activities proposed in Alternative 2 would lead to increases in concentrations of PAHs and total petroleum hydrocarbons in organisms and habitat matrices in the proposed action area. The cANIMIDA study found that PAH profiles in tissues of fish and invertebrates in the Beaufort Sea were consistent with a petrogenic and pyrogenic sources, and that PAHs in biological tissues of Beaufort Sea organisms originate from a combination of atmospheric deposition, industrial activity, erosion, and runoff from land (Neff 2010). A study specifically intended to determine concentrations of PAHs in bowhead whales harvested around Barrow found that no PAH compounds, nor PAH parent compounds or homologs, were present in detectable amounts in samples collected from different fractions of bowhead whales (Wetzel et al. 2008). Similarly, analyses to assess PAHs in stored samples of whale muscle and blubber produced no detectable levels of PAH compounds (Wetzel et al. 2008). The activities proposed under Alternative 2 would lead to measureable changes in PAH concentrations in some environmental matrices. Effects resulting from point-source discharges would be medium-intensity and local, and effects from atmospheric deposition would be low-intensity and widespread (i.e. state-wide as defined under the impact criteria). Proposed mitigation measures intended to reduce/ lessen non-acoustic impacts on marine mammals have the potential to reduce adverse impacts resulting from contaminants of concern.

Metals

Metals would be introduced into the EIS project area in measureable quantities as a result of the actions proposed under Alternative 2. Metals are also discussed under Section 4.1.5.6 (Water Quality); this discussion is based on the premise that not all metals of concern are water soluble, and as a result, water quality criteria do not necessarily account for all of the impacts associated with the introduction of metals to the EIS project area. While state and federal regulations establish criteria for concentrations of potentially toxic metals in water, these criteria do not account for concentrations of metals in other environmental matrices including sediments, which could lead to adverse effects in benthic organisms as well as effects on higher trophic levels. Chromium, copper, mercury, lead, and zinc would be the metals of greatest concern (Neff 1981). The major concerns associated with metals in the marine environment are that they could cause deleterious sublethal effects in sensitive organisms; and could accumulate to dangerous levels in higher trophic level organisms as a result of bioconcentration processes. Elevated concentrations of chromium, lead and zinc would occur in sediments in close proximity to discharges, however, concentrations of these metals in the sediments would likely decrease to background levels within several hundred meters of the discharge (Neff 1981).

Overexposure to chromium could lead to increases in the incidence of cancers in higher trophic level organisms and could interfere with the functioning of certain proteins (Cohen et al. 1993). Elevated levels of copper could interfere with the functioning of certain enzymes involved in respiration, and could cause delayed development of larval organisms (Flemming and Trevors 1989, Bianchini et al. 2004). Elevated concentrations of mercury, lead, and zinc could result in adverse effects to marine organisms (Bryan 1971, Boening 2000). The activities proposed under Alternative 2 would lead to measureable changes in concentrations of metals in some environmental matrices. Impacts resulting from point-source discharges would be medium-intensity and local, but the intensity of the impacts would decrease rapidly with distance from the point of discharge. Overall, effects of introduced metals resulting from the activities proposed in Alternative 2 would be minor.

Proposed mitigation measures intended to reduce/ lessen non-acoustic impacts on marine mammals have the potential to reduce adverse impacts resulting from contaminants of concern.

Exposure of Habitat and Biological Resources

In order for exposure of habitats and biological resources to occur, stressors (in this case contaminants of concern), and receptors (habitats and biological resources), would need to be present at the same time and at the same place (i.e. co-occurrence). Therefore, in order to assess the exposure of habitat and biological resources to contaminants of concern resulting from the actions proposed under Alternative 2, the behavior and partitioning of the contaminants in the environment should be considered. As described in Section 3.1.8.2, many of the contaminants of concern associated with the proposed action have low solubility in water as a result of their non-polar molecular structures. As a result of low aqueous solubility, these compounds would tend to associate with organic material or solid-phase particles (such as sediments) in the environment (Trefry et al. 2004, MMS 2004-031).

In general, because contaminants of concern partition into the organic and particulate phases, the concentrations of these contaminants in water would be low. Depending on their molecular structures and properties, organic contaminants originating from seismic and exploratory drilling activities would partition into sediments, which would settle out on to the seafloor. Therefore, in order for substantial exposure to occur, receptors would have to come into contact with sediments containing substantial levels of the contaminant of concern. We can conclude that the direct impact to pelagic organisms from contaminants of concern introduced to the EIS project area as a result of the activities proposed under Alternative 2 would be minor, with the exception of those organisms located directly in the plume of materials discharged from exploratory drilling operations.

Many of the contaminants of concern, including organic contaminants such as organochlorine compounds and PAHs, as well as metals such as chromium and mercury, have the potential to accumulate in higher trophic level organisms. With regard to such higher trophic level organisms, indirect effects could result from exposure to contaminants of concern through the food web, and the relevant pathway of exposure would involve trophic transfers of contaminants rather than direct exposure. Monitoring conducted as part of the ANIMIDA and cANIMIDA projects has shown that oil and gas developments in the Alaskan Beaufort Sea “are not contributing ecologically important amounts of petroleum hydrocarbons and metals to the near-shore marine food web of the area” (Neff 2010).

Effects on Ecosystem Functions

In response to comments and suggestions received as part of the scoping process for this EIS, effects of (contaminants of concern from) the proposed activities on ecosystem functions are assessed in the following section. Effects of the activities proposed under Alternative 2 on the four categories of ecosystem functions (defined in Section 4.4.1.6) are assessed below.

Regulation Functions

The actions proposed under Alternative 2 would affect regulation functions such as nutrient cycling and waste assimilation in the EIS project area. These ecosystem functions depend on biota and physical processes to facilitate storage and recycling of nutrients, and breakdown or assimilation of contaminants. The magnitude and extent of effects of Alternative 2 on regulation functions would depend upon interrelationships between impacts to biological and physical resources, which are addressed in other sections of this EIS.

Habitat Functions

Effects of Alternative 2 on habitat functions would include impacts to refugium functions and nursery functions (provision of suitable reproduction habitat) associated with benthic habitats resulting from discharges from exploratory drilling. Contaminants of concern, including hydrocarbons and metals, would affect benthic habitats in the vicinity of the discharges. Due to the relatively high octanol water partitioning ratios for most contaminants of concern, the contaminants of greatest concern would preferentially partition into sediments and the greatest impacts would be on functions associated with benthic habitats. Overall effects to benthic habitat functions would be temporary, local, and low-intensity. Effects would also occur to functions associated with pelagic and epontic habitats. Functions associated with terrestrial habitats would be affected to a lesser degree. Overall, effects of Alternative 2 on habitat functions would be medium-intensity, temporary and local. The functions affected could be common, important, or unique depending on the spatial location of the impact. On the spectrum from negligible to major, described in Section 4.1.3, the effects of Alternative 2 on habitat functions would be considered minor due to the limited spatial extent of the impacts.

Proposed mitigation measures intended to reduce/ lessen non-acoustic impacts on marine mammals have the potential to reduce adverse impacts to habitat functions and are described in greater detail below.

Production Functions

Effects of Alternative 2 on production functions would include not only impacts on primary productivity (discussed in the lower trophic levels section) but also impacts to higher-level trophic transfers, leading to indirect effects on a wide range of ecosystem goods and services. Impacts to production functions related to provision of raw materials and food (i.e. subsistence) could be affected by the activities proposed under Alternative 2. These impacts are described in the subsistence section of this EIS. In addition to introducing contaminants to secondary and tertiary consumers via trophic transfer processes, contaminants of concern could interrupt trophic transfer processes resulting in shorter food chains (less complex food webs) and reduced throughput of energy and nutrients at higher trophic levels.

Information Functions

Information functions contribute to the maintenance of human health by providing opportunities for spiritual enrichment, cognitive development, recreation, and aesthetic experience (DeGroot et al. 2002). The effects of Alternative 2 on information functions in the EIS project area would depend upon interrelationships between impacts to cultural resources, social resources and aesthetic resources, which are addressed in other sections of this EIS.

4.5.1.6.2 Conclusion

Direct and indirect impacts to ecosystem functions resulting from the implementation of Alternative 2 would be medium-intensity, temporary, localized, and common in context. The functional properties of ecosystems described in this section, such as nutrient cycling and habitat functions, are more robust (i.e. resistant to stressors) than are species composition and other structural properties. Overall effects of Alternative 2 on ecosystem functions would be negligible.

4.5.1.7 Mitigation Measures for the Physical Environment

Standard Mitigation Measures are outlined in Section 2.4.10 and Additional Mitigation Measures are outlined in Section 2.4.11, and both are described in detail in Appendix A. Requirements for implementation depend on type, time, and location of activities and co-occurrence of multiple activities. A combination of mitigation measures could be required for any one ITA. Of note, there are a large number of mitigation measures that are intended to reduce impacts to the acoustic environment with the ultimate goal of reducing impacts to a particular resource, such as marine mammals or subsistence hunts. These measures are evaluated within the context of those more targeted resources and are not repeated here.

4.5.2 Biological Environment

Table 4.5-17 indicates the mechanisms by which effects of oil and gas exploration activities identified in the alternatives on biological resources can be measured. This table summarizes the criteria for determining the level of impact to biological resources based on the magnitude, duration, extent, and context of occurrence.

Table 4.5-17 Impact Criteria for Effects on Biological Resources

Type of Effect	Impact Component	Effects Summary		
Behavioral Disturbance	Magnitude or Intensity	**High**: Acute or obvious/abrupt change in behavior due to exploration activity; animals depart from the EIS project area	**Medium**: Noticeable change in behavior due to exploration activity; animals move away from the specific activity area but remain in the EIS project area	**Low**: Changes in behavior due to exploration activity may not be noticeable; animals remain in the vicinity
	Duration	**Long-term**: Change in behavior patterns even if actions that caused the impacts were to cease; behavior not expected to return to previous patterns	**Interim**: Behavior patterns altered for several years and would return to pre-activity patterns at some time after actions causing impacts were to cease	**Temporary**: Behavior patterns altered infrequently but not longer than the span of one year and would be expected to return to pre-activity patterns after actions causing impacts were to cease
	Geographic Extent	**State-wide**: Affects resources beyond the region or EIS project area	**Regional**: Affects resources beyond a local area, potentially throughout the EIS project area	**Local**: Impacts limited geographically; <10% of Beaufort or Chukchi seas affected
	Context	**Unique**: Resources listed as threatened or endangered (or proposed for listing) under the ESA and/or depleted under the MMPA and the portion of the resource affected fills a unique ecosystem role within the locality or region	**Important**: Affects depleted resources within the locality or region or resources protected by legislation	**Common**: Affects usual or ordinary resources in the EIS project area; resource is not depleted in the locality or protected by legislation
Injury and Mortality	Magnitude or Intensity	**High**: Incident of mortality or multiple incidences of injury	**Medium**: Incident of injury	**Low**: No noticeable incidents of injury or mortality
	Duration	**Long-term**: Incidences of mortality or injury would continue to occur longer than five years or persist after actions that caused the disturbance ceased	**Interim**: Incidence of injury would continue for greater than one year to less than five years	**Temporary**: Interactions would occur for a brief, discrete period lasting less than one year
	Geographic Extent	**State-wide**: Impacts would occur beyond the EIS project area	**Regional**: Impacts would occur within the Beaufort or Chukchi seas	**Local**: Impacts would not extend to a broad region
	Context	**Unique**: Resources listed as threatened or endangered (or proposed for listing) under the ESA and/or depleted under the MMPA and	**Important**: Affects depleted resources within the locality or region or resources protected by legislation	**Common**: Affects usual or ordinary resources in the EIS project area; resource is not depleted in the locality or protected by legislation

Type of Effect	Impact Component	Effects Summary		
		the portion of the resource affected fills a unique ecosystem role within the locality or region		
Habitat Alterations	Magnitude or Intensity	**High**: Acute or obvious changes in resource character	**Medium**: Noticeable changes in resource character	**Low**: Changes in resource character may not be measurable or noticeable
	Duration	**Long-term**: Chronic effects; resource would not be anticipated to return to previous levels	**Interim**: Resource would be reduced for five to seven years and would return to pre-activity levels at some time after that point	**Temporary**: Resource would be reduced infrequently but not longer than the span of one year and would be expected to return to pre-activity levels
	Geographic Extent	**State-wide**: Affects resources beyond the region or EIS project area	**Regional**: Affects resources beyond a local area, potentially throughout the EIS project area	**Local**: Impacts limited geographically; <10% of Beaufort or Chukchi Sea affected
	Context	**Unique**: Resources listed as threatened or endangered (or proposed for listing) under the ESA and/or depleted under the MMPA and the portion of the resource affected fills a unique ecosystem role within the locality or region	**Important**: Affects depleted resources within the locality or region or resources protected by legislation	**Common**: Affects usual or ordinary resources in the EIS project area; resource is not depleted in the locality or protected by legislation

4.5.2.1 Lower Trophic Levels

The oil and gas exploration activities proposed in Alternative 2 can impact the lower trophic levels in a number of different manners. The direct and indirect effects may be caused by specific oil and gas exploration activities or a combination thereof. The categories of proposed exploration are: high resolution shallow hazard and site clearing surveys; 2D/3D deep penetration seismic surveys; and exploratory drilling (see Section 2.3 for a complete description of exploration activities). The effects most likely to be encountered during these activities are: disturbance of benthic habitat and displacement of organisms from drilling, sediment sampling, ship anchoring, or platform installation; toxicity due to production discharge; increased productivity due to ice breaking; and introduction of invasive species, due to ship traffic. A brief summary of each is provided below. On-ice seismic surveys are not expected to have any effects on lower trophic levels since the activity occurs on top of the ice and not in the water column.

4.5.2.1.1 Direct and Indirect Effects

Oil and gas exploration activities under Alternative 2 include the use of a variety of small and large support vessels and icebreakers. Seismic airgun arrays, and associated gear such as sensor arrays in streamers, on cables, and nodes are deployed in the water column and on the ocean bottom. Drilling rigs, helicopters, fixed-wing aircraft, and on-shore support facilities are also associated with exploration activities. All of these can directly and indirectly cause behavioral disturbance of marine mammals and other higher trophic level animals, and/or habitat loss/alteration, which in turn would affect lower trophic level organisms in the EIS project area.

Behavioral Disturbance

There is not much direct evidence regarding how oil and gas exploration activities affect or disturb behavior in lower trophic level organisms. However, it can be assumed any activities that might directly impact the seabed could also disturb benthic infaunal and macrofaunal populations. These activities could include ice breaking efforts that could disturb ice-associated organisms. However, ice typically returns to fill the wake as the ship passes (NMFS 2010c). Benthic organisms could be displaced from locations where drilling, sediment sampling, ship anchoring, or platform installation would occur. Because these populations are typically impacted by seasonal displacement due to natural ice scour and because the areas impacted would be minor in relation to the overall available benthic habitat the anticipated effect would be localized, minor and short-term.

Injury and Mortality

Any exploration activities that directly impact the seafloor, such as anchoring of drill ships and support vessels, and creation of artificial drilling islands, could cause direct injury and mortality to lower trophic level organisms. Ice scouring is a naturally occurring event. It is not clear if scouring would be affected by the use of icebreaking vessels during oil and gas exploration because these ships are not used in shallow waters, although ice floes that could extend to the ocean floor could be set in motion by ice breakers. Ice scouring can also directly cause injuries and mortalities to the benthos as ice is dragged across the seafloor. In addition, organisms can be buried and smothered as the ice moves through the substrate. Activities that disturb the bottom habitat in areas such as Hanna Shoal, the shelf break of the Beaufort Sea, and the Western Beaufort Sea can be particularly damaging since these areas support biologically unique communities, as well as provide important feeding and resting grounds for demersal species and macrofauna.

Recent studies show that metals associated with water-based drilling fluids are not readily absorbed by living organisms, but they do carry organic additives that can result in oxygen depletion, which could adversely affect benthic organisms in the immediate area of discharge. Likewise, increased sedimentation by the discharges could adversely affect benthic organisms via physical smothering in the area of discharge. Modeling indicates that under most scenarios, the majority of the drill cuttings would settle within 100 m (328 ft) and the solids associated with the drilling fluids are deposited within 1,000 m (3,280 ft) of the discharge. Overall, the drilling fluid and cuttings deposition are predicted to deposit on the seafloor in substantially different patterns due to the difference in solids characteristics and current speed. The drilling fluids are predicted to deposit in a thinner layer, and over a larger area, than the cuttings deposits.

There is the potential for lower trophic levels to be exposed to small, accidental fuel spills of less than 50 bbl (see Section 4.2.7). The effects of a small fuel spill would be dependent upon sea conditions at the time of the spill. With high wind conditions and rough seas, the diesel would be rapidly diluted and dispersed, and effects of the spill would be negligible. In calmer waters, evaporation of the diesel would be rapid, and the area covered by dispersion of the remaining hydrocarbons would be dependent upon wind speed, wind direction, and water temperature. Loss of benthic organisms due to hydrocarbon poisoning would probably not occur due to dispersion of hydrocarbons before reaching benthic surface. Effects on pelagic organisms would be localized, and the level of effect would be negligible.

Habitat Loss/Alteration

The primary cause of habitat loss and alteration would be due to exploratory drilling activities, which can cause disturbance to the benthic habitat; the effect is highly localized and disparate and therefore difficult to quantify. Some species are quick to repopulate the disturbed area, but it can take a decade for the habitat to fully recover from disturbance. Some species, such as the large clams walrus feed on, have been shown to take 9 years to recolonize an area, and even then, they did not recover completely (Conlan and Kvitek 2005, BOEM 2010).

The other potential cause of habitat loss/alteration is invasive species. As vessel traffic increases, the potential for non-native species to be introduced and alter the habitat increases.

4.5.2.1.2 Conclusion

Using the criteria identified in Table 4.5-17, the direct and indirect effects discussed above would likely be low in intensity, temporary to long-term in duration, of local extent and would affect common resources; resulting in a summary impact level of negligible. The only exception to these levels of impacts would be the introduction of an invasive species due to increased vessel traffic, which could be of medium intensity, long-term or permanent duration, of regional geographic extent, and affect common or important resources, which could cause a summary impact of moderate.

4.5.2.2 Fish and Essential Fish Habitat

The oil and gas exploration activities covered in Alternative 2 can impact fish resources in a number of different ways. Some effects are specific to a certain activity, while others are common to multiple activities. For the purposes of this analysis, the mechanisms for each effect are first explained, and then the effects from each of the four main categories of activity are described. The four categories of activity are: 2D/3D Seismic Surveys including an In-Ice Survey, Site Clearance and High Resolution Shallow Hazard Surveys, On-ice Seismic Surveys, and Exploratory Drilling (see Section 2.3 for a complete description of the activities). The effects most likely to be encountered during these activities are: exposure of fish to noise caused by seismic surveys, exploratory drilling, and vessel traffic; and temporary or long term fish habitat loss and/or alteration from icebreaking and exploratory drilling activities. Effects to fish from site clearance and high resolution shallow hazard surveys that use airguns would be expected to be similar to the effects from 2D/3D seismic surveys, but to a lesser extent due to the much smaller volume of the airgun(s). On-ice seismic surveys could affect under-ice-shelter for various fish life stages, including arctic cod eggs and developing larvae. The effects on fish resources resulting from a potential very large oil spill in the Beaufort and Chukchi seas are analyzed in Section 4.10.6.9 and 4.10.7.9.

During the scoping process, a number of stakeholders identified concerns related to fish resources within the EIS project area. The major issue identified was the impact of noise from oil and gas activities on marine species. In regards to fish, the concerns specifically centered on the potential for hearing loss, behavioral disruptions, and mortality of fish eggs and larvae, in addition to the impacts from acute and chronic stress and reductions in availability of fish as prey for marine mammals. Subsistence concerns addressed the potential effects of oil and gas activities on the availability of saffron cod and salmon. Saffron cod (known as tomcod in Native communities along the Arctic coast), and salmon (particularly pink and chum) are important to Alaska Native residents both directly as subsistence species and indirectly as prey for marine mammal subsistence species such as beluga whales, ice seals, and walrus. A final concern was the overall scarcity of scientific data regarding biological resources in the action area, yet a desire for quantifiable impacts was expressed. The concerns identified in the scoping process have been addressed in the analysis below.

Exposure to Noise

The range of potential effects to fish from intense sound sources, such as seismic airguns, varies widely, but is primarily influenced by the level of sound exposure. Higher sound levels are more damaging, as shown in Table 4.5-18. Data in this table are based on information from reports of responses of fish species (both Arctic and non-Arctic species) to seismic airgun pulses. Although direct physiological effects such as hearing damage or loss, tissue damage, or death can occur, indirect effects that modify fish behavior are much more common and likely. These behavioral modifications are highly variable and are dependent on a range of factors, including species, life history stage, time of day, whether the fish have fed, and how sound propagates in a particular setting (CNLOPB 2007).

Table 4.5-18 Physical and Behavioral Effects of Seismic Airguns on Fish, Eggs and Larvae

Effect	Sound Level (dB re 1 μPa)
Avoidance Behavior	160
Hearing Damage	180
Temporary Stunning	192
Egg/Larval Damage	210
Egg/Larval Mortality	220
Internal Injuries (swimbladder rupture, haemorrhaging, eye damage)	220
Fish Mortality	230-240

Source:
Modified from Turnpenny and Nedwell 1994, Davis et al. 1998

Research on acoustic impacts to fish has been limited to relatively few species, and specific data regarding the effects of noise on the species encountered in the arctic environment are lacking. While a number of studies have been undertaken, the number of species and species groups of fish is vast, and results obtained in studies on one species may not directly apply to other species. Likewise, the response to different types of stimuli can vary greatly, even when applied to the same species. For example, seismic signals have been shown to have a more pronounced effect on larger fish than on smaller fish of the same species (CNLOPB 2007). Despite the recognized need for further study on the effects of oil and gas activities on specific arctic fish species, sufficient information is available to support sound scientific judgments and reasoned managerial decisions regarding potential impacts of anthropogenic sound on fish. Given the nature of the proposed action, no significant effects are expected to occur to these resources under any alternative. Moreover, the missing information pertains to impacts that would be common to all action alternatives, and would not aid the decision between those alternatives. More information of this type is not essential for a reasoned choice among alternatives.

Fish rely heavily on sensory perceptions of sound and pressure for many activities vital for survival, such as feeding, navigation, spatial orientation, predator avoidance, and even communication. They possess hearing organs roughly comparable to other vertebrates with which they hear sounds, and also utilize a lateral line system which detects pressure waves near the fish. Combined, these two sensory systems provide fish with the ability to survive in their complicated underwater environment.

For a fish to detect a sound, two conditions must be met. First, the frequency needs to fall within the fish's audible range, and second, the intensity needs to be sufficiently strong for the fish to detect. In other words, the fish has to have the ability to hear the sound in the first place (frequency), and the sound needs to be loud enough for the fish to register (intensity). Most fish can detect sounds ranging in frequency from 50 Hz to 1,500 Hz, with some able to detect sounds up to 3 kHz (Popper and Hastings 2009).

The lateral line system is common to all fish and detects pressure waves in the water near the fish. It senses pressure differences along a line running down the length of the fish and enables the fish to detect movement nearby. It allows fish to detect currents and is vital for schooling fish, enabling them to sense and adjust their proximity and velocity within the body of their school (Stocker 2002). This system also enables fish to detect sound waves at very low frequencies of 100 Hz or less.

Direct harm to fish through physiological damage or death is very seldom documented, usually only in relation to repeated, extremely loud activities such as pile driving (Popper and Hastings 2009). Focused studies have been able to cause measurable physiological harm to fish using acoustic sources, such as permanent hearing loss or swim bladder damage, typically with sound sources measured at or above 180 dB re 1 µPa (McCauley et al. 2003, Stocker 2002, Turnpenny and Nedwell 1994). However, these observations have been under controlled experimental conditions that do not represent wild behavior of fish, and exposure to seismic sound is considered unlikely to result in direct fish or invertebrate mortality (DFO 2004). This is because fish are unlikely to remain in an area where intense sounds sources are present long enough to be injured or killed, though this is difficult to demonstrate in field conditions. Death can eventually result from a reduction in fitness due to hearing loss or tissue damage, but direct harm is generally limited to within 5 m (16 ft) of the sound source, at levels in excess of 230 dB (Turnpenny and Nedwell 1994). There is no recorded evidence that airguns have killed fish or caused injuries during seismic survey operations (Turnpenny and Nedwell 1994).

Eggs and larvae are more vulnerable to effects from sound than juvenile and adult fish as they are much less mobile, instead typically relying on currents for locomotion. In some instances, eggs are fixed to the substrate and therefore completely stationary. Sound levels in the vicinity of 220 dB have been shown to be lethal to fish eggs and larvae (Davis et al. 1998) (see Table 4.5-18). These sound levels correspond to a distance of 0.6 to 3 m (2 to 10 ft) from an airgun. Visible damage to larvae can occur at 210 dB, which corresponds to a distance of approximately 5 m (16 ft) from an airgun (Turnpenny and Nedwell 1994, Davis et al. 1998).

A more relevant concern is the indirect effect of noise on fish behavior. Typical effects from introduced noise include displacement, avoidance, startle responses, and stress (Turnpenny and Nedwell 1994). Scientific evidence suggests that some species of fish may be displaced from or choose not to enter areas of intense underwater noise, while short exposures to seismic sound may drive some demersal species to the seabed (Turnpenny and Nedwell 1994). Furthermore, numerous studies have shown catch rates to decline significantly immediately following the use of airguns for seismic surveys, with a period of up to five days required for catch rates to return to normal (Hassel et al. 2004, Popper and Hastings 2009). Researchers noted avoidance behavior in squid at levels between 156 and 174 dB re 1 µPa, and the peak source levels of airgun impulses are typically between 250 to 255 dB re 1 µPa (Stocker 2002).

The effects of avoidance and displacement can be numerous. By forcing fish away from their preferred habitats, risk of predation increases, and potential impacts from less desirable feeding and spawning habitat are also possible. There is also potential for disruption of reproductive behavior and the alteration of migration routes. More persistent sound intrusions have the potential for greater impacts, as they can displace fish for longer periods of time. Stress can result in increased mortality as well. Studies suggest that if exposure to sound results in highly-stressed fish, they may be more susceptible to predation or other environmental effects than non-stressed fish (Popper and Hastings 2009).

There are numerous sources of noise generated from oil and gas exploration activities that can affect fish resources. These sources are detailed below, along with their impacts on fish resources. The primary concern is noise generated from seismic surveys and exploratory drilling, while secondary concerns consider a noise generated from regular vessel operations and icebreaking activities.

Seismic Surveys

Acoustic energy pulses emitted by airguns are the principal impacting agents attributable to seismic surveys. The surveys are typically transient, passing through the survey area in a grid pattern. The energy emitted by a typical airgun shot is anticipated to range in frequency from 10 Hz to 120 Hz. This falls within the hearing range of most fish; however the sound level of airgun arrays can be as high as 255 dB, which is well above the level that has been shown to impact fish (see Table 4.5-18). Ramp-up procedures are likely to mitigate many impacts from exposure to these high sound levels as the gradual introduction of sound allows fish to move away from the source before exposure to detrimental sound levels occur.

Fish eggs and larvae would be unable to escape exposure to airgun noise associated with seismic surveys. However the potential for impact is very low given that the airguns would need to pass within meters of the eggs or larvae to have any detrimental effect (see Table 4.5-18). Although it is likely that some eggs and larvae will be exposed to detrimental sound levels, the small fraction of sea area covered by seismic surveys and the widespread nature of the resource make a population level impact highly unlikely.

Exploratory Drilling

The noises generated from exploratory drilling differ from seismic surveys in two key ways: they are less intense but are more stationary and persistent. A drilling operation has a single source of sound emanating from a fixed location for up to 90 days at a time. The sound produced by the drilling operation consists of loud mechanical noises emitted over a range of frequencies and intensities (see Section 2.3.3 for details). While the intensity of the sound is less than airgun arrays, a potential stationary zone of displacement will be created around the well site. If this zone of displacement is located in important spawning, fish-rearing, or feeding habitat, fish could be negatively impacted over time. However, this impact could be naturally mitigated by habituation of fish to the noise produced by the drilling activity. Since the noise would be somewhat regular in type and source, it is possible that some fish species may become habituated to them and the zone of displacement may be reduced over time.

Vessel Noise

Vessels produce baseline levels of noise when under power. Engines, generators, propellers, and pumps, produce sound, much of which is transferred directly to the marine environment. Some of this noise falls within the range of fish sensory perception, and fish have been shown to exhibit avoidance behaviors when confronted with noisy vessels (Mitson and Knudson 2003). However, vessel noise constitutes a relatively small component of the overall soundscape, especially when compared to the amount of noise introduced by seismic survey sources.

Icebreaking

The noise levels resulting from icebreaking operations vary depending on ice thickness, ice condition, vessel used, and vessel speed. Despite the variations due to these factors, operations can reach peak levels of 190 dB, and are typically continuous in nature (Roth and Schmidt 2010). This sound level is above the threshold to initiate avoidance behavior in fish (see Table 4.5-18), although the transient nature of the operation is not likely to result in long term displacement.

Habitat Loss/Alteration

Habitat loss and alteration can result from several activities involved in oil and gas exploration and can be temporary or permanent. Most activities will result in very few habitat impacts, mostly of a temporary nature, although any structures created during exploratory drilling would be considered long term from a fish resource standpoint. Temporary habitat loss could result from displacement associated with introduced noise or from direct alteration of the seafloor. Long term habitat loss would be associated with the removal or addition of substrate to the seafloor, such as the construction of a gravel island.

The specific activities likely to result in habitat loss or alteration are icebreaking during fall or winter seismic surveys, anchoring of seismic or support vessels, mud cellar construction, and exploratory drilling and associated gravel island construction.

Icebreaking

Icebreaking from support vessels during fall and early winter for seismic in-ice surveys would result in the direct loss of habitat for the cryopelagic fish assemblage, particularly Arctic cod. Sea ice forms the centerpiece for the entire cryopelagic community, and any alteration to the sea ice has the potential to impact the entire community. As an icebreaking vessel passes through sea ice, the ship causes the ice to part and travel alongside the hull. This ice typically returns to fill the wake as the ship passes. The effects are transitory, hours at most, and constrained to a narrow swath of ~30 ft (10 m) to each side of the vessel (NMFS 2010c).

Icebreakers could cause rapid pack ice movement at a time of year when the ice may not normally be breaking and moving in some locations; these ice movements could affect ice-associated fish species, particularly arctic cod eggs and larvae.

Anchoring

Vessel anchoring, which may be necessary at times during the course of exploration activities, can cause fish habitat loss or alteration through direct seafloor contact. Demersal fish, larvae, or eggs can be impacted directly if the anchor or chain contacts them, causing injury or even mortality. They may also be indirectly impacted due to sediment displacement, suspension, and deposition downstream, and by the scars caused by deployment, setting, and retrieval of the anchors and chains. A more likely effect will result indirectly through destruction or alteration of habitat. Anchors and chains are capable of destroying or damaging fish habitat by crushing and dragging along the sea floor during deployment, movement, and retrieval. Anchoring in fragile areas valuable as fish habitat such as kelp beds and coral will result in more damage than anchoring in sand or mud. The few known kelp beds in the EIS project area are located in nearshore areas or coastal lagoons, unlikely sites for a vessel to anchor unless necessary for safety (BOEM 2011b). Likewise, there is a known boulder patch in Steffanson Sound that provides relief from predators in the form of a hiding area or refuge from predators. The magnitude of any damage to the seafloor will depend chiefly on the type of substrate the anchor is deployed in and whether any dragging occurs.

Exploratory Drilling

Exploratory drilling operations may involve the discharge of drilling fluids and cuttings directly into the ocean at the drill site. Discharges can be detected over a much broader area than the effects of those discharges; while the zone of detection for drilling discharges can be up to 8 km (5 mi) from the drill site, the impacts to benthic communities is typically not detected further than 1 km (0.6 mi) out (Hurley and Ellis 2004).

Most of the major ingredients of drilling fluids have a low toxicity to marine organisms (Luyeye 2005), and, although observed impacts of drilling wastes have generally been attributed to chemical toxicity or organic enrichment, there is increasing evidence to indicate that fine particles in drilling wastes, such as bentonite and barite, can have detrimental effects to filter feeders (Hurley and Ellis 2004).

Heavy particles tend to settle within a few meters of the discharge site and can form a pile on the seafloor. There is potential that the cutting piles resulting from the heavy particles can smother benthic communities and result in artificial reef effects where the piles attract marine organisms and epifaunal animals such as crabs to colonize (BOEM 2007). These measurable effects on benthic communities have the potential to impact fish resources, particularly benthic feeders. However, scientific evidence suggests that drilling discharges and cuttings have minor effects on fish health (Hurley and Ellis 2004). The mobility of fish species and the relevant scale of environmental change appear to be the primary reasons for a lack of documented effects in the fish species studied.

Gravel Island Construction

Gravel island construction involves the addition of gravel to the seafloor to create an artificial island to be used as a drilling platform. Gravel islands are typically constructed in shallow areas, and any construction would result in the long term loss of any spawning, rearing, or feeding habitat located within the impacted area.

4.5.2.2.1 Direct and Indirect Effects

Marine Fish (Cryopelagic, Nearshore Demersal, Nearshore Pelagic, Offshore Demersal, Offshore Pelagic)

Of the noise sources introduced by Alternative 2, most have been shown to have no long term impact on fish or fish resources. Because marine fish are widely dispersed and are largely unrestricted in their movements, noises associated with these activities are not expected to have a measurable effect on marine fish populations. All fish assemblages could potentially be exposed to noise, although pelagic and cryopelagic species are more likely to be affected, mainly through behavioral disturbance. However, the transient nature of the noise sources associated with seismic surveys, vessel traffic, and icebreaking minimize the exposure to fish and fish resources, with standard ramp up procedures allowing further opportunity for mobile fish to escape the area of impact before any detrimental effects are felt. For more stationary noises associated with exploratory drilling, habituation provides a mechanism for fish to eliminate any effects from displacement. Therefore, the effect on juvenile and adult fish would be negligible. Based on the small footprint of the seismic surveys relative to the amount of habitat over the entire EIS project area, the effect would be minor, as a mechanism for population change exists, but no measurable change would result.

General population trends and life histories are sufficiently understood to support sound scientific judgments, and expected impacts to fish resources are minor. While further study would provide a more complete understanding of the fish resources within the EIS project area, existing information on the distribution of eggs and larvae throughout the EIS project area is sufficient to make an informed choice among the alternatives. Given the nature of the proposed action, no significant impacts are expected to occur to these resources under any alternatives. Moreover, the missing information pertains to impacts that would be common to all action alternatives, and would not aid the decision between those alternatives. More information of this type is not essential for a reasoned choice among alternatives.

The opportunity for habitat loss or alteration resulting from Alternative 2 is very small. Direct effects to nearshore and offshore demersal fish and fish habitats from exploratory drilling, gravel island construction, icebreaking, and anchoring would be restricted to very limited areas, particularly when compared to the total area of benthic habitat available. Therefore, the negative impacts are considered minor.

Migratory Fish (Anadromous, Amphidromous)

The effects on migratory fish resulting from Alternative 2 would be similar to those described for marine fish, although on a lesser scale. As migratory fish spend substantial parts of their life cycles away from the marine environment, and therefore away from any potential effects, the risk of exposure is reduced substantially.

Within the broad classification of migratory fish, anadromous species (salmon) are more likely to be impacted than are amphidromous fish due to the increased time they spend in the ocean. As discussed in Section 3.2.2.3.3, amphidromous fish typically spend most of their lives in fresh or brackish waters, rarely venturing out to sea. Anadromous fish, however, spend the majority of their adult lives at sea, and are therefore more susceptible to impacts from oil and gas exploration activities. They would therefore be susceptible to effects from noise and loss of habitat, particularly if any important feeding areas were impacted. However, pink and chum salmon, the most commonly encountered salmon species in the Arctic, are not very abundant in the areas impacted by oil and gas activities. Chum salmon are known to migrate as juveniles to the Bering Sea to mature, and pink salmon have been very infrequently encountered in marine arctic surveys (see Section 3.2.2.6).

Therefore, as with marine fish, the potential for impacts to migratory fish are so small when compared to the overall size of the habitat area and population that the effects are considered to be minor.

Essential Fish Habitat

As discussed in Section 3.2.2.5, EFH has been identified for all five species of Pacific salmon in addition to Arctic cod and saffron cod. Large portions of the EIS project area fall within the boundaries of the described EFH for these species. However, the amount of habitat actually essential to the survival of these fish that falls within the boundaries of the described EFH is likely considerable smaller than what is described.

Of the activities described in Alternative 2, only those resulting in potential habitat loss or alteration are relevant to EFH. Effects to fish habitat from exploratory drilling, gravel island construction, and anchoring would be restricted to very limited areas, particularly when compared to the total area of benthic habitat available. Icebreaking would impact a small percentage of ice, which is essential for arctic cod. Salmon species spend much of their adult life at sea and therefore require feeding habitat. Saffron cod spend their entire lives in the marine environment and require spawning, rearing, or feeding habitat. However, as with the analysis for marine fish, the opportunity for habitat loss or alteration resulting from Alternative 2 is very small. Most impacts would be of such low intensity and of such small geographic extent that the effects would be considered minor.

There is the potential for fish and EFH to be exposed to small, accidental fuel spills of less than 50 bbl (see Section 4.2.7). A fuel spill of this size and type would introduce hydrocarbons and effects with respect to toxicity to the surface water. Pelagic fish adults, juveniles, eggs, and larvae would be exposed, and there could be acute effects on these various life stages for the fish species in the area. However, at these concentrations, the spill effects would be short-term and spatially limited.

4.5.2.2.2 Conclusion

Given the potential implementation of standard mitigation measures considered by NMFS in this EIS (discussed in Section 4.5.2.4), the effects on fish and EFH would likely be low in magnitude, temporary to interim in duration, of local extent, and would affect common resources. The direct and indirect effects resulting from Alternative 2 would therefore be considered minor for fish and fish resources.

4.5.2.3 Marine and Coastal Birds

This section describes the potential effects of oil and gas exploration activities on marine and coastal birds of the Beaufort and Chukchi seas. Four of these species are listed under the ESA: spectacled eider (threatened); Steller’s eider (threatened); Kittlitz’s murrelet (candidate species); and yellow-billed loon (candidate species). As a result of ESA Section 7 consultations with the USFWS, BOEM has required lessees and permittees to implement specific mitigation measures to protect listed eiders when conducting permitted activities. In recent years, NMFS has required the oil and gas industry to implement a number of mitigation measures to reduce potentially adverse impacts on marine mammals and subsistence users and is considering additional mitigation measures in this EIS. These measures are intended to protect marine mammals and to ensure no unmitigable adverse impact on the availability of marine mammals for subsistence uses, but these measures may also have direct and indirect effects on marine and coastal birds, including listed eiders.

The potential effects of oil and gas exploration activities of Alternative 2 on marine and coastal birds include:

- Disturbance from exploration vessels, seismic activities, and aircraft (fixed-wing and helicopter);
- Injury/mortality from collisions with vessels/structures and oil spills; and
- Habitat changes/contamination.

4.5.2.3.1 Direct and Indirect Effects

Exploration activities under Alternative 2 include the use of a variety of large and small vessels, icebreakers, seismic airgun arrays, associated gear such as hydrophones and sensor arrays on cables that are deployed in marine waters and on the ocean bottom, drilling rigs, helicopters and fixed-wing aircraft, and on-shore support facilities. These facilities and activities could have effects on marine and coastal birds through various mechanisms as discussed below.

This EIS includes a number of standard and additional mitigation measures as part of each alternative that are intended to reduce adverse effects on marine mammals and the availability of marine mammals for subsistence uses but these mitigation measures may also help to reduce adverse effects on marine and coastal birds, which are under the jurisdiction of the USFWS. In addition to the mitigation measures imposed by NMFS, the oil and gas industry operates under regulations and permits from BOEM that authorize oil and gas exploration activities. Because these authorizations are federal actions subject to Section 7 consultation requirements of the ESA, BOEM has consulted with the USFWS on the effects of the authorized exploration activities on the ESA-listed spectacled and Steller's eiders and candidate species yellow-billed loon and Kittlitz's murrelet. The USFWS issued a programmatic Biological Opinion (BiOp) for exploration activities in the Beaufort and Chukchi seas (USFWS 2012) that includes an Incidental Take Statement and required Reasonable and Prudent Measures to minimize incidental take of the two listed eider species. The implementing Terms and Conditions would also effectively reduce adverse effects on other marine and coastal bird species, especially those using the Ledyard Bay Critical Habitat Unit (LBCHU) after July 1. The Reasonable and Prudent Measures and Terms and Conditions contained in the BiOp are designed to avoid and minimize bird collisions and to avoid and minimize impacts of disturbance from aircraft, vessels, and drilling operations on listed eiders (USFWS 2012). NMFS does not include stipulations to explicitly protect birds in the ITAs they issue for exploration activities because the agency does not have the authority to do so within an MMPA authorization. However, the following measures are required by BOEM and BSEE for permitted oil and gas exploration activities on the Beaufort and Chukchi seas to minimize incidental take of listed eiders and are thus incorporated into the analysis of potential effects under Alternative 2. NMFS would work with MMPA applicants to ensure that MMPA authorizations do not conflict with any required USFWS measures to protect ESA-listed birds.

Disturbance

Birds' responses to disturbance vary according to the species, physiological and reproductive status of the individual, distance from the disturbance, and the type/intensity/duration of the disturbance. Reactions of birds to vessels associated with exploration activity would be expected to be the same as reactions noted for other vessels used in Arctic waters. Vessel traffic may cause localized, temporary displacement and disruption of feeding or resting for some species. However, other species such as gulls and fulmars often follow vessels to forage on small fish and invertebrates brought to the surface in their wakes.

The presence of seismic survey ships would likely increase disturbance from vessel traffic, but changes would be incremental since a variety of ships regularly transit the Beaufort and Chukchi Seas to supply goods and services to the communities or for military, search-and-rescue, or scientific purposes.

Seismic surveys with airgun arrays result in both horizontal and vertical sound propagation in the water column. There has been some directed research on the potential effects of these sounds on birds. Stemp (1985) observed birds in the proximity of seismic surveys and did not see noticeable disturbance of birds during airgun deployment. Stemp (1985) concluded that negative effects from seismic operations were not likely, as long as the activities were conducted away from the colonies of birds and their feeding concentrations.

Lacroix et al. (2003) examined the potential effects of seismic surveys on a particularly sensitive group of birds, molting long-tailed ducks, along barrier islands near Prudhoe Bay. Aerial surveys were conducted before, during, and after the seismic activity, which lasted 21 days, and the abundance of birds around islands near the seismic activities were compared to those around islands that were far from the seismic work. The number of birds recorded declined substantially between the pre-seismic survey (July 24) and during-seismic survey (August 6) at all locations, but the decline was greater at the near islands (89 percent) than at the far islands (42 percent). There was a further decline in numbers after the post-seismic survey (September 7), but the magnitude of decline was similar among all areas. Lacroix et al. (2003) also used radio-tagged ducks and a series of automated receiver stations to investigate movement patterns in relation to the seismic work and found essentially no difference between ducks around the near-seismic islands and those around the distant islands. These results indicated that even though ducks were moving away from the islands during the study period as they completed their molts, ducks did not move away from seismic areas any faster than they did from distant areas. The telemetry data also included information on diving rates (indicating feeding behavior), and there was no difference in the diving patterns between near-seismic birds and those far away. Lacroix et al. (2003) concluded that the similarity of data from near-seismic birds and distant birds meant that other factors determined the abundance and movement patterns of long-tailed ducks other than their proximity to the seismic survey. However, they cautioned that their study methods did not account for short-term or localized disturbance, such as those that occur from passing vessels and recommended additional behavioral studies to examine these potential effects.

There is a limited spatial/temporal overlap of ESA-listed eiders with seismic surveys in the Beaufort and Chukchi seas (USFWS 2009c). King eiders begin migrating through the spring lead system from the Chukchi Sea to the Beaufort Sea in April-May (males) and May-June (females) (Phillips 2005, Suydam et al. 2000, Quakenbush et al. 2009) and fly inland to nesting areas soon afterward. A similar pattern occurs for many other marine species. The great majority of birds are therefore not present in offshore waters when the ice recedes enough to allow seismic survey vessels to operate. The number of eiders and other marine and coastal birds that would likely be exposed to seismic survey vessel activity in offshore waters of the Beaufort and Chukchi seas in the early open-water season would be relatively small, but more birds would be expected to occur in the Chukchi Sea than the Beaufort Sea. Designated vessel travel routes for support vessels supporting stationary drilling structures could allow for habituation by some bird species (Schwemmer et al. 2011).

The number of birds in the Chukchi Sea increases later in the open-water season, after the breeding season as adults and hatch-year birds move west out of the Beaufort Sea towards molting and wintering areas. After breeding, tens of thousands of eiders move to nearshore marine areas to molt, with large concentrations using the LBCHU, which would not receive any OCS oil and gas industry traffic after July 1 of each year.

The potential effects on birds through disturbance and other mechanisms could be magnified if exploration activities occurred adjacent to nesting colonies, which occur on many barrier islands. However, because most nesting occurs in June and early July and most open-water activities in the Beaufort Sea occur later in the season, there may be little potential for overlap and disturbance of nesting birds on barrier islands. Similarly, the nesting season occurs after the conclusion of on-ice seismic activities, which usually end by May because of concerns over ice thickness.

Another situation where effects on birds could be magnified is if exploration activities occurred in areas and times used by high concentrations of birds or when they are especially vulnerable to disturbance. This would be the case if exploration activities occurred in coastal waters and lagoons used by molting waterfowl and seabirds. Many nearshore areas along the Beaufort Sea are used by birds staging during migration in the spring and fall, but, since vibroseis surveys would be completed before open leads developed in the spring and other exploration activities generally take place further offshore in late summer-fall during open-water season, disturbance of birds in fall staging areas would be limited.

In the Chukchi Sea, LBCHU was designated as a critical habitat for ESA-listed spectacled eiders in 2001 due to its importance for the persistence and recovery of spectacled eiders. Ledyard Bay is also important habitat for many other species of waterfowl and seabirds, including ESA-listed Steller's eider and ESA candidate species, yellow-billed loon, and Kittlitz's murrelet. Because of the importance of this area to spectacled eiders, no OCS-related vessel or low-level aircraft are allowed in the area after July 1 of each year, which eliminates the potential for disturbance and other effects in this important habitat.

Frequent low-level traffic can result in chronic stress responses that could harm birds, especially during sensitive life stages like molting. Low-flying aircraft used to support oil and gas exploration activities can cause temporary disturbance of nearby birds, but minimum flight altitudes (above 1,500 ft ASL) over the LBCHU by all OCS lessees/permittees (or their agents) considered as standard mitigation measure B1 should minimize potential disturbance. Helicopters may disturb nearby birds more than fixed-wing aircraft, at least at take-off and landing, because they hover in one place for some minutes, but birds are likely to recover soon after the source of disturbance has left.

Injury/Mortality

Seismic surveys with airgun arrays result in both horizontal and vertical sound propagation in the water column. As with other animals, there is some potential for a bird to be injured by a seismic airgun pulse if the bird was in very close proximity (<2 m [<6.6 ft]) to an operating airgun. This situation is anticipated to be rare because birds tend to avoid operating vessels and the airborne sound associated with an active airgun. During a start-up, birds on the water close to the seismic vessel would be alerted to the initiation of the airgun by the required ramping up procedure.

Many waterfowl and seabird species fly at low altitudes over water (Johnson and Richardson 1982), so the potential exists for these birds to collide with offshore structures and ships, especially under conditions of poor visibility such as fog, precipitation, and darkness. Some birds are also attracted to lights from the vessels, which can increase the risk of collisions and result in injury or death (Marquenie 2007).

As a result of Section 7 consultation with the USFWS, BOEM requires OCS lessees to explore and implement a suite of methods to reduce the amount of light directed outward and upward from exploration drilling structures to reduce the risk of bird collisions. These could include shading and/or light fixture placement, different types of lights, adjustment of the number and intensity of lights as needed during specific activities, dark paint colors for selected surfaces, low-reflecting finishes or coverings for selected surfaces, and refined facility or equipment configuration.

Studies in the North Sea indicated that different colored lights caused different responses. White lights caused attraction, red caused disorientation, and green and blue caused a weak response (Marquenie 2007). White lights were replaced with lights that appeared green, and this resulted in 2 to 10 times fewer birds circling the offshore platforms (Marquenie 2007).

A study on the effects of anti-collision lighting systems on Northstar Island for eiders and other birds found in the Beaufort Sea showed that there was a significant slowing of flight speeds at night and movement away from the island when strobe lights (40 flashes per minute) were used. The lights did not cause other bird species to avoid the island but caused attraction. Therefore, the effectiveness was not clear and was inconsistent (Day et al. 2003, Day et al. 2005).

The risk of birds colliding with vessels would increase incrementally. A full complement of vessels for a full season as considered under this alternative may result in a greater number of strikes than occurred during the 2012 drilling season. Based on the existing preliminary bird strike reports from 2012, two simultaneous future drilling operations could result in as many as 178 bird strikes per open-water season—this could include an estimated 98 passerines, 22 shearwaters/storm petrels/auklets, 9 shorebirds, and 48 seaducks. Of the seaducks, 24 could be king eiders, 16 could be long-tailed ducks, and 8 could be common eiders. This potential mortality for each species is small by comparison with the post-breeding population; thus, no species would experience a population-level effect. However, small flocks of eiders can strike a vessel, suggesting that the authorized incidental take of listed eiders could be exceeded in one strike event.

There is the potential for marine and coastal to be exposed to small accidental fuel spills of less than 50 bbl (see Section 4.2.7). As explained in greater detail in the Lease Sale 193 EIS (USDOI, MMS, 2007a) and the Lease Sale 193 SEIS (BOEMRE 2011a), spilled hydrocarbons can adversely affect marine and coastal birds because these species spend so much time on the water surface and are highly susceptible to mortality if contacted. It is assumed that any bird contacted by hydrocarbons would die. However, the most likely outcome is an accidental spill that is immediately contained and would have a negligible effect on marine and coastal birds. Moreover, if a small accidental spill of less than 50 bbl were to escape containment or response measures offshore, it would not persist very long, resulting in few opportunities to contact many marine and coastal birds.

Habitat Changes/Contamination

Seismic airguns may affect invertebrates and fish (prey species used by birds). However there are very few effects on invertebrates and fish from the airgun noise unless they are within a few feet of the sound source (McCauly 1994). These disturbance effects are highly localized and transient and not likely to decrease the availability of prey to any bird species. See Section 4.5.2.2 for effects on fish and Section 4.5.2.1 for effects on lower trophic level species.

Exploratory drilling could directly affect a very small area of benthic habitat with increased turbidity and discharge of drilling cuttings. Given the very small number of sites involved in exploratory drilling under Alternative 2 and the temporary nature of the habitat disturbance, the potential for effects on any bird species is considered negligible.

4.5.2.3.2 Conclusion

Most marine and coastal birds are legally protected under the Migratory Bird Treaty Act and several are protected under the ESA. Birds fulfill important ecological roles in the Arctic. Depending on the species, they are considered to be important or unique resources in a NEPA perspective. In the absence of a large oil spill, the effects of disturbance, injury/mortality, and changes in habitat for marine and coastal birds would likely be temporary, localized, and not likely to have population-level effects for any species. The overall effects of oil and gas exploration activities authorized under Alternative 2 on ESA-listed species would be considered minor and, for other marine and coastal birds, the effects would be considered negligible according to the impact criteria in Table 4.5-17. Conclusions about impacts to birds in the event of a large oil spill are described in Sections 4.10.6.10 and 4.10.7.10. Impacts are anticipated to be reduced based on the mitigation measures required by BOEM in G&G permits, which are described in Section 4.5.2.3.1.

4.5.2.4 Marine Mammals

Noise exposure, habitat degradation, and vessel activity (potentially causing displacement from preferred habitats or ship strikes) are the primary mechanisms by which activities associated with oil and gas exploration in the Beaufort and Chukchi Seas could directly or indirectly affect marine mammals. The impacts of anthropogenic noise on marine mammals has been summarized in numerous articles and reports including Richardson et al. (1995), Cato et al. (2004), NRC (2003, 2005), Southall et al. (2007), Nowacek et al. (2007), and Weilgart (2007). The following introduction to general effects of noise from oil and gas exploration activities on marine mammals is drawn largely from these and other available literature. Impacts specific to the marine mammal species of interest in the EIS project area are discussed and evaluated separately. Because the occurrence of a large oil spill is a highly unlikely event, it is not part of the proposed action for any alternative. However, in the highly unlikely event a large spill were to occur, it could result in adverse impacts on the following resources. The oil spill analysis is not contained in the sections that analyze direct and indirect effects of the alternatives on marine mammals; rather, it is discussed and analyzed separately in Section 4.10 of this EIS.

In this section of the EIS, a general discussion of the potential effects of the various activities on marine mammals is presented first. Following this general discussion, more specific examples and information are presented for the different species or marine mammal groups, where available. Finally, an analysis of the standard and additional mitigation measures is presented for each species or group of marine mammals. The impact criteria for marine mammals are outlined for magnitude or intensity, duration, extent, and context in Table 4.5-19.

Table 4.5-19 Impact Criteria for Marine Mammals

Type of effect	Impact Component	Effects Summary	
Behavioral disturbance	Magnitude or Intensity	Low	Changes in behavior due to exploration activity may not be noticeable; animals remain in the vicinity; Level B take of marine mammals is not anticipated
		Medium	Noticeable change in behavior due to exploration activity; animals move away from activity area; Level B take of marine mammals expected, number of individuals taken is less than 30% of population
		High	Level B take of more than 30% of the individuals in the population expected
	Duration	Temporary	Temporary effect that lasts days to 1 month; animals revert back to pre-activity condition
		Interim	Temporary effect that lasts 1 to 6 months; animals revert to pre-activity conditions
		Long-term	Effects that last more than 6 months in a given year (i.e. one season) and in which change in behavior patterns do not return to pre-activity condition even after cessation of actitivies that caused impacts have ceased
	Geographic Extent	Local	Impacts limited geographically; <10% of EIS project area affected
		Regional	Affects resources beyond a local area, potentially throughout the EIS project area
		State-wide	Affects resources beyond the region or EIS project area
	Context	Common	Affects usual or ordinary resources in the EIS project area; species are not listed as threatened or endangered (or proposed for listing) under the ESA and/or as depleted under the MMPA; impacts *will not* occur in times or areas of specific importance for affected spcies (e.g. feeding, calving areas, migratory corridor) or across a large portion of the range of a resident population
		Important	Species are not listed as threatened or endangered (or proposed for listing) under the ESA and/or as depleted under the MMPA; impacts *will* occur in times or areas of specific importance for affected spcies (e.g. feeding, calving areas, migratory corridor) or across a large portion of the range of a resident population
		Unique	Species are listed as threatened or endangered (or proposed for listing) under the ESA and/or as depleted under the MMPA or the population is decreasing; impacts *will* occur in times or areas of specific importance for affected spcies (e.g. feeding, calving areas, migratory corridor) or across a large portion of the range of a resident population
Injury and mortality	Magnitude or Intensity	Low	No noticeable incidents of injury or mortality
		Medium	Incident of injury
		High	Incident of mortality or multiple incidences of injury
	Duration	Temporary	Injury to affected animal(s) lasts days to 1 month; animal reverts back to pre-activity condition once healed from injury
		Interim	Incidences of injury of affected animal(s) lasts 1 to 6 months; animal reverts back to pre-activity condtion once healed from injury
		Long-term	Mortality of animal(s) or incidences of injury persist for more than 6 months; Injury is permanent in some cases
	Geographic Extent	Local	Impacts localized; would not extend to a broad region or sector of the population
		Regional	Impacts would occur beyond a local area
		State-wide	Affects resources beyond the region or EIS project area
	Context	Common	Affects usual or ordinary resources in the EIS project area; species are not listed as threatened or endangered (or proposed for listing) under the ESA and/or as

Type of effect	Impact Component	Effects Summary	
			depleted under the MMPA
		Important	Species is listed as threatened or endangered (or proposed for listing) under the ESA and/or as depleted under the MMPA but the population is stable or increasing
		Unique	Species are listed as threatened or endangered (or proposed for listing) under the ESA and/or as depleted under the MMPA or the population is decreasing
Habitat alterations	**Magnitude or Intensity**	**Low**	Changes in resource character may not be measurable or noticeable
		Medium	Noticeable changes in resource character
		High	Acute or obvious changes in resource character
	Duration	**Temporary**	Habitat would be impacted for days to 1 month; no permanent changes to habitat
		Interim	Habitat would be impacted from 1 to 6 months; minimal, temporary alterations to marine mammal habitat
		Long-term	Habitat would be impacted for more than 6 months (i.e. one season); potential for permanent changes to marine mammal habitat
	Geographic Extent	**Local**	Impacts limited geographically; <10% of EIS project area affected
		Regional	Affects resources beyond a local area, potentially throughout the EIS project area
		State-wide	Affects resources beyond the region or EIS project area
	Context	**Common**	Affects usual or ordinary resources in the EIS project area; species are not listed as threatened or endangered (or proposed for listing) under the ESA and/or as depleted under the MMPA
		Important	Species is listed as threatened or endangered (or proposed for listing) under the ESA and/or as depleted under the MMPA but the population is stable or increasing
		Unique	Species are listed as threatened or endangered (or proposed for listing) under the ESA and/or as depleted under the MMPA or the population is decreasing

4.5.2.4.1 General Effects of Noise on Marine Mammals

Marine mammals use hearing and sound transmission to perform vital life functions. Sound (hearing and vocalization/echolocation) serves four primary functions for marine mammals, including: (1) providing information about their environment; (2) communication; (3) prey detection; and (4) predator detection. Introducing sound into the ocean environment could disrupt those functions. The distance from oil and gas exploration activities at which noises are audible depends upon source levels, frequency, ambient noise levels, the propagation characteristics of the environment, and sensitivity of the receptor (Richardson et al. 1995, Nowacek et al. 2007).

In assessing potential effects of noise, Richardson et al. (1995) suggested four criteria for defining zones of influence:

Zone of audibility – the area within which the marine mammal might hear the noise. Marine mammals as a group have functional hearing ranges of 10 Hz to 180 kHz, with best thresholds near 40 dB (Ketten 1998, Kastak et al. 2005, Southall et al. 2007). These data show reasonably consistent patterns of hearing sensitivity within each of four groups: small odontocetes (such as the harbor porpoise), medium-sized odontocetes (such as the beluga and killer whales), large cetaceans (such as bowhead whales), and pinnipeds.

Zone of responsiveness – the area within which the animal reacts behaviorally or physiologically. The behavioral responses of marine mammals to sound depend on: 1) the acoustic characteristics of the noise source; 2) the physical and behavioral state of animals at time of exposure; 3) the ambient acoustic and ecological characteristics of the environment; and 4) the context of the sound (e.g. whether it sounds similar to a predator) (Richardson et al. 1995, Southall et al. 2007). Temporary behavioral effects, however, often merely show that an animal heard a sound and may not indicate lasting consequences for exposed individuals (Southall et al. 2007). Additionally, in the context of the MMPA, not all responses will rise to the level of a "take."

Zone of masking – the area within which the noise may interfere with detection of other sounds, including communication calls, prey sounds, or other environmental sounds.

Zone of hearing loss, discomfort, or injury – the area within which the received sound level is potentially high enough to cause discomfort or tissue damage to auditory or other systems. This includes temporary threshold shifts (TTS, temporary loss in hearing) or permanent threshold shifts (PTS, permanent loss in hearing at specific frequencies or deafness). Non-auditory physiological effects or injuries that theoretically might occur in marine mammals exposed to strong underwater sound include stress, neurological effects, bubble formation, resonance effects, and other types of organ or tissue damage.

4.5.2.4.2 Potential Effects of Noise from Airguns

The effects of airgun noise on marine mammals could include one or more of the following: tolerance; masking of natural sounds; behavioral disturbance; temporary or permanent hearing impairment; or non-auditory physical effects (Richardson et al. 1995).

Tolerance

Pulsed sounds from airguns are often detectable in the water at distances of several kilometers, without necessarily eliciting behavioral responses. Numerous studies have shown that marine mammals at distances over a few kilometers from operating seismic vessels may show no apparent response (Richardson et al. 1995). That is often true even when pulsed sounds must be readily audible to the animals based on measured received levels and the hearing sensitivity of that mammal group. Although various baleen whales, toothed whales, and (less frequently) pinnipeds have been shown to temporarily react behaviorally to airgun pulses under some conditions, at other times they have shown no overt reactions (Richardson et al. 1995).

Masking

Masking occurs when biologically meaningful sounds (e.g. communication, prey, other environmental cues) are obscured by ambient or anthropogenic noise (Richardson et al. 1995, Clark et al. 2009). Introduced underwater sound will, through masking, reduce the effective communication distance of a marine mammal species if the frequency of the source is close to that used by the marine mammal, and if the anthropogenic sound is present for a significant period of time (Richardson et al. 1995).

Marine mammals are highly dependent on sound, and their ability to recognize sound signals amid other noise is important in communication, predator and prey detection, navigation and sensing other important environmental cues, and, in the case of toothed whales, echolocation. Even in the absence of manmade sounds, the sea is usually noisy. Background ambient noise often interferes with or masks the ability of an animal to detect a sound signal even when that signal is above its absolute hearing threshold. Natural ambient noise includes contributions from wind, waves, precipitation, other animals, and (at frequencies above 30 kHz) thermal noise resulting from molecular agitation (Richardson et al. 1995). Based on autonomous acoustic recordings from September 2006 to June 2009 north of Barrow, Alaska, on the continental slope between the Beaufort and Chukchi Seas, mean monthly spectrum levels (selected to exclude impulsive events) show that months with open-water had the highest noise levels (80-83 dB re: 1 μPa^2/Hz at 20-50 Hz), months with ice coverage had lower spectral levels (70 dB at 50 Hz), and months with both ice cover and low wind speeds had the lowest noise levels (65 dB at 50 Hz). Background noise also can include sounds from human activities. Masking of natural sounds can result when human activities produce high levels of noise. Conversely, if the background level of underwater noise is high (e.g. on a day with strong wind and high waves), an anthropogenic noise source will not be detectable as far away as would be possible under quieter conditions and will itself be masked.

Although some degree of masking is inevitable when high levels of manmade broadband sounds are introduced into the sea, marine mammals have evolved systems and behavior that function to reduce the impacts of masking. Structured signals, such as the echolocation click sequences of small toothed whales, may be readily detected even in the presence of strong background noise because their frequency content and temporal features usually differ strongly from those of the background noise (Au and Moore 1988, 1990). The components of background noise that are similar in frequency to the sound signal in question primarily determine the degree of masking of that signal.

Redundancy and context can also facilitate detection of weak signals. These phenomena may help marine mammals detect weak sounds in the presence of natural or manmade noise. Most masking studies in marine mammals present the test signal and the masking noise from the same direction. The sound localization abilities of marine mammals suggest that, if signal and noise come from different directions, masking would not be as severe as the usual types of masking studies might suggest (Richardson et al. 1995). The dominant background noise may be highly directional if it comes from a particular anthropogenic source such as a ship or industrial site. Directional hearing may significantly reduce the masking effects of these noises by improving the effective signal-to-noise ratio. In the cases of high-frequency hearing by the beluga whale and killer whale, empirical evidence confirms that masking depends strongly on the relative directions of arrival of sound signals and the masking noise (Penner et al. 1986, Dubrovskiy 1990, Bain et al. 1993, Bain and Dahlheim 1994). Toothed whales and probably other marine mammals as well, have additional capabilities besides directional hearing that can facilitate detection of sounds in the presence of background noise. There is evidence that some toothed whales can shift the dominant frequencies of their echolocation signals from a frequency range with a lot of ambient noise toward frequencies with less noise (Au et al. 1974, 1985; Moore and Pawloski 1990; Thomas and Turl 1990; Romanenko and Kitain 1992; Lesage et al. 1999). A few marine mammal species are known to increase the source levels or alter the frequency of their calls in the presence of elevated sound levels (Dahlheim 1987; Au 1993; Lesage et al. 1993, 1999; Terhune 1999; Foote et al. 2004; Parks et al. 2007, 2009; Di Iorio and Clark 2009; Holt et al. 2009).

These data demonstrating adaptations for reduced masking pertain mainly to the very high frequency echolocation signals of toothed whales. There is less information about the existence of corresponding mechanisms at moderate or low frequencies or in other types of marine mammals. For example, Zaitseva et al. (1980) found that, for the bottlenose dolphin, the angular separation between a sound source and a masking noise source had little effect on the degree of masking when the sound frequency was 18 kHz, in contrast to the pronounced effect at higher frequencies. Directional hearing has been demonstrated at frequencies as low as 0.5 to 2 kHz in several marine mammals, including killer whales (Richardson et al. 1995). This ability may be useful in reducing masking at these frequencies. In summary, high levels of noise generated by anthropogenic activities may act to mask the detection of weaker biologically important sounds by some marine mammals. This masking may be more prominent for lower frequencies. For higher frequencies, such as that used in echolocation by toothed whales, several mechanisms are available that may allow them to reduce the effects of such masking.

Although there is little data describing the ultimate affects of masking on animals, there can be a measurable loss of communication space that would likely be of more concern for low-frequency species (mysticetes) from lower frequency sources, both because of the communication strategies used by mysticetes (they can communicate over 100s of kilometers for days) and the physical propagation properties of lower frequency sounds (less absorption). Some whales are known to continue calling in the presence of seismic pulses; however, observers typically note some proximity around the source within which the calls decrease in number or become less frequent (Richardson et al. 1986, McDonald et al. 1995, Greene et al. 1999, Nieukirk et al. 2004, Di Iorio and Clark 2009). Additionally, as described above, some marine mammals, such as the small toothed whales communicate within frequency bands that are quite different from the frequencies of background sounds. Marine mammals that are able to use directional hearing may also be less impacted by masking effects. The greatest limiting factor in estimating impacts of masking is a lack of understanding of the spatial and temporal scales over which marine mammals actually communicate, although some estimates of distance are possible using signal and receiver characteristics. Estimates of communication masking, however, depend on assumptions for which data are currently inadequate (Clark et al. 2009).

The *Cumulative Effects of Anthropogenic Underwater Sound on Marine Mammals* is a University of California project sponsored by British Petroleum (BP) for which an expert committee was convened and tasked with developing a model for systematically evaluating the potential effects of multiple sound sources. Although additional work is needed, the model provides a first step to better understanding the cumulative impacts of the sound sources associated with oil and gas exporation (Streever et al. 2012). After outlining a quantitative method, the committee conducted a trial to assess impacts to bowheads based broadly on operational conditions in the Alaskan Beaufort in September and October of 2008. The model results highlighted some of the limitations of the model, which primarily arose from the simplifying assumptions necessary due to the lack of empirical data. However, the model also illustrated how these types of tools can be used for improved, scenario-driven, evaluations of multiple-source sounds (e.g., to compare sound exposure or extra distance traveled off migration path given different individual sound avoidance strategies.) Further, the committee recognized the complexities and resource cost of developing and implementing a quantitative model-based framework, and how they may constrain the regular use of such models. However, the committee continues to work on a more qualitative method for more routine use and also to further flesh out the quantitative method.

Disturbance Reactions

Reactions to sound, if any, depend on species, state of maturity, experience, current activity, reproductive state, time of day, environmental conditions, and many other factors (Richardson et al. 1995). Responses also depend on whether an animal is less likely (habituated) or more likely (sensitized) to respond to sound exposure (Southall et al. 2007). Responses to anthropogenic sounds are highly variable. Meaningful interpretation of behavioral responses should not only consider the relative magnitude and severity of reactions but also the relevant acoustic, contextual variables (e.g. proximity, subject experience and motivation, duration, or recurrence of exposure), and ecological variables (Southall et al. 2007).

If a marine mammal does react briefly to an underwater sound by minimally changing its behavior or moving a short distance, the impacts of the change are unlikely to be substantial to the individual and will not impact the stock or the species as a whole. However, if a sound source displaces marine mammals from an important feeding or breeding area for a prolonged period, impacts on the animals could be noteworthy. Data on short-term reactions (or lack of reactions) do not necessarily provide information about long-term effects. It is not known whether impulsive noises affect marine mammal reproductive rate or distribution and habitat use in subsequent days or years. However, the Western Arctic stock of bowhead whales has been increasing at approximately 3.4 percent per year (George et al. 2004), despite exposure to exploration activities in the Beaufort and Chukchi seas since the late 1960s (MMS 2006). Additionally, enough information is available to make a reasoned choice among alternatives. Further, impacts to other marine mammal species’ reproductive rates or stock sizes have not been documented.

Disturbance includes a variety of effects, including subtle changes in behavior, more conspicuous changes in activities, and displacement. Observable reactions of marine mammals to sound include attraction to the sound source, increased alertness, modification to their own sounds, cessation of feeding or interacting, alteration in swimming or diving behavior (change direction or speed), short or long-term habitat abandonment (deflection, short or long-term avoidance), and, possibly, panic reactions, such as stampeding or stranding (Nowacek et al. 2007, Richardson et al. 1995, Southall et al. 2007).

Because the physiological and behavioral responses of the majority of the marine mammals exposed to anthropogenic sound cannot be detected or measured (not all responses visible external to animal, portion of exposed animals underwater (so not visible), many animals located many miles from observers and covering very large area, etc.) and because NMFS must authorize take prior to the impacts to marine mammals, a method is needed to estimate the number of individuals that will be taken, pursuant to the

MMPA, based on the proposed action. To this end, NMFS developed acoustic criteria that estimate at what received sound levels the Level B Harassment, Level A Harassment, and mortality of marine mammals would occur from different types of sounds. The current NMFS acoustic criterion for Level B behavioral harassment is 160 dB re 1 μPa rms received level for impulse noises (such as airgun pulses) and 120 dB re 1 μPa rms for continuous sounds (such as drill ships and icebreaking) (70 FR 1871, January 11, 2005). However, NMFS is in the process of revising these criteria and is considering how those revisions (if adopted) could potentially affect our analyses in this document, as described in Section 4.2.6.

Noise Induced Threshold Shift

Animals exposed to intense sound may experience reduced hearing sensitivity for some period of time following exposure. This increased hearing threshold is known as noise induced threshold shift (TS). The amount of TS incurred is influenced by amplitude, duration, frequency content, temporal pattern, and energy distribution of the noise (Kryter 1985, Richardson et al. 1995, Southall et al. 2007). It is also influenced by characteristics of the animal, such as behavior, age, history of noise exposure, and health. The magnitude of TS generally decreases over time after noise exposure and if it eventually returns to zero, it is known as temporary threshold shift (TTS). If TS does not return to zero after some time, it is known as permanent threshold shift (PTS). Sound levels associated with TTS onset are generally considered to be below the levels that will cause PTS, which is considered to be auditory injury.

NMFS has established acoustic thresholds that identify the received sound levels above which hearing impairment or other injury could potentially occur (Level A take), which are 180 and 190 dB re 1 μPa (rms) for cetaceans and pinnipeds, respectively (NMFS 1995, 2000). The established 180- and 190-dB re 1 μPa (rms) criteria are the received levels above which, in the view of a panel of bioacoustics specialists convened by NMFS before additional TTS measurements for marine mammals became available, one could not be certain that there would be no injurious effects, auditory or otherwise, to marine mammals. As discussed in Section 4.2.6, NMFS is considering revisions to these acoustic criteria, which, as currently proposed, would not significantly change (as compared to current criteria) the distance within which one would expect injury to potentially occur. Many marine mammal species avoid ships and/or seismic operations at distances that likely avoid TTS onset. In addition, monitoring and mitigation measures often implemented during seismic surveys are designed to detect marine mammals near the airgun array to avoid exposure to sound pulses that may cause hearing impairment. If animals do incur TTS, it is a temporary and reversible phenomenon unless exposure exceeds the TTS-onset threshold by an amount sufficient to cause PTS.

In a study on monkeys, Lonsbury-Martin et al. (1987) found that the long-lasting nature of changes in neural responsiveness suggests that each TTS episode may produce an increment of damage to the ear and eventually contribute to measurable PTS. This was tested by exposing monkeys to short-lasting TTS sound repeatedly for many months and then comparing their cochlear ducts for hearing loss damages. Hamernik et al. (2002) compared the inferior colliculus in chinchillas that were exposed to three different thresholds of noise exposure and found there was a consistent relationship between PTS and TTS. The following subsections summarize the available data on noise-induced hearing impairment in marine mammals.

Temporary Threshold Shift

TTS is the mildest form of hearing impairment that can occur during exposure to loud sound (Kryter 1985). It is not considered to represent physical injury, as hearing sensitivity recovers relatively quickly after the sound ends. It can, however, indicate the potential for physical injury if the animal is exposed to higher levels of sound, especially on a repetitive, constant basis. The onset of TTS is defined as a temporary elevation of the hearing threshold by at least 6 dB (Schlundt et al. 2000). Several physiological mechanisms are thought to be involved with inducing TTS. These include reduced sensitivity of sensory hair cells in the inner ear, changes in the chemical environment in the sensory cells, residual middle-ear muscular activity, displacement of inner ear membranes, increased blood flow, and post-stimulatory reduction in efferent and sensory neural output (Kryter 1994, Ward 1997).

The magnitude of TTS depends on the level and duration of noise exposure and to some degree on frequency (Kryter 1985, Richardson et al. 1995, Southall et al. 2007). Very few data are available regarding the sound levels and durations that are necessary to cause TTS in marine mammals. TTS has only been studied in captive odontocetes and pinnipeds (reviewed in Southall et al. 2007). No data are available for mysticete species. No data are available for any wild marine mammals or for exposure to multiple pulses of sound during seismic surveys (Southall et al. 2007). However, simulation modeling based on extrapolations of TTS in odontocetes by Gedamke et al. (2011) suggests that baleen whales 1 km (0.62 mi) or more from seismic surveys could potentially be susceptible to TTS. For species or groups of marine mammals for which studies have been conducted, those data or information are presented in the specific subsections below. It is extremely difficult for researchers to collect such information in the wild, and it is not possible to conduct laboratory experiments on large baleen whales. Using extrapolated data from other species is considered an acceptable proxy for determining TTS in baleen whales.

Permanent Threshold Shift

PTS is defined as "irreversible elevation of the hearing threshold at a specific frequency" (Yost 2000). It involves physical damage to the sound receptors in the ear and can result in either total or partial deafness or impaired ability to hear sounds in specific frequency ranges (Kryter 1985). Some causes of PTS are severe extensions of effects underlying TTS (e.g. irreparable damage to sensory hair cells). Others involve different mechanisms, for example, exceeding the elastic limits of certain tissues and membranes in the middle and inner ears and resultant changes in the chemical composition of inner ear fluids (Ward 1997, Yost 2000). The onset of PTS is determined by pulse duration, peak amplitude, rise time, number of pulses, inter-pulse interval, location, species and health of the receivers ear (Ketten 1994).

The relationships between TTS and PTS thresholds have not been studied in marine mammals, and there is currently no evidence that exposure to airgun pulses can cause PTS in any marine mammal, however there has been speculation about that possibility (e.g. Richardson et al. 1995, Gedamke et al. 2008).

Southall et al. (2007) used available marine mammal TTS data and precautionary extrapolation procedures based on terrestrial mammal data to estimate exposures that may be associated with PTS onset. They assumed PTS would be likely if the hearing threshold increased by more than 40 dB and there was an increase of 2.3 dB in TTS with each additional dB of sound exposure. This translates to an injury criterion for pulses that is 15 dB above the Sound Exposure Level (SEL) of exposures causing TTS onset. The PTS threshold would, therefore, be approximately 198 dB re 1 $\mu Pa^2 s$ for a single pulse. Table 4.5-20 outlines the in-water SELs and Sound Pressure Levels (SPLs) thought to cause auditory injury to cetaceans and pinnipeds presented in Southall et al. (2007). These levels are higher than the 180 and 190 dB re 1 µPa (rms) criteria currently used by NMFS.

There are no data on the sound level of pulses that would cause TTS onset in pinnipeds. Southall et al. (2007) therefore assumed that known pinniped-to-cetacean differences in TTS-onset for non-pulsed sounds also apply to pulsed sounds. Harbor seals experience TTS onset at received levels that are 12 dB lower than those required to elicit TTS in beluga whales (Kastak et al. 2005, Finneran 2002a). Therefore, TTS onset in pinnipeds exposed to a single underwater pulse was estimated to occur at an SEL of 171 dB re 1 $\mu Pa^2 s$. Adding 15 dB results in a PTS onset of 186 dB re 1 $\mu Pa^2 s$ for pinnipeds exposed to a single pulse (Kastak et al. 1999, 2005).

It is unlikely that a marine mammal would remain close enough to a large airgun array long enough to incur PTS. The levels of successive pulses received by a marine mammal will increase and then decrease gradually as the seismic vessel approaches, passes and moves away, with periodic decreases also caused when the animal goes to the surface to breath, reducing the probability of the animal being exposed to sound levels large enough to elicit PTS.

Table 4.5-20 Proposed injury criteria (as described in Section 4.2.6 of this EIS) for cetaceans and pinnipeds exposed to "discrete" noise events (Finneran and Jenkins 2012)

Draft Proposed Injury Criteria		
	PTS Onset (Received Level)	
Hearing Group	**Impulsive**	**Non-impulsive**
Low-Frequency Cetaceans	*Cell 1* *230 dB_{peak}* **&** *187 dB cSEL***	*Cell 2* *230 dB_{peak}* **&** *198 dB cSEL***
Mid-Frequency Cetaceans	*Cell 3* *230 dB_{peak}* **&** *187 dB cSEL***	*Cell 4* *230 dB_{peak}* **&** *198 dB cSEL***
High-Frequency Cetaceans	*Cell 5* *201 dB_{peak}* **&** *161 dB cSEL***	*Cell 6* *201 dB_{peak}* **&** *171 dB cSEL***
Phocid Pinnipeds **(Underwater)**	*Cell 7* *224 dB_{peak}* **&** *181 dB cSEL***	*Cell 8* *224 dB_{peak}* **&** *186 dB cSEL***
Otariid Pinnipeds **(Underwater)**	*Cell 9* *230 dB_{peak}* **&** *215 dB cSEL***	*Cell 10* *230 dB_{peak}* **&** *220 dB cSEL***

* Dual criteria: Use on one [dB_{peak} or dB cSEL] exceeded first.

** NOTE – When comparing these thresholds to existing 180/190-dB rms thresholds, two important differences must be kept in mind: 1) these thresholds are based on the frequency of highest sensitivity for each taxa and are intended to be used in conjunction with frequency weighting, and 2) the metric of these thresholds are SEL instead of SPL.

Non-Auditory Physiological Effects

Non-auditory physiological effects or injuries could include stress, neurological effects, bubble formation, and other types of organ or tissue damage. If any such effects do occur, they may be limited to unusual situations when animals might be exposed at close range for unusually long periods. Issues that may arise from stress responses over a period of time include accelerated aging, sickness-like symptoms, suppression of the immune system, elevated stress hormones, and suppression of reproduction (physiologically and behaviorally) (Wright et al. 2008).

There are times during an animal's life when they have lower reserves and are more vulnerable to impacts from stressors. For example, if a mammal is stressed at the end of a feeding season just prior to a long distance migration, it may have sufficient energy reserves to cope with the stress. If stress occurs at the end of a long migration or fasting period, energy reserves may not be sufficient to adequately cope with the stress (Tyack 2008, McEwen and Wingfield 2003, and Romano et al. 2004).

Young animals (and fetuses) are sensitive to neurological consequences of the stress response and can suffer permanent neurological alterations. Deep diving marine mammals may also be more sensitive to neurological consequences of stress responses (Wright et al. 2008).

In an examination of beaked whales (which are not found in the Beaufort and Chukchi seas) that were stranded in association with military exercises involving sonar (psychological stressor), intracellular globules composed of acute phase proteins were found in cells in six out of eight livers examined, therefore, there is some indication that a stress response was partly involved (Wright et al. 2008). Hypoxia may also pose an issue for marine mammals being exposed to stressors at depth, due to increases in heart rate, which in turn causes an increase in oxygen consumption. This added oxygen demand could push the whales over the physiological edge. The combination of both the psychological stressor and the physiological stressor may have detrimental consequences (Wright et al. 2008). Classic stress responses begin when an animal's central nervous system perceives a potential threat to its homeostasis. That perception triggers stress responses regardless of whether a stimulus actually threatens the animal; the mere perception of a threat is sufficient to trigger a stress response (Moberg 2000, Sapolsky et al. 2005, Seyle 1950). Once an animal's central nervous system perceives a threat, it mounts a biological response or defense that consists of a combination of the four general biological defense responses: behavioral responses; autonomic nervous system responses; neuroendocrine responses; or immune responses.

In the case of many stressors, an animal's first and most economical (in terms of biotic costs) response is behavioral avoidance of the potential stressor or avoidance of continued exposure to a stressor. An animal's second line of defense to stressors involves the sympathetic part of the autonomic nervous system and the classical "fight or flight" response which includes the cardiovascular system, the gastrointestinal system, the exocrine glands, and the adrenal medulla to produce changes in heart rate, blood pressure, and gastrointestinal activity that humans commonly associate with "stress." The frequency of such short-term exposures and responses may have an important role on whether or not there would be a significant short- or long-term effect on an animal's welfare. Baker et al. (1983) described two avoidance techniques whales used in response to vessels: horizontal avoidance (faster swimming, and fewer long dives) and vertical avoidance (swimming more slowly but remaining submerged more frequently. Watkins et al. (1981) found that humpback and fin whales appeared startled and increased their swimming speed to move away from the approaching vessel. Johada et al. (2003) studied responses of fin whales in feeding areas when they were closely approached by inflatable vessels. The study concluded that close vessel approaches caused the fin whales to swim away from the approaching vessel and to stop feeding. These animals also had increases in blow rates and spent less time at the surface. This suggests increases in metabolic rates, which may indicate a stress response. All these responses can manifest as a stress response in which the mammal undergoes physiological changes with chronic exposure to stressors, it can interrupt essential behavioral and physiological events, alter time budget, or a combination of all these stressors (Frid and Dill 2002, Sapolsky 2000). All of these responses to stressors can cause an abandonment of an area, reduction in reproductive success, and even death (Mullner et al. 2004, and Daan et al. 1996).

An animal's third line of defense to stressors involves its neuroendocrine or sympathetic nervous systems; the system that has received the most study has been the hypothalmus-pituitary-adrenal system (also known as the HPA axis in mammals or the hypothalamus-pituitary-interrenal axis in fish and some reptiles). Unlike stress responses associated with the autonomic nervous system, virtually all neuro-endocrine functions that are affected by stress – including immune competence, reproduction, metabolism, and behavior – are regulated by pituitary hormones. Stress-induced changes in the secretion of pituitary hormones have been implicated in failed reproduction (Moberg 1987, Rivier 1995), altered metabolism (Elasser et al. 2000), reduced immune competence (Blecha 2000), and behavioral disturbance. Increases in the circulation of glucocorticosteroids (cortisol, corticosterone, and aldosterone in marine mammals; see Romano et al. 2004) have been equated with stress for many years.

The primary distinction between stress (which is adaptive and does not normally place an animal at risk) and distress is the biotic cost of the response. During a stress response, an animal uses glycogen stores that can be quickly replenished once the stress is alleviated. In such circumstances, the cost of the stress response would not pose a risk to the animal's welfare. However, when an animal does not have sufficient energy reserves to satisfy the energetic costs of a stress response, energy resources must be diverted from other biotic functions, which impair those functions that experience the diversion. For example, when mounting a stress response diverts energy away from growth in young animals, those animals may experience stunted growth. When mounting a stress response diverts energy from a fetus, an animal's reproductive success and fitness will suffer. In these cases, the animals will have entered a pre-pathological or pathological state which is called "distress" (sensu Seyle 1950) or "allostatic loading" (sensu McEwen and Wingfield 2003). This pathological state will last until the animal replenishes its biotic reserves sufficient to restore normal function. Note that these examples involved a long-term (days or weeks) stress response exposure to stimuli.

Relationships between these physiological mechanisms, animal behavior, and the costs of stress responses have also been documented fairly well through controlled experiment; because this physiology exists in every vertebrate that has been studied, it is not surprising that stress responses and their costs have been documented in both laboratory and free-living animals (for examples see, Holberton et al. 1996, Hood et al. 1998, Jessop et al. 2003, Krausman et al. 2004, Lankford et al. 2005, Reneerkens et al. 2002, Thompson and Hamer 2000). Although no information has been collected on the physiological responses of marine mammals to anthropogenic sound exposure, studies of other marine animals and terrestrial animals would lead one to expect some marine mammals to experience physiological stress responses and, perhaps, physiological responses that would be classified as "distress" upon exposure to anthropogenic sounds.

For example, Jansen (1998) reported on the relationship between acoustic exposures and physiological responses that are indicative of stress responses in humans (e.g. elevated respiration and increased heart rates). Jones (1998) reported on reductions in human performance when faced with acute, repetitive exposures to acoustic disturbance. Trimper et al. (1998) reported on the physiological stress responses of osprey to low-level aircraft noise, while Krausman et al. (2004) reported on the auditory and physiology stress responses of endangered Sonoran pronghorn to military overflights. Smith et al. (2004a, 2004b) identified noise-induced physiological transient stress responses in hearing-specialist fish (i.e. goldfish) that accompanied short- and long-term hearing losses. Welch and Welch (1970) reported physiological and behavioral stress responses that accompanied damage to the inner ears of fish and several mammals.

Hearing is one of the primary senses marine mammals use to gather information about their environment and communicate with conspecifics. Although empirical information on the relationship between sensory impairment (TTS, PTS, and acoustic masking) on marine mammals remains limited, it seems reasonable to assume that reducing an animal's ability to gather information about its environment and to communicate with other members of its species would be stressful for animals that use hearing as their primary sensory mechanism. Therefore, NMFS assumes that acoustic exposures sufficient to trigger onset PTS or TTS would be accompanied by physiological stress responses because terrestrial animals exhibit those responses under similar conditions (NRC 2003). More importantly, marine mammals might experience stress responses at received levels lower than those necessary to trigger onset TTS. Based on empirical studies of the time required to recover from stress responses (Moberg 2000), NMFS also assumes that stress responses could persist beyond the time interval required for animals to recover from TTS and might result in pathological and pre-pathological states that would be as significant as behavioral responses to TTS.

There is little information available on sound-induced stress in marine mammals or on its potential to affect the long-term health or reproductive success of marine mammals (Fair and Becker 2000, Hildebrand 2005, Wright et al. 2007a, 2007b). Potential long-term effects, if they occur, would be mainly associated with chronic noise exposure (Nieukirk et al. 2009). Disruption in feeding, especially within small populations could have impacts on whales, their reproductive success and even the survival of the species (NRC 2005).

The National Research Council (NRC) developed a model; [the population consequences of acoustic disturbance] (NRC 2005); which includes a conceptual framework that outlines several stages required to relate acoustic disturbance, through effects on life functions and vital rates, to effects on marine mammal populations, and identifies the transfer functions that specify the relationships between the stages. Case studies, including one based on an analysis of energy changes during foraging trips by northern and southern elephant seals and the effects this change had on pup survival (Walmsley 2007), are used to illustrate the potential for population-level effects from disturbance. Anthropogenic noise, by itself or in combination with other stressors, can reduce fitness of individuals and decrease the viability of some marine mammal populations (Wright et al. 2008).

Available data on potential stress-related impacts of anthropogenic noise on marine mammals are extremely limited; research on the stress responses of marine mammals and the technologies for measuring hormonal, neuroendocrinological, cardiological, and biochemical indicators of stress in marine mammals are in the early stages of development (ONR 2009). Obtaining samples from free-ranging marine mammals is complicated by the brief periods of time most are visible while either hauled-out or at the surface to breath, by home ranges that may include expansive and inaccessible areas of ocean which limits the potential for continued or repeated monitoring, and many species cannot be easily captured or sampled using traditional methods (ONR 2009). Blood sampling is not currently possible for large, free-swimming whales. Conducting stress research on marine mammals, therefore, requires novel approaches to obtaining physiologic data and samples. Real time measurement of existing stress hormones and biomarkers are further limited by the invasive nature of many of the sampling methods (e.g., chase, restraint), which may, themselves, be stressors that could mask the physiological signal of interest (ONR 2009).

Recent novel, non-invasive approaches developed for collecting corticosteroid and hormone samples from free-swimming large whales include fecal sampling (Hunt et al. 2006) and sampling whale blows (Hogg et al. 2009, NEA 2011). Both techniques have been used to collect samples from North Atlantic right whales (Eubalaena glacialis) and show promise. The former, however, is limited by the frequency with which feces are encountered. Methods for sampling whale blows, obtaining sufficiently large samples, and measuring stress hormones were being developed and tested by the New England Aquarium during 2011 (NEA 2011). These methods are still being developed and their practicability and viability have not been tested on Arctic species.

Stranding and Mortality

Causes of strandings and mortality related to sound could include: 1) swimming into shallow water to avoid sound; 2) a change in dive behavior; 3) a physiological change; and 4) tissue damage directly from sound exposure, such as through acoustically mediated bubble formation and growth or acoustic resonance of tissues. Some of these are unlikely to apply to airgun impulse sounds.

Seismic pulses and mid-frequency sonar signals are quite different, and some mechanisms by which sonar sounds have been hypothesized to affect beaked whales are unlikely to apply to airgun pulses. Sounds produced by airgun arrays are broadband impulses with most of the energy below 1 kHz. Typical military mid-frequency sonar emits non-impulse sounds at frequencies of 2 to 10 kHz, generally with a relatively narrow bandwidth at any one time. A further difference between seismic surveys and naval exercises is that naval exercises can involve sound sources on more than one vessel. Thus, it is not appropriate to assume that there is a direct connection between the effects of military sonar and seismic surveys on marine mammals. However, evidence that sonar signals can, in special circumstances, lead (at least indirectly) to physical damage and mortality (e.g. Balcomb and Claridge 2001, NOAA and USN 2001, Jepson et al. 2003, Fernández et al. 2004, 2005, Hildebrand 2005, Cox et al. 2006) suggests that caution is warranted when dealing with exposure of marine mammals to any high-intensity "pulsed" sound.

There is no conclusive evidence of cetacean strandings or deaths at sea as a result of exposure to seismic surveys, but a few cases of strandings in the general area where a seismic survey was ongoing have led to speculation concerning a possible link between seismic surveys and strandings. Suggestions that there was a link between seismic surveys and strandings of humpback whales in Brazil (Engel et al. 2004) were not well founded (IAGC 2004, IWC 2007). In September 2002, there was a stranding of two Cuvier's beaked whales in the Gulf of California, Mexico, when the Lamont-Doherty Earth Observatory vessel *R/V Maurice Ewing* was operating a 20 airgun (8,490 in^3) array in the general area. The link between the stranding and the seismic surveys was inconclusive and not based on any physical evidence (Hogarth 2002, Yoder 2002).

4.5.2.4.3 Potential Effects from Other Acoustic Sources Used during Surveys

In addition to a single airgun or airgun arrays, the industry typically uses additional acoustic devices during survey activities, such as single and multi-beam echosounders, sub-bottom profilers, and side scan sonars (many of which operate at frequencies outside of the ranges of best hearing for many baleen whales and pinnipeds). The majority of these sources is smaller and emits sounds at higher frequencies than airguns. The source levels of these devices range from 180 dB re 1 µPa at 1 m to 250 dB re 1 µPa at 1 m and have frequency ranges from 0.2 kHz to 1,600 kHz. Section 2.3.2 of this EIS describes each of these sound sources, with source levels and frequency ranges, in more detail.

Given the directionality and small beam widths for these sources, marine mammal communications are not anticipated to be masked appreciably. Because of the small beam widths, marine mammals would not be in the direct sound field for more than one to two pulses. Additionally, many of these sources emit sounds at frequencies higher than that used by marine mammals for hearing and/or vocalizing.

Behavioral reactions of free-ranging marine mammals to sonars, echosounders, and other sound sources appear to vary by species and circumstance. Observed reactions have included silencing and dispersal by sperm whales (Watkins et al. 1985) and increased vocalizations and no dispersal by pilot whales (Rendell and Gordon 1999). When a 38 kHz echosounder and a 150 kHz acoustic Doppler current profiler were transmitting during studies in the Eastern Tropical Pacific, baleen whales showed no significant responses, while spotted and spinner dolphins were detected slightly more often and beaked whales less often during visual surveys (Gerrodette and Pettis 2005). Very few data are available on the reactions of pinnipeds to echosounder sounds at frequencies similar to those used during seismic operations. Hastie and Janik (2007) conducted a series of behavioral response tests on two captive gray seals to determine their reactions to underwater operation of a 375 kHz multibeam imaging echosounder that included significant signal components down to 6 kHz. Results indicated that the two seals reacted to the signal by significantly increasing their dive durations.

4.5.2.4.4 Potential Effects of On-ice Seismic Surveys

Because these activities occur during the winter and early spring months over the ice, no impacts to cetaceans are anticipated, as cetaceans are typically not present in the Beaufort Sea during this time period. Impacts to pinnipeds could potentially occur when they are hauled out on the ice or inside subnivean lairs. Disturbance from noise produced by the seismic survey equipment is expected to include localized displacement from lairs by the seals in proximity (within 150 m [492 ft]) to seismic lines (Kelly et al. 1988). Impacts would only occur to pinnipeds in the Beaufort Sea, as no such surveys are expected to occur in the Chukchi Sea. See Sections 4.5.2.4.9 through 4.5.2.4.14 for details regarding potential effects on bowhead whales, beluga whales, other cetaceans, pinnipeds, walrus, and polar bears, respectively.

4.5.2.4.5 Potential Effects of Aircraft Activities

Potential effects to marine mammals from aircraft activity could involve both acoustic and non-acoustic effects. It is uncertain if the animals react to the sound of the aircraft or to its physical presence flying overhead. Minor and short-term behavioral responses of cetaceans to helicopters have been documented in several locations, including the Beaufort Sea (Richardson et al. 1985a, b, Patenaude et al. 2002). Reactions of hauled out pinnipeds to aircraft flying overhead have been noted, such as looking up at the aircraft, moving on the ice or land, entering a breathing hole or crack in the ice, or entering the water (Born et al. 1999, Blackwell et al. 2004a). Reactions depend on several factors including the animal's behavioral state, activity, group size, habitat, and flight pattern (Richardson et al. 1995). Additionally, a study conducted by Born et al. (1999) found that wind chill was also a factor in level of response of ringed seals hauled out on ice, as well as time of day and relative wind direction. Marine mammal reactions to helicopter disturbance are difficult to predict and may range from no reaction to minor course changes or, occasionally, leaving the immediate area of the activity. Currently, NMFS' threshold for determining if an aircraft overflight may take a marine mammal or not is 1,000 ft altitude (except for takeoffs, landings, and emergency situations).

4.5.2.4.6 Potential Effects of Icebreaking and Ice Management Activities

Icebreakers produce more noise while breaking ice than when transiting open waters primarily because of the sounds of propeller cavitation (Richardson et al. 1995). Icebreakers typically ram into heavy ice until losing momentum, then back off to build momentum before ramming again. The highest noise levels usually occur while backing full astern in preparation to ram forward through the ice. Overall, the noise generated by an icebreaker pushing ice is typically 10 to 15 dB greater than the noise produced by the ship underway in open water (Richardson et al. 1995). Roth and Schmidt (2010) noted a source level of 200 dB re 1 µPa at 1 m during backing and ramming of ice. Industry in-ice seismic surveys recently conducted in the U.S. Arctic did not employ the "backing and ramming" approach described above but rather required continuous forward progress at 3-4 knots in mostly newly forming juvenile first year ice or young first year ice less than 0.5 m (1.6 ft) thick instead of in thick, multi-year ice (ION 2012). Sounds generated by the icebreaker moving through relatively light ice conditions are expected to be far below the high sound levels often attributed to "backing and ramming" icebreaking in very heavy ice conditions, which are created by cavitation of the propellers as the vessel is slowed by the ice or reverses direction (Erbe and Farmer 1998, Roth and Schmidt 2010). Icebreaking is considered by NMFS to be a continuous sound. Haley et al. (2010a) estimated that as the icebreaker travels through the ice, a swath 3,500 m (2.17 mi) wide would be subject to sound levels ≥120 dB, based on the source level of 185 dB attenuating to 120 dB in about 1,750 m (1.09 mi).

Icebreaking activities may also have non-acoustic effects such as the potential for causing injury, ice entrapment of animals that follow the ship, and disruption of ice habitat (reviewed in Richardson et al. 1989:315). The species of marine mammals that may be present and the nature of icebreaker activities are strongly influenced by ice type. Some species are more common in loose ice near the margins of heavy pack ice while others appear to prefer heavy pack ice. Propeller cavitation noise of icebreaking ships in loose ice is likely similar to that in open water while noise is expected to be much greater in areas of heavier pack ice or thick landfast ice where ship speed will be reduced, power levels will be higher, and there will be greater propeller cavitation (Richardson et al. 1995).

There is little information available about the effect on marine mammals of the increased sound levels due to icebreaking, although beluga whales have been documented swimming rapidly away from ships and icebreakers in the Canadian high Arctic (Richardson et al. 1995). Little information is available regarding the effects of icebreaking ships on baleen whales, but a similar behavioral response would be expected as those mentioned above. Whales could be diverted or could rapidly swim away from the source. Please refer to Sections 4.5.2.4.9 through 4.5.2.4.14 for details regarding potential effects on bowhead whales, beluga whales, other cetaceans, pinnipeds, walrus, and polar bears, respectively.

4.5.2.4.7 Potential Effects of Vessel Activity

Reactions of marine mammals to vessels often include changes in general activity (e.g. from resting or feeding to active avoidance), changes in surfacing-respiration-dive cycles, and changes in speed and direction of movement. Past experiences of the animals with vessels are important in determining the degree and type of response elicited from an animal-vessel encounter. Whale reactions to slow-moving vessels are less dramatic than their reactions to faster and/or erratic vessel movements. Some species have been noted to tolerate slow-moving vessels within several hundred meters, especially when the vessel is not directed toward the animal and when there are no sudden changes in direction or engine speed (Wartzok et al. 1989, Richardson et al. 1995, Heide-Jorgensen et al. 2003). Few authors have specifically described the responses of pinnipeds to boats, and most of the available information on reactions to boats concerns pinnipeds hauled out on land or ice. In places where boat traffic is heavy, there have been cases where seals have habituated to vessel disturbance (e.g. Bonner 1982, Jansen et al. 2006).

Collisions with seismic or support vessels are possible but highly unlikely. Ship strikes with marine mammals can lead to death by massive trauma, hemorrhaging, broken bones, or propeller wounds (Knowlton and Kraus 2001). Massive propeller wounds can be immediately fatal. If more superficial, whales may be able to survive the collisions (Silber et al. 2009). Vessel speed is a key factor in determining the frequency and severity of ship strikes, with the potential for collision increasing at ship speeds of 15 kn and greater (Laist et al. 2001, Vanderlaan and Taggart 2007).

Incidence of injury caused by vessel collisions appears to be low in the Arctic. Less than 1 percent of bowhead whales have scars indicative of vessel collision. This could be due to either collisions resulting in death (and not accounted for) or a low incidence of co-occurrence of ships and bowhead whales (George et al. 1994).

4.5.2.4.8 Potential Effects of Exploratory Drilling

Exploratory drilling could affect marine mammals through noise, discharge of drilling waste, and accidental discharges such as oil spills. Sounds from exploratory drilling are different from airgun sounds. As described in Section 4.5.1.4 (Acoustics), most drilling sounds from vessels produce sounds at relatively low frequencies below 600 Hz with tones up to around 1,850 Hz (Greene 1987). The potential effects of noise from drilling operations are very similar to airguns, although at a lesser magnitude because source levels of drilling units are not as high as airgun arrays.

Exploratory drilling operations may involve the discharge of drill cuttings and drilling fluids directly into the ocean. As described in Section 4.5.1.5 (Water Quality) these discharges could result in elevated concentrations of metals such as chromium, copper, mercury, lead, and zinc, as well as increased concentrations of hydrocarbons and other organic compounds in the water. Some of the discharge streams that may be permitted for oil and gas activities in the proposed action area have been associated with impacts to marine resources, yet, despite a considerable amount of investment in research of exposures of marine mammals to organochlorines or other toxins, there have been no marine mammal deaths in the wild that can be conclusively linked to the direct exposure to such substances (O'Shea 1999). However, the impact of drill cuttings and drilling mud discharges would be localized and temporary. Discharged drilling fluid should be well diluted within 100 m (330 ft) so that any impacts would be localized and temporary, assuming that whales continue to swim through and past the discharge plume. If toxic contaminants are present in discharges, only a small area of potential habitat and prey base for marine mammals might be contaminated.

Many of the contaminants of concern, including organic contaminants such as organochlorine compounds and PAHs, as well as metals such as chromium and mercury, have the potential to accumulate in marine mammals. Indirect effects to marine mammals could result from exposure to contaminants of concern through the food web and the relevant pathway of exposure would involve trophic transfers of contaminants rather than direct exposure. Monitoring conducted as part of the ANIMIDA and cANIMIDA projects has shown that oil and gas developments in the Alaskan Beaufort Sea "are not contributing ecologically important amounts of petroleum hydrocarbons and metals to the near-shore marine food web of the area" (Neff 2010). Additional mitigation measures C3, C4, and C5 include requirements to ensure reduced discharge of the specific discharge streams identified with potential impacts to marine mammals or marine habitat. Those discharge streams include drill cuttings, drilling fluids, sanitary waste, domestic waste, ballast water, and bilge water. Elimination or reduction of those discharge streams is expected to reduce the potential for adverse impacts to marine mammals. Additional mitigation measures requiring operators to recycle drilling muds may also reduce the potential for adverse impacts to marine mammals and other organisms within the EIS project area.

Accidental discharges of oil or other contaminants could also occur during exploratory drilling and would likely adversely affect marine mammals. Standard mitigation measures requiring operators to have plans in place to minimize the likelihood of a spill would reduce the potential for adverse impacts from such discharges. The effects of a very large oil spill on marine mammals are analyzed in Sections 4.10.6.11 and 4.10.7.11.

4.5.2.4.9 Bowhead Whales

4.5.2.4.9.1 Direct and Indirect Effects

The primary direct and indirect effects on bowhead whales from activities associated with oil and gas exploration in the Beaufort and Chukchi seas considered under Alternative 2 would result from noise exposure. Ship strikes and habitat degradation are also possible, but low probability. Sources of noise include 2D/3D seismic survey equipment (airgun arrays), echosounder and sonar devices associated with site clearance and shallow hazards surveys, support, monitoring and receiving vessels associated with these surveys, icebreaking activities, on-ice vibroseis seismic surveys (Beaufort Sea only), exploratory drilling, and helicopter and fixed wing aircraft associated with the different programs. Details of these activities and associated components can be found in Chapter 2.

Behavioral Disturbance

Anthropogenic noise from oil and gas exploration activities may elicit behavioral responses from bowhead whales. The suite of possible reactions is listed above; known reactions by bowhead whales are included here and described and assessed by region and activity.

Beaufort Sea Activities

2D/3D Seismic Surveys (July through November)

Airgun arrays are the most common source of seismic survey noise. Baleen whales generally avoid operating airguns, but avoidance distances vary by species, locations, behavioral activities, as well as environmental conditions that influence sound propagation (Richardson et al. 1995, Gordon et al. 2004).

Airgun sounds can propagate horizontally for many kilometers (Greene and Richardson 1988). In waters 25 to 50 m (82 to 164 ft) deep, airgun sound can be detected 50 to 75 km (31 to 46 mi) away; in deeper water, ranges can exceed 100 km (62 mi) (Richardson et al. 1995). Ranges from airgun arrays to SPL thresholds between 190 and 120 dB re 1 μPa rms were calculated from different directions from the source vessel for 3D seismic surveys in the Beaufort Sea in 2008 using a 30 in^3 single airgun and an arry of up to 3,147 in^3. Ranges were 10 to 770 m (33 to 2,526 ft) for 190 dB re 1 μPa rms, 46 to 2,500 m (151 to 8,202 ft) for 180 dB re 1 μPa rms, 910 to 9,000 m (2,986 ft to 5.29 mi) for 160 dB re 1 μPa rms, and 23 to 120 km (14 to 74.5 mi) for 120 dB re 1 μPa rms. Ranges from airgun arrays to SPL thresholds between 190 and 120 dB re 1 μPa rms were calculated from different directions from the source vessel for a 3D seismic survey in the Chukchi Sea in 2010 using a 60 in^3 single airgun and an array of up to 3,000 in^3. Ranges were 11 to 430 m (36 to 1,411 ft) for 190 dB re 1 μPa rms, 57 to 1,400 m (187 to 4,593 ft) for 180 dB re 1 μPa rms, 1,300 to 11,000 m (4,265 ft to 6.8 mi) for 160 dB re 1 μPa rms, and 25 to 123 km (15.5 to 76.4 mi). (Refer to Table 4.5-11 in Section 4.5.1.4, Acoustics, for additional details on measurements.)

Observed responses of bowhead whales to seismic noise depend on whether the whales are feeding or migrating. Feeding bowheads tend to show less avoidance of sound sources than do migrating bowheads.

Bowhead whales feeding in the Canadian Beaufort Sea in the 1980s showed no obvious behavioral changes in response to airgun pulses from seismic vessels 6 to 99 km (3.7 to 61.5 mi) away, with received sound levels of 107 to 158 dB rms (Richardson et al. 1986). They did, however, exhibit subtle changes in surfacing–respiration–dive cycles. Seismic vessels approaching within approximately 3 to 7 km (1.9 to 4.3 mi), with received levels of airgun sounds of 152 to 178 dB, usually did not elicit strong avoidance reactions (Richardson et al. 1986, 1995, Ljungblad et al. 1988, Miller et al. 2005). Richardson et al. (1986) observed feeding bowheads start to turn away from a 30-airgun array with a source level of 248 dB re 1 µPa at a distance of 7.5 km (4.7 mi) and swim away when the vessel was within about 2 km (1.2 mi); other whales in the area continued feeding until the seismic vessel was within 3 km (1.9 mi). More recent studies have similarly shown greater tolerance of feeding bowhead whales to higher sound levels than migrating whales (Miller et al. 2005, Harris et al. 2007). Koski et al. (2008) observed several groups of bowhead whales that continued feeding near a seismic survey in the central Beaufort Sea in 2007 where received sound levels reached between 150 and 180 dB re 1 µPa. Data from an industry aerial monitoring program in the Alaskan Beaufort Sea during 2006 through 2008 and 2010 noted that bowhead whale mean distance from the center of active seismic operations increased for traveling but not for feeding whales; however, ice conditions appear to be a factor as well (Funk et al. 2011). This apparent tolerance, however, should not be interpreted to mean that bowheads are unaffected by the noise. Feeding bowheads may be so highly motivated to stay in a productive feeding area that they remain in an area with noise levels that could, with long term exposure, cause adverse effects (NMFS 2010c).

Migrating bowhead whales respond behaviorally more strongly to seismic noise pulses than do feeding whales. Bowhead whales migrating west across the Alaskan Beaufort Sea in autumn showed avoidance out to 20 to 30 km (12.4 to 18.6 mi) from a medium-sized airgun source at received sound levels of around 120 to 130 dB re 1 µPa rms (Miller et al. 1999, Richardson et al. 1999). Avoidance of the area did not last more than 12 to 24 hours after seismic shooting stopped. Deflection might start as far as 35 km (21.7 mi) away and may persist 25 to 40 km (15.6 to 24.9 mi) to as much as 40 to 50 km (24.9 to 31.1 mi) after passing seismic-survey operations (Miller et al. 1999). Analyses of data on traveling bowheads in the Alaskan Beaufort Sea also showed a stronger tendency to avoid operating airguns than was evident for feeding bowheads (Christie et al. 2009, Koski et al. 2009). Richardson et al. (1999) suggests that migrating bowheads start to show significant behavioral disturbance from multiple pulses at received levels around 120 dB re 1 µPa.

The effect of seismic airgun pulses on bowhead whale calling behavior has been extensively studied in the Beaufort Sea. During the autumn season in 2007 and 2008, calling rates decreased significantly in the presence (<30 km [<18.6 mi]) of airgun pulses (Blackwell et al. 2010a). There was no observed effect when seismic operations were distant (>100 km [>62 mi]). Call detection rates dropped rapidly when cumulative sound exposure levels (CSELs) were greater than 125 dB re 1 $\mu Pa^2 \cdot s$ over 15 minutes. The decrease was likely caused by a combination of less calling by individual whales and by avoidance of the area by some whales in response to the seismic activity. Calls resumed near the seismic operations area shortly after operations ended. Aerial surveys showed high sighting rates of feeding, rather than migrating, whales near seismic operations (Blackwell et al. 2010a). In contrast, reduced calling rates during a similar study in 1996 to 1998 were largely attributed to avoidance of the area by whales that were predominantly migrating, not feeding (Miller et al. 1999, Richardson et al. 1999).

The open water season (July through October) during which proposed seismic activities would occur (for up to 90 days), overlaps with summer feeding and the late-summer/fall westward migration of bowhead whales across the Alaskan Beaufort Sea. Therefore, the potential for exposure and disturbance is high during this time period. Data available from the Bowhead Whale Aerial Survey Project (BWASP) and other surveys (Ashjian et al. 2010, Clarke et al. 2011a, 2011b, 2011c, Koski and Miller 2009, Moore et al. 2010, Okkonen et al. 2011) reveal areas where concentrations, including feeding aggregations and/or aggregations of females and calves, are more likely to occur in the Beaufort Sea. These areas include a bowhead whale feeding "hotspot" during late summer to fall from Point Barrow to Smith Bay and the

Kaktovik area where whales are occasionally observed feeding as early as July, and often occur in higher concentrations beginning in late-August and September.

Seismic activity in the Beaufort Sea would likely impact bowhead whales, although the level of disturbance will depend on whether the whales are feeding or migrating, as well as other factors such as the age of the animal, whether or not is is habituated to the sound, etc. Responses can range from apparent tolerance to interrupted communication, minor displacement, or avoidance of an area. If multiple 2D/3D seismic surveys occurred in areas with concentrations of bowheads present, large numbers of bowheads could potentially be disturbed or potentially excluded by avoidance from feeding habitat for the duration of the survey period. Most observed disturbance reactions appear to be short-term (meaning the length of the exposure to seismic pulses or less time), and short-term reactions to airgun noises are not necessarily indicative of long-term or biologically significant effects. It is not known whether impulsive sounds affect reproductive rate or distribution and habitat use over periods of days or years. The Western Arctic stock of bowhead whales has, however, been increasing at approximately 3.4 percent per year (George et al. 2004), despite exposure to exploration activities in the Beaufort and Chukchi seas since the late 1960s (MMS 2006). In addition, the potential for increased stress, and the long-term effects of stress, are unknown, as research on stress effects in marine mammals is limited (see discussion above). The level of available information is sufficient to support sound scientific judgments and reasoned managerial decisions, even in the absence of additional data of this type.

In terms of the impact criteria of Table 4.5-19, the disturbance effects of exploratory activity under Alternative 2 would be considered of medium intensity. Additionally, contextually, these impacts take place within a known migratory corridor through which these endangered whales must travel with calves and some may be temporarily displaced from preferred feeding areas. The EIS project area encompasses a large portion of bowhead whale habitat between the Bering Strait and Canadian border, so leaving the area entirely to avoid impacts is not a likely option. The duration of exposures from these surveys, which is considered interim, would be limited to the open water season, and any behavioral responses by bowhead whales to activities is expected to be temporary and contained primarily within the time-period that an individual is exposed to the sounds. The extent of the impact will depend on the number of seismic activities and associated support vessels in an area, but, for individual sound source vessels, impacts are expected to be localized. Multiple activities in one area or in several areas across the migratory corridor could result in a broader, regional impact.

In-ice Seismic Survey (2D/3D) with Icebreaker Support (October to mid-December)

Disturbance effects from seismic activities are anticipated to be the same as described above. The difference with this activity is the additional noise input from icebreaking activities and the extended period of activity into late fall and early winter. The temporal component of this activity and the potential effects of icebreakers are addressed here.

Increased noise from icebreaking activities may present concerns for bowhead whales (NMFS 2010c). Estimated source levels for an icebreaker range from 177 to 191 dB re 1 μPa (Richardson et al. 1995). A study by Miles et al. (1987) used models to predict responses of bowhead whales to icebreaker noise and determined that response was likely at distances of 2 to 25 km (1.24 to 15.53 mi). Zones of responsiveness for intermittent sounds, such as an icebreaker pushing ice, were not studied. They further predicted that approximately half of the bowhead whales exhibited avoidance behavior to a traveling icebreaker in open water at 2 to 12 km (1.25 to 7.46 mi) when the sound-to-noise ratio is 30 dB and to an icebreaker pushing ice at a distance of 4.6 to 20 km (2.86 to 12.4 mi) when the sound-to-noise ratio is 30 dB. Migrating bowhead whales avoided an icebreaker-accompanied drillship (with nearly daily icebreaking) by >25 km (>15.5 mi) in 1992 (Brewer et al. 1993).

The additional sound from an icebreaker accompanying seismic activity could cause temporary avoidance of bowhead whales from areas where the vessels are operating and potentially cause temporary deflection of the migration corridor (NMFS 2010c). BWASP surveys flown in September and October of 2006 through 2010 of the Alaskan Beaufort Sea include sightings of bowhead whales through at least mid-October, with sightings occurring from the U.S./Canadian border to Point Barrow (Clarke et al. 2011b, 2011c, 2011d). It is during this time period that the likelihood of co-occurrence of bowhead whales and icebreaker-accompanied seismic activity is most probable. Avoidance by bowhead whales of important feeding areas and displacement during migration are possible. The likelihood of interaction diminishes by late October as most bowheads will have migrated out of the Beaufort Sea; therefore, impacts to bowhead whales from this type of activity are only anticipated for the first few weeks of the survey.

Because in-ice seismic surveys are designed to begin in early to mid-October towards the end of the bowhead whale fall migration westward through the Beaufort Sea, anticipated impacts of in-ice activities would be anticipated to be somewhat lower than those described for 2D/3D seismic surveys above (see Table 4.5-19 for impact criteria definitions). Surveys utilizing icebreakers could, however, cause avoidance and displacement over a larger radius with the additional noise input from the icebreaking activities, but the period of time over which this activity would overlap with bowhead whales in the Beaufort Sea is much shorter. Based on these factors, anticipated impacts of in-ice activities are anticipated to be of medium intensity, interim duration, local in extent, and would affect a unique resource for any bowhead whales that may occur in vicinity at the beginning of in-ice operations. However, as operations continue, bowheads would no longer occur in the project area, as they overwinter south of the EIS project area.

Ocean-Bottom-Cable Survey (July to October)

Ocean-bottom-cable (OBC) seismic surveys are used in nearshore areas where water is too shallow (≤14 m [≤45.9 ft]) for a towed marine streamer seismic survey vessel and too deep to have bottomfast ice in the winter. An OBC seismic survey typically covers a smaller area than the streamer surveys discussed above and may spend several days in an area. One such survey is anticipated in the Beaufort Sea under Alternative 2. OBC surveys require the use of multiple vessels (see Chapter 2, Table 2.4). Noise and disturbance effects of support vessels are discussed separately below.

Reactions to sounds from OBC surveys are similar to those reported for 2D/3D streamer seismic surveys. A partially-controlled study of the effect of OBC seismic surveys on westward-migrating bowhead whales was conducted in late summer and fall in the Alaskan Beaufort Sea in 1996 to 1998. Whales avoided the sound source out to 20 to 30 km (12.4 to 18.6 mi) at received sound levels of around 120 to 130 dB re 1 μPa rms (Miller et al. 1999, Richardson et al. 1999). Miller et al. (1999) estimated that deflection may have begun about 35 km (22 mi) to the east. Several bowheads moved into the area close to the seismic vessel during periods when airguns were inactive. Avoidance of the area of seismic operations did not persist beyond 12 to 24 hours after seismic shooting stopped.

The open water season of July to October, during which OBC surveys are likely to occur, coincides with summer feeding and late-summer/fall migration periods for bowhead whales in the Beaufort Sea. Although most bowhead whales feed in the Canadian Beaufort and Amundson Gulf during the summer months, some may occur near Kaktovik as early as July (Koski and Miller 2009). From late-summer through October, bowhead whales commonly occur in nearshore, shallow waters. The median depths of bowhead sightings during 2006 to 2009 BWASP surveys ranged from 15 to 44 m (49.2 to 144.4 ft) (Clarke et al. 2011b, 2011c). In addition, the distance from which migrating bowheads appear to deflect from OBC sound sources suggest possible disturbance to whales traveling or feeding farther offshore.

Anticipated impacts of OBC surveys, in terms of magnitude (medium), duration (interim), extent (local), and context (unique) would be similar to those described for 2D/3D seismic surveys above. See Table 4.5-19 for impact criteria definitions. Although disturbance effects may extend 20 to 30 km (12.4 to 18.6 mi) from the sound source, with one OBC survey anticipated in the Beaufort Sea, short-term effects should remain localized.

Site Clearance and High Resolution Shallow Hazards Survey Programs (July to November)

High-resolution shallow hazards surveys are of short duration, and the airguns are smaller, generating lower energy sounds and a smaller zone of influence than the larger airgun arrays used for 2D/3D seismic surveys (NMFS 2010b). The radii of ensonification at 120, 160, 180, and 190 dB re 1 μPa rms were calculated for sound sources proposed for use in 2010. Radii calculated for the 40 in^3 airgun were 14,000 m (45,932 ft), 1,220 m (4,003 ft), 125 m (410 ft), and 35 m (115 ft) for the respective sound source levels. Additional information on measured sound radii for such sound sources in the Beaufort and Chukchi seas between 2006 and 2010 is contained in Table 4.5-10. Ensonified zones were not calculated for side scan sonar, single-beam or multi-beam echosounders, or for the bathymetric sonar (NMFS 2010b), as many of these sources are outside the range of best hearing for mysticetes and possibly for other marine mammals. Additionally, as mentioned above, the beam widths of these sources are quite narrow, which would only expose marine mammals to the sounds for one or two pulses, at most, if the animal swims in the direct beam width of the source.

Bowheads appear to continue normal behavior when exposed to noise generated by high-resolution seismic surveys. Richardson et al. (1985) tested this by firing a single 40 in^3 airgun at a distance of 2 to 5 km (1.2 to 3.1 mi) from whales. Some bowheads continued feeding, surfacing, diving, or traveling when the airgun began firing 3 to 5 km (1.9 to 3.1 mi) away (received noise levels at least 118 to 133 dB re 1 μPa rms. In other tests, some whales oriented away at 2 to 4.5 km (1.2 to 2.8 mi) and at 0.2 to 1.2 km (0.12 to 0.75 mi) (received noise levels at least 124 to 131 and 124 to 134 dB, respectively). Turning, diving, surfacing, respiration and calling were similar with or without airguns (Richardson et al. 1985a, b).

Site clearance and high resolution shallow hazards surveys on active leases in the Beaufort Sea could overlap spatially and temporally with feeding bowhead whales in some years from Harrison Bay to Camden Bay, particularly during their migration from the eastern Beaufort Sea to the Chukchi Sea.

Based on the criteria defined in Table 4.5-19, anticipated impacts of these surveys, in terms of magnitude (medium), duration (interim), extent (local), and context (unique) would be similar to those described for 2D/3D seismic surveys above.

On-ice Vibroseis Survey (January to May)

The presence of bowhead whales are not likely to overlap with an on-ice vibroseis survey due to their absence from the Beaufort Sea during the winter months. If, however, the activity continues into April and May, it could coincide with the spring migration through the nearshore lead system from the Chukchi Sea into the Beaufort Sea. The migratory pathway of bowheads is more narrowly defined during the spring migration largely due to constraints imposed by ice configurations and leads and fractures. The migration corridor through the Beaufort Sea extends farther offshore than that through the Chukchi Sea (Figure 3.2-12), so migrating whales may be sufficiently distant from noise produced from vibroseis to not be disturbed.

Bowhead whales are sensitive to sound, including on-ice sounds, during the spring migration, as noted by Iñupiat whalers:

> *The whales are very sensitive to noise and water pollution. In the spring whale hunt, the whaling crews are very careful about noise. In my crew, and in other crews I observe, the actual spring whaling is done by rowing small boats, usually made from bearded sealskins. We keep our snow machines well away from the edge of the ice so that the machine sound will not scare the whales* (NMFS 2013).

Exploratory Drilling (July through October)

Exploratory drilling is anticipated to initially occur on active leases offshore of Camden Bay. In addition to a drillship or steel drilling caisson (SDC), there will be additional vessels for support and ice management (potentially as many as 11 or 12). Potential impacts from additional vessel traffic will be discussed separately from the effects of the drillship operations (see Associated Vessels and Aircraft below). Multiple sites could be drilled each season with up to three wells being a reasonable number for analysis purposes. This is based on the amount of time needed to drill each individual well and the available amount of time to conduct such operations during the ice free months. See Chapter 2 for details of this activity.

Reaction of bowhead whales to drillship operation noises varies. Whales exhibiting apparently normal behavior were observed several times within 10 to 20 km (6.2 to 12.4 mi) of drillships in the eastern Beaufort Sea, and whales have been sighted within 0.2 to 5 km (0.12 to 3 mi) of drillships (Richardson et al. 1985a, b, Richardson and Malme 1993). Bowheads may, however, avoid drillships and accompanying support vessels at 20 to 30 km (12.4 to 18.6 mi) (MMS 2003). The presence of actively operating icebreakers in support of drilling operations introduces additional noise into the marine environment and affects responses of whales. In 1992, Brewer et al. (1993) noted that migrating bowhead whales avoided an icebreaker-accompanied drillship by >25 km (>15.5 mi). Richardson et al. (1995) observed avoidance behavior in half of the bowhead whales exposed to 115 dB re 1 μPa rms broadband drillship noises. Reaction levels depended on whale activity, noise characteristics, and the physical situation, similar to that observed with seismic sounds. Richardson and Greene (1995) concluded that the observed playback effects of drilling noise were localized and temporary and that effects on distribution, movements, and behavior were not biologically important. Continued long-term monitoring of effects may be needed to better address the issue of biological importance.

Continuous noise emitted from stationary sources, such as drillships, elicits less dramatic behavioral reactions (e.g. changes in swim speed, dive behavior, etc.) by bowhead whales than do moving sources, particularly ships (Richardson and Malme 1993). Most observations of bowheads apparently tolerating noise from stationary operations were opportunistic sightings of whales near oil-industry operations; whether more whales would have been present in the absence of those operations is not known.

Some bowheads likely avoid closely approaching drillships by changing their migration speed and direction, making distances at which reactions to drillships occur difficult to determine. In a study by Koski and Johnson (1987), one whale appeared to alter course to stay 23 to 27 km (14.3 to 16.8 mi) from the center of the drilling operation. Migrating whales passed both north and south of the drillship, apparently avoiding the area within 10 km (6.2 mi) of the drillship. No bowheads were detected within 9.5 km (5.9 mi) of the drillship, and few were observed within 15 km (9.3 mi). They concluded that westward migrating bowheads appeared to avoid the offshore drilling operation during the fall of 1986, and some may avoid noise from drillships at 20 km (12.4 mi) or more.

Monitoring of the Kuvlum drilling site north of Point Thompson occurred during the 1993 fall bowhead whale migration by Hall et al. (1994). These data were later reanalyzed by Davies (1997) and Schick and Urban (2000). Davies (1997) concurred with Hall et al. (1994) that the whales were not randomly distributed in the study area, and that they avoided the area around the drill site at a distance of approximately 20 km (12.4 mi). Hall et al. (1994) noted that the distribution of whales observed in the Kuvlum drilling site is consistent with previous studies (Moore and Reeves 1993), where whales were observed farther offshore in this part of the Beaufort Sea than they were to the east of Barter Island, and that it was difficult to separate the effect of the drilling operation from other independent variables, such as water depth. However, Davies (1997) noted that whales were closer to shore and in shallower water. Results in Schick and Urban (2000) indicated that whales within hearing range of the drillship (<50 km [<31.1 mi]) were distributed farther from the rig than they would be under a random scenario. They concluded that spatial distribution was strongly influenced by the presence of the drillship but lacked data to assess noise levels. Other factors that could influence distribution relative to the drillship were support vessels and icebreakers operating in the vicinity, as well as ice thickness (Schick and Urban 2000). All of these studies noted some level of bowhead whale deflection from active drilling operations.

Bowhead whales, including mothers and calves, may occur in Camden Bay as early as July but more typically from late-August through September (Koski and Miller 2009). It appears to be part of the fall migration corridor. There is, therefore, a high likelihood that drilling operations would coincide with bowhead whale occurrence in the area, with reactions ranging from apparent tolerance (mostly by feeding whales) to displacement and avoidance of the drilling operations.

Based on the impact criteria defined in Table 4.5-19, anticipated impacts of exploratory drilling activities, in terms of magnitude (medium), duration (interim), extent (local), and context (unique) would be similar to those described above for seismic surveys. The zone of possible displacement around a drillship would also be influenced by accompanying support vessel and icebreaker activity and their respective working distances from the drill rig.

Associated Vessels and Aircraft

Bowhead whales react to approaching vessels at greater distances than they react to most other activities. Vessel-disturbance experiments in the Canadian Beaufort Sea by Richardson and Malme (1993) showed that most bowheads begin to swim rapidly away when fast moving vessels approach directly. Avoidance usually begins when a rapidly approaching vessel is 1 to 4 km (0.62 to 2.5 mi) away. Whales move away more quickly when approached closer than 2 km (1.2 mi) (Richardson and Malme 1993). A few whales reacted at distances of 5 to 7 km (3.1 to 4.3 mi), while others did not react until the vessel was <1 km (<0.62 mi) away. Received noise levels as low as 84 dB re 1 μPa, or 6 dB above ambient, elicited strong avoidance of an approaching vessel from 4 km (2.5 mi) away. During the experiments, vessel disturbance temporarily disrupted activities, and socializing whales moved apart from one another. Fleeing from a vessel usually stopped soon after the vessel passed, but scattering lasted for a longer time period. Some bowheads returned to their original locations after the vessel disturbance (Richardson and Malme 1993). Bowheads react less dramatically to and appear more tolerant of slow-moving vessels, especially if they do not approach directly.

Data are not sufficient to determine sex, age, or reproductive characteristics of bowhead whale response to vessels. Data are also not available to determine whether female bowheads with calves react differently than other segments of the population.

Iñupiat whalers expressed concern over vessel impacts on bowhead whales, noting observed displacement caused by barge activity:

> *Bowhead whales have a different view of how they interact with things. For instance, I want to say, again, I've met with you guys, and I explained when I was a whaling captain in '05 was my first year, I saw 100 -- over 100 whales diverted from one barge, and there was no other whales beyond that for the next 15 miles. So I've seen the activity and the diversion of bowhead whales from industry* (testimony provided by Thomas Napageak, Jr. at Nuiqsut Public Scoping Meeting for this EIS, March 11, 2010).

Data on reactions of bowheads to helicopters are limited. Most bowheads showed no obvious response to helicopter overflights at altitudes above 150 m (500 ft) (Richardson and Malme 1993). Patenaude et al. (2002) found that most reactions by bowhead whales to a Bell 212 helicopter occurred when the helicopter was at altitudes of ≤150 m (500 ft) and lateral distances of ≤250 m (820 ft). Reactions included abrupt dives, short surfacings, and breaching, and, most, if not all, reactions seemed brief. The majority of bowheads, however, showed no obvious reaction to single passes, even at those distances. Data were insufficient to analyze effects of repeated low-altitude passes (Patenaude et al. 2002).

Fixed-wing aircraft flying at low altitude often cause bowheads to dive rapidly. Reactions to circling aircraft may be conspicuous at altitudes <300 m (1,000 ft), uncommon at 460 m (1,500 ft), and generally undetectable at 600 m (2,000 ft). Repeated low-altitude overflights at 150 m (500 ft) during aerial photogrammetry studies of feeding bowheads sometimes elicited abrupt turns and quick dives (Richardson and Malme 1993). Aircraft on a direct course are audible only briefly, and whales are likely to resume their normal behavior within minutes after the plane passes (Richardson and Malme 1993). Only 2.2 percent of bowheads during the spring migration reacted to Twin Otter overflights at altitudes of 60 to 460 m (197 to 1,509 ft) (Patenaude et al. 2002). Reactions diminished with increasing lateral distance and altitude. Most observed reactions by bowheads occurred when the Twin Otter was at altitudes of ≤182 m (597 ft) and lateral distances of ≤250 m (820 ft). There was little, if any, reaction when the aircraft circled at an altitude of 460 m (1,509 ft) and a radius of 1 km (0.62 mi) (Patenaude et al. 2002). The effects from an encounter with aircraft are brief, and the whales generally resume their normal behavior within minutes.

During their study, Patenaude et al. (2002) observed one bowhead whale cow-calf pair during four passes totaling 2.8 hours of the helicopter and two pairs during Twin Otter overflights. All of the helicopter passes were at altitudes of 15 to 30 m (49 to 98 ft). The mother dove both times she was at the surface, and the calf dove once out of the four times it was at the surface. For the cow-calf pair sightings during the Twin Otter overflights, the authors did not note any behaviors specific to those pairs. Rather, the reactions of the cow-calf pairs were lumped with the reactions of other groups that did not consist of calves.

The likelihood of spatial and temporal overlap between support vessels and aircraft with bowhead whales in the Beaufort Sea is high. The degree of overlap and interaction depends on the spatial and temporal distribution of activities and whether they are broadly dispersed or clustered. The greatest potential for helicopter or fixed-wing aircraft to cause adverse effects on bowhead whales is in areas where whales are aggregated, especially if aggregations contain large numbers of cow/calf pairs. Activities, such as exploratory drilling, will utilize multiple support vessels, as well as resupply trips and flights to the dock at Prudhoe Bay (see Chapter 2, Tables 2.2 and 2.4). The number of kilometers transited by seismic and various types of support vessels in the Beaufort Sea in 2006 to 2008 ranged from 9,580 km (5,953 mi) in 2006 to 67,627 km (42,021 mi) in 2008 (Funk et al. 2010). During operations, most source vessel speeds are relatively slow, in the range of 3 to 5 kn, although transit speeds are likely to be much higher. Source vessel transit speeds for 2D/3D seismic surveys are estimated at 8 to 20 kn (refer to Chapter 2 for details). If such activity coincides with aggregations of whales, then disruption is likely.

Most observed disturbance reactions to vessel and aircraft activity appear to be short-term. The longer term effects of repeated vessel interactions over a broad area or in a localized area where there are concentrations of whales are unknown. Based on the impact criteria for marine mammals defined in Table 4.5-19, disturbance effects of vessel and aircraft activity would likely be considered of medium intensity since at least some whales would be displaced, but they are not likely to leave the EIS project area entirely. The duration of disturbance is expected to be interim; long term effects are unknown. The extent of the impact would depend on the number of support vessels in an area, but, for individual activities, impacts are expected to be localized. Multiple activities in one area or in several areas across the migratory corridor could result in a broader, regional impact. Bowhead whales are considered unique in context, given both their endangered species status and protection and importance to North Slope communities as a subsistence resource.

Chukchi Sea Activities

2D/3D Surveys (July through November)

Effects of 2D/3D seismic noise on bowhead whales in the Chukchi Sea would likely be similar to those described above for the Beaufort Sea. There may be regional differences in sound propagation and areas of ensonification due to bathymetric and water property differences between the two areas (see Tables 4.5-10 and 4.5-11, Section 4.5.1.4, Acoustics) that would affect distances at which noise impacts may occur. Differences also exist regionally within the Chukchi Sea Lease Sale 193 area. For example, endfire sound level threshold distances for 180, 160, and 120 dB re 1 μPa rms were 1.27 km (0.79 mi), 6.69 km (4.16 mi), and 104.3 km (64.8 mi), respectively, at the Kakapo Prospect and 1.14 km (0.71 mi), 7.15 km (4.44 mi), and 58.4 km (36.3 mi), respectively, at the Burger Prospect (Martin et al. 2010).

Most bowhead whales that encounter airgun sounds from seismic operations in the Chukchi Sea would be migrating. At the onset of seismic operations in July, few bowhead whales will likely be in the Chukchi Sea. Whales are occasionally seen feeding during summer in the northeast Chukchi Sea, although those observed in June and July 2009 were in the nearshore waters between Point Franklin and Barrow (Clarke et al. 2011a), well inshore of the federal lease sale areas. In September and October, bowhead whales migrate west from the Beaufort Sea into the Chukchi Sea, and most traverse the lease sale area (Figure 3.2-13). It is during this time that disturbance is most probable. Satellite-tagged bowhead whales were most common in the Chukchi Sea Lease Sale 193 Area in September. The areas with the greatest probability of use were in the northeastern part of the Lease Area, not in the area of the currently leased blocks. Leased blocks contained only 2 percent of the total probability of use by bowhead whales (Quakenbush et al. 2010a).

As detailed above, migrating bowhead whales in the Beaufort Sea respond to seismic noise pulses at lower received levels than do feeding whales, with avoidance out to 20 to 30 km (12.4 to 18.6 mi) from a medium-sized airgun source at received sound levels of around 120 to 130 dB re 1 μPa rms (Miller et al. 1999, Richardson et al. 1999). The estimated 120 dB re 1 μPa rms sound level threshold distances for seismic operations on the Kakapo and Burger Prospects in the Chukchi Sea were two to three times this distance (Martin et al. 2010). Haley et al. (2010b) found a lower percentage of cetacean sightings near source vessels in the Chukchi Sea, suggesting cetacean avoidance of underwater seismic sound. The small sample size of cetaceans exposed to received sound levels ≥160 dB rms was too small to make strong conclusions. The migration corridor in the Beaufort Sea is more concentrated in a relatively narrow band along the Alaskan coast, whereas the migration through the Chukchi Sea is less defined and spread out over a broader area, thereby providing more area for the whales to migrate through on their way to the overwintering grounds (see Figures 3.2-14 and 3.2-15).

Avoidance at some distance from the sound sources is likely and depends on spatial and temporal overlap with migrating bowhead whales. Operations commencing in July may be complete before the peak of migration in September and October. Surveys starting later in the summer or fall, however, would likely ensonify some portion of the bowhead whale migratory corridor with sounds levels known to elicit avoidance responses.

Based on the impact criteria defined in Table 4.5-19, anticipated impacts of these activities, in terms of magnitude (medium), duration (interim), extent (local), and context (unique) would be similar to those described above for the Beaufort Sea.

In-ice Seismic Survey (2D/3D) with Icebreaker Support (October to mid-December)

Disturbance effects on bowhead whales that may occur in the vicinity of in-ice seismic surveys with icebreaker support in the Chukchi Sea would likely be similar to those described above for the Beaufort Sea. In-ice seismic surveys could occur both on- and off-lease.

The additional sound from icebreakers accompanying seismic activity could cause temporary avoidance of bowhead whales from areas where the vessels are operating and potentially cause temporary deflection of the migration corridor (NMFS 2010c). Bowhead whales are migrating into and through the Chukchi Sea during September and October and typically traverse the Lease Sale 193 area at that time (Clarke et al. 2011a, Brueggeman et al. 2009, Brueggeman et al. 2010, Quakenbush et al. 2010b). Based on satellite-tag data, most bowheads are along the Chukotka coast by November and December (Quakenbush et al. 2010b), and no bowhead whales have been detected during limited COMIDA aerial surveys in November (Clarke et al. 2011a). Small numbers of bowhead whales have been acoustically detected in the Chukchi Sea until early January during low ice years (Delarue et al. 2009). There are limited data on the distribution and abundance of bowhead whales in the Beaufort Sea from mid-October to mid-December. Migrating bowhead whales and icebreaker-accompanied seismic activity are most likely to co-occur during October. Displacement during migration is possible, although the migratory corridor across the Chukchi Sea is broad and spans approximately 3 degrees of latitude (Quakenbush et al. 2010b).

Anticipated impacts of in-ice activities, in terms of magnitude (medium), duration (interim), extent (local), and context (unique) would be similar to those described for the Beaufort Sea despite the less defined migratory corridor in the Chukchi Sea. However, impacts are anticipated on a smaller number of animals based on the fact that seismic operations and bowhead whale migration would only co-occur for a short period of time at the beginning of operations. If a similar survey were occurring at the same time in the Beaufort Sea, there is a potential for some later migrating bowhead whales to encounter survey activities in both seas. However, there would likely be considerable distance between the two operating programs.

Site Clearance and High Resolution Shallow Hazards Survey Programs (July to November)

Disturbance effects on bowhead whales from site clearance and high resolution shallow hazards surveys in the Chukchi Sea would likely be similar to those described above for the Beaufort Sea.

Bowhead whales are most likely to coincide with these operations in the Chukchi Sea during fall migration. Few bowhead whales occur in the Chukchi Sea in July and August (Clarke et al. 2011a). In September and October, bowhead whales migrate west from the Beaufort Sea into and across the Chukchi Sea (Figure 3.2-13). Potential disturbance depends on spatial and temporal overlap with migrating bowhead whales. Operations commencing in July may be complete before the peak of migration in September and October. Surveys starting later in the summer or fall, however, would likely ensonify some portion of the bowhead whale migratory corridor. However, the ensonified zones for these types of surveys are much smaller than those for the 2D/3D seismic surveys.

Based on the impact criteria defined in Table 4.5-19, anticipated impacts of these activities, in terms of magnitude (medium), duration (interim), extent (local), and context (unique) would be similar to those described for the Beaufort Sea.

Exploratory Drilling (July through October)

Known effects of drilling operations on bowhead whales are as described above for the Beaufort Sea and would be expected to be similar for the Chukchi Sea. Drilling operations in the Chukchi Sea would likely initially occur in areas on federal leases for which exploration plans have recently been submitted or would be submitted during the time period of this EIS and where there have been recent requests for approval of ancillary activities. It is anticipated that either a drillship or jackup rig with six to eight support vessels would be used for exploratory drilling, which is anticipated to start in early July and continue through October.

The drilling unit and support vessels typically do not enter the Chukchi Sea until after July 1 when most of the spring bowhead migration is complete. Few bowheads are expected to be encountered during the early season drilling operations, minimizing any effects at that time. Drilling operations occurring during September and October could potentially disturb and displace bowheads migrating through and across the Chukchi Sea.

Anticipated impacts of these activities, in terms of magnitude (medium), duration (interim), extent (local), and context (unique) would be similar to those described above for the Beaufort Sea.

Associated Vessels and Aircraft

Known and potential effects of support vessel and aircraft on bowhead whales in the Chukchi Sea are as described above for the Beaufort Sea and would be expected to be similar for the Chukchi Sea.

Bowhead whales feeding and migrating in the Chukchi Sea could encounter numerous seismic vessels, support vessels, and associated aircraft. The number of kilometers transited by seismic and various types of support vessels in the Chukchi Sea in 2006 to 2008 ranged from 48,100 km (29,888 mi) (2007) to 106,838 km (66,386 mi) (2006) (Funk et al. 2010). The extent of disturbance depends on the areas in which vessels are transiting or operating, the number in a given area, and the time of operation.

Bowheads feeding near shore in the northeast Chukchi Sea may be in the flight path for support flights and transits between Wainwright and Nome and possibly more susceptible to disturbance.

Based on the criteria defined in Table 4.5-19, anticipated impacts of these activities, in terms of magnitude (medium), duration (interim), extent (local), and context (unique) would be similar to those described above for the Beaufort Sea.

Hearing Impairment, Injury, and Mortality

Although the likelihood of such impacts occurring is considered highly unlikely, the primary direct mechanisms of potential hearing impairment, injury, or mortality due to oil and gas exploration activities are hearing loss or damage (auditory injury) and collisions with vessels. The potential effects of a very large oil spill, which is considered improbable and for which incidental take would not be authorized by NMFS under any alternative, are discussed separately in Section 4.10.

Auditory Impairment (TTS and PTS)

Noise induced TS (including TTS and PTS) is described above. The potential for seismic airgun pulses to cause acoustic injury in marine mammals is not well understood (Gedamke et al. 2011), and data on levels or properties of sound that are required to induce TTS are lacking for baleen whales. Recent simulation models, using data extrapolated from TTS in toothed whales, suggest the possibility that baleen whales 1 km (0.62 mi) or more from seismic surveys could potentially be susceptible to TTS (Gedamke et al. 2011). There is no information on TTS or PTS specifically for bowhead whales.

Because bowhead whales generally respond to loud noise by moving away, they are less likely to suffer hearing loss from increased noise. They are not likely to remain close enough to a large airgun array long enough to incur TTS, let alone PTS. The levels of successive pulses received by a marine mammal would increase and then decrease gradually as the seismic vessel approaches, passes and moves away, with periodic decreases also caused when the animal goes to the surface to breath, reducing the probability of the animal being exposed to sound levels large enough to elicit PTS. However, data suggest that exposures of longer duration and lower levels can lead to more TTS (i.e. onset at lower level and greater amount of TTS) compared to exposures of higher level and short duration with the same cumulative sound exposure level (Finneran et al. 2010, Kastak et al. 2005, 2007, Kastelein et al. 2012a, b, Mooney et al. 2009), and seismic airguns can ensonify larger areas to higher levels in which whales may remain in the proximity of for longer times. This, in combination with the fact that monitoring reports include occasional observations of bowheads within the 180-dB zone of seismic surveys suggests that TTS and PTS, though unlikely, cannot be entirely ruled out.

Since bowhead whales appear to be more tolerant of noise when feeding, work is needed to determine potential effects of repeated exposure to loud noise at distances tolerated in feeding areas. The potential for increased noise to cause physiological stress responses should also be considered, as it is not currently known (NMFS 2011a). Obtaining data on stress responses in large free-swimming whales would require potentially disruptive invasive techniques.

Assessing whether or not TTS or PTS is occurring is not currently possible. There is no information on these thresholds specific to bowheads, and the likelihood of obtaining the information is low. Hearing and hearing damage can only be readily analyzed in smaller cetaceans, primarily in captivity, or through studying ears of dead whales. Determining intensity is not possible, unless noise exposure were severe enough to result in observed mortality where cause of death could be attributed to sound impulses. There are no known such incidences with bowhead whales. The duration of impact would be temporary for TTS but permanent if PTS were to occur. The extent of such impacts would be local and the context unique, since bowhead whales are listed as endangered.

Ship Strikes

Marine vessels could potentially strike bowhead whales, causing either injury or death. Incidence of ship strikes appears low, but could rise with increasing vessel traffic. Only three ship-strike injuries were documented in the 236 bowhead whales examined from the subsistence harvest from 1976 to 1992 (George et al. 1994). All of the injuries indicate the whales were struck by propellers of large (>30 m [>98.4 ft]) ships.

The low incidence of observed ship strikes, as of the early-1990s, was likely an artifact of the comparatively low rate of vessels passing through most of the bowhead's range or that many bowheads struck by ships do not survive (George et al. 1994). Ship strikes are a major cause of mortality and serious injury in North Atlantic right whales, accounting for 35 percent of deaths from 1970 to 1999 (Knowlton and Kraus 2001). Experimental playback studies revealed that right whales did not respond to sounds of approaching vessels or to actual vessels, suggesting habituation to engine sounds that are ubiquitous throughout most of their range (Nowacek et al. 2004). Most bowhead whales, in contrast, show strong avoidance reactions to approaching ships. Eskimo hunters report that bowheads are less sensitive to approaching boats when they are feeding (George et al. 1994), leaving them more vulnerable to vessel collisions.

The frequency and severity of ship strikes is influenced by vessel speed. The potential for collision increases at speeds of 15 kn and greater (Laist et al. 2001, Vanderlaan and Taggart 2007). For the activities considered under Alternative 2, speeds for most source vessels are relatively slow (approximately 3 to 5 kn) during oil and gas exploration activities. Transit speeds, however, are likely to be much higher. Seismic survey source vessel transit speeds are, for example, estimated at 8 to 12 kn (refer to Chapter 2, Alternatives for details), suggesting that, if collisions were to occur, they are more likely when vessels are in transit than when conducting active exploration operations. Vessels transiting to the Beaufort or Chukchi seas from Dutch Harbor at the start of the open water season, or returning across these areas to the Bering Strait at the end of the season, transiting between sites, or for resupply in and out of Nome or Wainwright in the Chukchi Sea or Prudhoe Bay in the Beaufort have the highest chance of encountering migrating bowheads or aggregations feeding in more coastal regions of the northeast Chukchi and between Point Barrow and Smith Bay in the Beaufort Sea.

The reported incidence of ship strikes is low, but, since collisions have occurred in the past, the intensity of the impact should be considered medium. The impact would be temporary, although the results (injury or mortality) would be permanent for the whale. The extent of impact would be local, given the infrequency of occurrence and the non-random distribution of both bowhead whales and exploration activity in the EIS project area. The context would be unique, since bowhead whales are listed as endangered. Refer to Table 4.5-19 for marine mammal impact criteria definitions.

Habitat Alterations

Oil and gas exploration activities that may result in alteration of habitat include disturbance of sea ice from icebreaking, disturbance of benthic sediments during drilling, and contamination of the marine environment from discharge of drilling muds and other waste streams from ships and support facilities. Effects of icebreaking and exploratory drilling are discussed above in the introduction to effects on marine mammals (Section 4.5.2.4). Potential effects of a very large oil spill, including long-term displacement from areas impacted by oil, are discussed in Section 4.10. Additional details and impact assessments are provided here.

Potential impacts of drilling mud discharged into the marine environment are among concerns expressed by Iñupiat subsistence hunters:

> *I've experienced drilling mud on an iceberg north of Northstar at that time when Northstar was in a stage of being developed. So there were quite a few drilling muds being caught at -- on Northstar on a real calm, calm day. Not even one marine mammal was inside it. And you could*

> *hear that Northstar drill rig pounding away. Not one marine mammal, not even one waterfowl was sighted. And the only thing we encountered was an iceberg totally covered with drilling mud. It's not a natural mud.* (Testimony provided by Archie Ahkiviana at the Nuiqsut Public Scoping Meeting for this EIS, March 11, 2010).

Adverse effects of discharges on bowhead whales are directly related to whether or not any potentially harmful substances are released into the marine environment and whether they rapidly dilute or bioaccumulate through the food chain. Bowhead whales are long lived, and some individuals potentially could accumulate contaminants. Bowhead whales, however, feed on lower trophic level organisms (zooplankton) so are considered at lower risk of bioaccumulation of contaminants, such as persistent organic compounds, than higher level consumers. Levels of persistent organic compound concentrations in samples collected from bowhead whales in Alaska are low compared to other marine mammals (O'Hara and Becker 2003).

Drill cuttings and drilling mud discharges are regulated by the EPA NPDES Permits. The impact of drill cuttings and drilling mud discharges would be localized and temporary. Drill cuttings and mud discharges could temporarily displace marine mammals a short distance from the drilling site. The EPA modeled a hypothetical 750 bbl/hr discharge of drilling fluids in 20 m (66 ft) of water in the Beaufort and Chukchi seas and predicted a minimum dilution of 1,326:1 at 100 m (330 ft) from the discharge point (Shell 2011a). Discharged drilling fluid should be well diluted within 100 m (330 ft) so that any impacts would be localized and temporary assuming that whales continue to swim through and past the discharge plume. If toxic contaminants are present in discharges, only a small area of potential habitat and prey base might be contaminated. Population-level effects would, therefore, be negligible.

Bottom-founded drilling units or gravel islands could impact small areas of benthic habitat that support epibenthic invertebrates that bowhead whales feed on, including through increased turbidity or sediment suspension in marine waters. Exploration drilling on past and current leases would add incrementally to potential discharges into the Beaufort and Chukchi seas but would remain localized to areas immediately surrounding exploration drilling activity.

Additionally, the acoustic habitat, within which whales use sound to communicate and detect prey, predators, and other environmental cues, can be temporarily altered by the presence of sounds in the frequency bands of the signals of interest for the whales. Depending on the level, frequency, and duration of these sounds, these acoustic habitat alterations can result in reduced ability to detect or interpret important sounds. Acoustic habitat alterations would be expected to be more of a potential issue for mysticetes and low frequency sound sources (than other taxa and sound source types) because of the long distances and times over which these species communicate, combined with the physical properties of low frequency sounds, which are not absorbed nearly as quickly underwater as higher frequency sounds, and therefore travel much longer distances.

Effects on Zooplankton

In a review of available information on the effects of seismic sound on invertebrates, the Canadian Department of Fisheries and Oceans reported that, under experimental conditions, lethal and/or sublethal effects have sometimes been observed in invertebrates (e.g., crustaceans, gastropods) exposed to airgun sounds at distances of <5 m (<16.4 ft) (DFO 2004). They considered exposure to seismic sound unlikely to result in direct invertebrate mortality, although invertebrates may exhibit short-term behavioral reactions to sound (DFO 2004). They found few studies on the effects of seismic noise on zooplankton. Zooplankton very close to the seismic source may react to the shock wave, but effects are expected to be localized (LGL 2010). Potential non-seismic effects on zooplankton are noted above and in the respective sections on Lower Trophic Levels (see, for example, 4.5.2.1).

Potential impacts to bowhead whale habitat (including from discharge and to zooplankton and acoustic habitat) from oil and gas exploration activities permitted under Alternative 2 would, based on the criteria defined in Table 4.5-19, be of medium intensity. Most impacts would be localized in the area immediately adjacent to the impacts (discharges, sediment disruption, or icebreaking), but disruptions to acoustic habitat could be over a regional scale. Most impacts would also be temporary, although longer-term and regional effects could occur through the process of bioaccumulation through the food chain. The context would be unique, since bowhead whales are listed as endangered.

Small Fuel Spill

There is the potential for bowhead whales to be exposed to small accidental fuel spills of less than 50 bbl (see Section 4.2.7). If a small accidental spill were to escape containment or response measures, it would not persist very long, resulting in few opportunities to contact bowhead whales. Further, vessel activity associated with spill response would likely keep bowhead whales out of the spill area, and individual whales would likely avoid the spill by leaving the area during spill response activities. Oil generally poorly adheres to the skin of mysticete whales, and cetaceans are believed to have the ability to detect and avoid oil spills (Geraci, 1990; St. Aubin, 1990). Moreover, the weathering process should act to quickly break up or dissipate oil/fuel through the local environment to harmless residual levels that would eventually become undetectable. Therefore, accidental small spills are anticipated to have no more than a negligible level of effect on bowhead whales.

4.5.2.4.9.2 Conclusion

Like in other resource sections, consideration of the effects of implementation of the required standard mitigation measures is included in the conclusion immediately below. Unlike in other resource sections, the Standard Mitigation Measure section is *not* included immediately prior to this Conclusion section, but rather, the separate section analyzing the measures themselves is included once at the end of the Marine Mammal section after all of the individual species sections because the measures apply to multiple species and including them multiple times in separate species sections would be repetitive and potentially confusing.

Oil and gas exploration activities in the Beaufort and Chukchi seas, as analyzed under Alternative 2, would likely cause behavioral disturbance to bowhead whales, including varying degrees of disturbance to feeding, resting, or migrating bowhead whales depending on actual level of effort, type of activity, time of year, and whether activities run concurrent in the Beaufort and Chukchi seas. Disturbance could lead to displacement from and avoidance of areas of exploration activity. The EIS project area encompasses a large portion of bowhead whale habitat between the Bering Strait and Canadian border, so leaving the area entirely to avoid impacts is not likely. The duration of disturbance (and acoustic habitat disturbance) from oil and gas activities is expected to be of interim duration, lasting less than six months, but repeating over multiple years. Surveys utilizing icebreakers could cause avoidance and displacement over a larger radius with the additional noise input from the icebreaking activities, but the period of time over which this activity would overlap with bowhead whales is much shorter. Although bowhead whales react to approaching vessels at greater distances than they react to most other activities, most observed disturbance reactions to vessels and aircraft appear to be short-term. The extent of the impact will depend on the number of exploration activities and associated support vessels in an area, but, for individual sound sources, impacts are expected to be localized. However, over the course of the season and considering the maximum level of activity potentially conducted under this activity, and considering areas that are potentially ensonified above 120 dB, the geographic scale could be considered regional.

Because whales respond behaviorally to loud noise, and because of the required standard mitigation measures, they are less likely to suffer auditory damage from increased noise due to oil and gas exploration activities.

The geographic area and extent of the population over which effects would be felt (especially considering the distances over which bowhead whales communicate and seismic sounds travel) would likely increase with multiple activities occurring simultaneously or consecutively throughout much of the summer-fall range of this population. Potential long-term effects from repeated disturbance, displacement or habitat disruption on an extremely long-lived species such as the bowhead whale are unknown. The Western Arctic stock of bowhead whales has, however, continued to increase at an estimated 3.4 percent per year despite past and present exploration activities within their range (George et al. 2004). It is not currently possible to predict which behavioral responses to anthropogenic noise might result in significant population consequences for marine mammals, such as bowheads, in the future (NRC 2005).

Bowhead whales are listed as endangered, which places them in the context of being a unique resource in the region. Potential impacts of individual activities associated with oil and gas exploration considered under Alternative 2 on bowhead whales would be mostly of medium intensity, interim duration, and on a localized to regional geographic scale. Evaluated collectively, and with consideration given to reduced adverse impacts through the implementation of the standard mitigation measures, as appropriate, the overall impact to bowhead whales is likely to be moderate.

Type of effect	Impact Component	Effects Summary	
Behavioral disturbance	Magnitude or Intensity	Low	
		Medium	Behavioral harassment occurring, but likely < 30% of population disturbed
		High	Impacts from max level activity might exceed take of 30% of population
	Duration	Temporary	
		Interim	All activity types last more than month, but combination < 6 months
		Long-term	
	Geographic Extent	Local	Lower to mid-level of ativities considered local
		Regional	Impacts from max levels of activity might be considered regional when consider area over which travel and which is ensonified over 120 dB (>10% EIS area)
		State-wide	
	Context	Common	
		Important	
		Unique	ESA-listed species, impacts across migratory corridor through which mother/calve pairs traverse, potential disruption of feeding and resting
Injury and mortality	Magnitude or Intensity	Low	Injury or death unlikley
		Medium	Though unlikely, cannot rule out PTS
		High	
	Duration	Temporary	
		Interim	Type of potential injury (though unlikely) would likely have moderate effects
		Long-term	
	Geographic Extent	Local	Since unlikely, any few impacts would be considered local
		Regional	
		State-wide	
	Context	Common	
		Important	ESA listed species, but population is increasing
		Unique	

Type of effect	Impact Component	Effects Summary	
Habitat alterations	Magnitude or Intensity	**Low**	
		Medium	Combination of potential habitat impacts, including acoustic habitat, are medium
		High	
	Duration	**Temporary**	
		Interim	Although other alterations shorter, acoustic habitat is altered for duration of activities
		Long-term	
	Geographic Extent	**Local**	Lower to mid-level of ativities considered regional
		Regional	Impacts from max levels of activity might be considered regional, especially when consider area over which sound exceeds 120 dB, and the communication distances of baleen whales.
		State-wide	
	Context	**Common**	
		Important	ESA listed species, but population is increasing
		Unique	

4.5.2.4.10 Beluga Whales

4.5.2.4.10.1 Direct and Indirect Effects

The primary direct and indirect effects on beluga whales from activities associated with oil and gas exploration in the Beaufort and Chukchi seas considered under Alternative 2 would result from noise exposure. Ship strikes and habitat degradation are also possible. Sources of noise include 2D/3D seismic survey equipment (airgun arrays), CSEM electromagnetic signals, echosounder and sonar devices associated with site clearance and shallow hazards surveys, support, monitoring and receiving vessels associated with these surveys, icebreaking activities, on ice vibroseis seismic surveys (Beaufort Sea only), exploratory drilling, and helicopter and fixed wing aircraft associated with the different programs. Details of these activities and associated components can be found in Chapter 2.

Behavioral Disturbance

2D/3D Seismic Surveys (July through November)

Anthropogenic noise from oil and gas exploration activities may elicit behavioral responses from beluga whales. The possible reactions by marine mammals are listed above; known reactions by beluga whales are included here and described and assessed by region and activity. Most of these mechanisms are common to both seas and these potential effects will be discussed together. Where activities or mechanisms are unique to one sea or the other, they will be discussed separately. Beluga whales are observed in both seas. Vessels associated with the exploration activities identified in Chapter 2 introduce sound into the water and have a physical presence that could affect beluga whales. Although many of these vessels carried PSOs in the past, beluga whales are rarely seen from these vessels, particularly in the Chukchi Sea.

Miller et al. (2005) reported, based on observations collected during two years of seismic studies in the Beaufort Sea, that beluga whale sightings were unexpectedly high 20-30 km (12.4-18.6 mi) from the seismic vessel, and significantly lower 10-20 km (6.2-12.4 mi) from the vessel, indicating that whales may be avoiding operations by 10-20 km (6.2-12.4 mi). Studies of captive beluga whales have shown that they exhibit changes in behavior when exposed to strong, pulsed sounds similar in duration to those used in seismic surveys (Finneran et al. 2000, 2002a), but the received sound levels were relatively high before aversive behaviors were observed (peak to peak level >200 dB re 1 µPa). Behaviors such as vocalizing after the exposure and reluctance to station at the test site were observed (Finneran et al. 2002). Similar behaviors were observed by a beluga whale exposed to a single underwater pulse similar to those produced by distant underwater explosions (Finneran et al. 2000). The applicability of these observations in trained, captive beluga whales exposed to a single transient sound to the natural environment of free-ranging animals exposed to multiple pulses over time, is unknown.

Most of the energy from airgun arrays is below 100 Hz, which is below the frequencies of calling and best hearing of beluga whales, however, behavioral observations indicate that they are not insensitive to sounds produced by these activities.

Anticipated impacts of 2D/3D surveys would be expected to be of medium magnitude (behavioral disturbance, but less than 30% of population effected), interim duration (between 1 and 6 months), local extent (not spanning more than 10% of the EIS area), and important context as, although beluga whales are not ESA-listed, industry activities will overlap with areas of importance for belugas.

In-ice Seismic Survey (2D/3D) with Icebreaker Support (October to mid-December)

While not many studies have been conducted to evaluate the potential interference of icebreaking noise with marine mammal vocalizations, a few studies have looked specifically at icebreaking noise and beluga whales. Erbe and Farmer (1998) reported that the Canadian Coast Guard ship, *Henry Larsen*, ramming ice in the Beaufort Sea, masked recordings of beluga vocalizations at a signal-to-noise ratio of 18 dB. However, an in-ice seismic survey cannot be conducted in ice thick enough to require ramming to break it up.

Erbe and Farmer (2000) modeled zones of impact for the bubbler system noise in addition to the propeller cavitation (ramming) noise. The propagation model predicted that icebreaker bubbler system noise could mask beluga whale communication out to 14 km (8.7 mi) from the vessel over the continental slope, as measured near the surface. The modeled zone of behavioral disturbance for the bubbler system noise extended to approximately 32 km (19.9 mi). Based on historical modeled estimates, in-ice surveys likely result in a larger number of harassed belugas than other activity types.

Ocean-Bottom-Cable Survey (July to October)

Ocean-bottom-cable (OBC) seismic surveys are used in nearshore areas where water is too shallow (≤14 m [≤45.9 ft]) for a towed marine streamer seismic survey vessel and too deep to have bottomfast ice in the winter. An OBC seismic survey typically covers a smaller area than the streamer surveys discussed above and may spend several days in an area. One such survey is anticipated in the Beaufort Sea under Alternative 2. Beluga whales are present throughout the Beaufort Sea during this time period and may be concentrated in nearshore areas. Reactions to sounds from OBC surveys are similar to those reported for 2D/3D steamer seismic surveys. Anticipated impacts of OBC surveys, in terms of magnitude (medium), duration (interim), extent (local), and context (important) would be similar to those described for 2D/3D seismic surveys above. Although disturbance effects may extend 20 to 30 km (12.4 to 18.6 mi) from the sound source, with one OBC survey anticipated in the Beaufort Sea, short-term effects should remain localized.

Site Clearance and High Resolution Shallow Hazards Survey Programs (July to November)

High-resolution shallow hazards surveys are of short duration, and the airguns generate lower energy sounds and have a smaller zone of influence than the larger airgun arrays used for 2D/3D seismic surveys (NMFS 2010b). The radii of ensonification at 120, 160, 180, and 190 dB re 1 μPa rms were calculated for sound sources proposed for use in 2010. Radii calculated for the 40 in^3 airgun were 14,000 m (45,932 ft), 1,220 m (4,003 ft), 125 m (410 ft), and 35 m (115 ft) for the respective sound source levels. The beam widths of these sources are quite narrow, which would only expose marine mammals to the sounds for one or two pulses at most if the animal swims in the direct beam width of the source. Ensonified zones were not calculated for side scan sonar, single-beam or multi-beam echosounders, or for the bathymetric sonar (NMFS 2010b). The higher frequency sub-bottom profilers, side scan sonar, and echosounders often produce sounds at high enough energy to result in disturbance, primarily masking, to beluga whales. Captive bottlenose dolphins and a beluga whale exhibited changes in behavior when exposed to 1 s tonal signals at frequencies similar to those emitted by some of these higher frequency sound sources and to shorter broadband pulsed signals. Behavioral changes typically involved what appeared to be deliberate attempts to avoid the sound exposure (Schlundt et al. 2000, Finneran et al. 2002, Finneran and Schlundt 2004).

Based on results of noise studies on captive and wild populations of beluga whales, belugas would likely avoid the area directly around the shallow hazard operations using the higher frequency equipment, resulting in a temporary, localized effect. If such types of shallow hazard operations were conducted in areas where belugas are feeding or nursing, continued operations may result in displacement from these important habitats. Anticipated impacts of these surveys, in terms of magnitude (medium), duration (interim), extent (local), and context (important) would be similar to those described for 2D/3D seismic surveys above.

On-ice Vibroseis Survey (January to May)

Beluga whales are not likely to experience impacts resultant from an on-ice survey due to their absence from the Beaufort Sea during the winter months. If, however, the activity continues into April and May, it could coincide with the spring migration.

Exploratory Drilling (July through October)

Reactions of beluga whales to drillship operation noises vary. As summarized in Richardson et al. (1995), belugas are often observed near drillsites within 100 to 150 m (328.1 to 492.1 ft) from artificial islands, which are production islands and are different than exploratory drilling platforms. However, belugas swimming in the spring leads change course when they came within 1 km (0.62 mi) of a drillship and exhibited aversive behavior when support vessels were operating near the drillship (Richardson et al. 1995). Reactions of belugas (captive and wild) to playbacks of the semisubmersible drillship *SEDCO 708* indicate that belugas exhibit slight avoidance reactions to drillship sounds (Richardson et al. 1995). Furthermore, belugas may not be able to detect the lower frequency sounds of drillships, which usually emit sounds below 1 kHz because they are below their best hearing sensitivity.

Associated Vessels and Aircraft

Helicopter noise may be a source of disturbance to beluga whales, particularly during exploratory drilling crew transfers. During spring migration in the Beaufort Sea, beluga whales reacted to helicopter noise more frequently and at greater distances than did bowhead whales (Patenaude et al. 2002). Most reactions occurred when the helicopter passed within 250 m (820 ft) lateral distance at altitudes <150 m (492 ft). Neither species exhibited noticeable reactions to single passes at altitudes >150 m (492 ft). Belugas within 250 m (820 ft) of stationary helicopters on the ice with the engine running showed the most overt reactions. Whales were observed to make only minor changes in direction in response to sounds produced by helicopters, so all reactions to helicopters were considered brief and minor. Patenaude et al. (2002) noted that fewer belugas reacted to a Twin Otter than to a helicopter (3.2% instead of 38%).

Lesage et al. (1999) report that beluga whales changed their call type and call frequency when exposed to vessel noise. Beluga whales have been documented swimming rapidly away from ships and icebreakers in the Beaufort Sea when a ship approached to within 35 to 50 km (21.7 to 31.1 mi) and received levels ranged from 94 to 105 dB re 1 µPa in the 20 to 1,000 Hz band, and they may travel up to 80 km (49.7 mi) from the vessel's track (Finley et al. 1990). In addition to avoidance, changes in dive behavior and pod integrity were also noted.

Hearing Impairment, Injury, and Mortality

The primary mechanisms of potential hearing impairment, injury, or mortality of beluga whales due to oil and gas exploration activities are hearing loss or damage (auditory injury) and collisions with vessels.

Auditory Impairment

Noise-induced threshold shift, including TTS and PTS, is described in Section 4.5.2.4.

NMFS currently considers the appropriate metric for TTS levels to be the rms received level, which is typically 10 to 15 dB higher than the SEL for the same pulse, therefore, a single airgun pulse would need to have a received level of ~196 to 201 dB to result in a brief, mild TTS in beluga whales. As also noted, NMFS is considering revisions to these injury criteria, although even with the changes, the 180-dB rms mitigation zone is still expected to protect mid-frequency hearing specialists from potential injury. As reported in the Section 4.5.1.4 (Acoustics), distances to the 180 dB rms received level from various sizes of airgun arrays are <2,570 m (8,432 ft). Therefore, TTS would be expected if beluga whales remained within this distance from the source vessel during airgun operations. However, beluga whales have been observed to avoid seismic vessels. Some beluga whales summering in the Eastern Beaufort Sea may have avoided the area around seismic program using 2 arrays with 24 airguns per array by 10 to 20 km (6.2 to 12.4 miles), although some occurred as close as 1,540 m (5,052 ft) to the operations (Miller et al. 2005). Based on these observed reactions, the likelihood of beluga whales being exposed to adverse sound levels is low. Recent seismic monitoring studies have confirmed that belugas remained further away from seismic operations than has been shown for other odontocetes (Harris et al. 2007).

Researchers have derived TTS information for odontocetes from studies on the bottlenose dolphin and beluga. For the one harbor porpoise tested, the received level of airgun sound that elicited onset of TTS was lower (Lucke et al. 2009). If these results from a single animal are representative, it is inappropriate to assume that onset of TTS occurs at similar received levels in all odontocetes (cf. Southall et al. 2007). Some cetaceans apparently can incur TTS at considerably lower sound exposures than are necessary to elicit TTS in the beluga or bottlenose dolphin.

Exploratory drilling activities are not anticipated to induce TTS or PTS, as source levels for the drill ship and other equipment are typically between 175 and 185 dB re 1 µPa rms.

Ship Strikes

Marine vessels could potentially strike beluga whales, causing either injury or death. Incidence of ship strikes appears low but could rise with increasing vessel traffic.

The frequency and severity of ship strikes is influenced by vessel speed. The potential for collision increases at speeds of 15 kn and greater (Laist et al. 2001, Vanderlaan and Taggart 2007). Most source vessel speeds are relatively slow (approximately 3 to 5 kn) during oil and gas exploration activities. Transit speeds, however, are likely to be much higher. Seismic survey source vessel transit speeds are, for example, estimated at 8 to 20 kn (refer to Chapter 2, Alternatives for details), suggesting that, if collisions were to occur, they are more likely when vessels are in transit. Vessels transiting to the Beaufort or Chukchi seas from Dutch Harbor at the start of the open water season, or returning across these areas to the Bering Strait at the end of the season, transiting between sites, or for resupply in and out of Nome or Wainwright in the Chukchi Sea or Prudhoe Bay in the Beaufort have the highest chance of encountering migrating and feeding beluga whales.

Habitat Loss/Alteration

Oil and gas exploration activities that may result in the alteration of beluga whale habitat include drill cuttings and drilling mud discharges from exploratory drilling. The impact of drill cuttings and drilling mud discharges would be localized and temporary. Drill cuttings and mud discharges could temporarily displace marine mammals a short distance from the drilling location. Based on a hypothetical EPA model in the Beaufort and Chukchi seas, the potential source of an impact, the discharged drilling fluid is diluted to the extent that any impacts would be minimal and temporary, due to the whale’s motility, assuming that the animal continues to swim through the discharge plume (Shell 2011a).

Discharges related to drilling would occur and, if released into the marine environment, effects would remain localized in relation to affecting whale habitat and prey populations. The effects of such discharges are anticipated to remain localized as a result of rapid deposition and dilution and potential contamination (if toxic contaminants are present in discharges) of an extremely small proportion of the habitat or the prey base available to beluga whales; thus, population-level effects would be negligible.

Additionally, the acoustic habitat, within which whales use sound to communicate and detect prey, predators, and other environmental cues, can be temporarily altered by the presence of sounds in the frequency bands of the signals of interest for the whales. Depending on the level, frequency, and duration of these sounds, these acoustic habitat alterations can result in reduced ability to detect or interpret important sounds. Acoustic habitat alterations would be expected to be more of a potential issue for mysticetes and low frequency sound sources (than other taxa and sound source types) because of the long distances and times over which these species communicate combined with the physical properties of low frequency sounds, which are not absorbed nearly as quickly underwater as higher frequency sounds, and therefore travel much longer distances.

Small Fuel Spill

There is the potential for beluga whales to be exposed to small accidental fuel spills of less than 50 bbl (see Section 4.2.7). However, few beluga whales are anticipated to occur in the vicinity of oil and gas activities and few would be exposed to an accidental spill. Moreover, if a small accidental spill were to escape containment or response measures, it would dissipate over a few days, resulting in few opportunities to contact beluga whales. Also, vessel activity associated with spill response would likely keep beluga whales out of the spill area, and individual whales would likely avoid the spill by leaving the area during spill response activities. Accidental small spills are anticipated to have no more than a negligible level of effect on beluga whales.

4.5.2.4.10.2 Conclusion

Like in other resource sections, consideration of the effects of implementation of the required standard mitigation measures is included in the conclusion immediately below. Unlike in other resource sections, the Standard Mitigation Measure section is *not* included immediately prior to this Conclusion section, but rather, the separate section analyzing the measures themselves is included once at the end of the Marine Mammal section after all of the individual species sections because the measures apply to multiple species and including them multiple times in separate species sections would be repetitive and potentially confusing.

Oil and gas exploration activities in the Beaufort and Chukchi seas, as analyzed under Alternative 2, would likely cause behavioral disturbance to beluga whales, including varying degrees of disturbance to feeding, calving, or migrating whales depending on actual level and location of effort, type of activity, time of year, and whether activities run concurrent in the Beaufort and Chukchi seas. Disturbance could lead to displacement from and avoidance of areas of exploration activity. The EIS project area encompasses a large portion of beluga whale habitat between the Bering Strait and Canadian border, so leaving the area entirely to avoid impacts is not likely. The duration of disturbance, and acoustic habitat disturbance, from oil and gas activities is expected to be of interim duration, lasting less than six months, but repeating over multiple years. Surveys utilizing icebreakers could cause avoidance and displacement over a larger radius with the additional noise input from the icebreaking activities. The extent of the impact will depend on the number of exploration activities and associated support vessels in an area, but, for individual sound sources, impacts are expected to be localized.

Because whales respond behaviorally to loud noise, and because of the required standard mitigation measures, they are less likely to suffer auditory damage from increased noise due to oil and gas exploration activities. Of note also, although they still respond to these sources, the low frequency sounds form most exploration activiites are outside of the range of highest hearig sensitivity for belugas and less likely to overlap with important interspecies communication. The magnitude of impacts is moderate.

The geographic area and extent of the population over which effects would be felt would likely increase with multiple activities occurring simultaneously or consecutively throughout much of the summer-fall range of this population, however, considering the range of acoustic impacts, the extent would likely be considered local.

Beluga whales in the Arctic are not listed under the ESA but do have a couple of feeding and calving areas that are important to the popoulations, making their context important.

The intensity and duration of the various effects and activities considered are mostly medium and temporary. However, potential long-term effects from repeated disturbance are unknown. Currently, population trends for the Beaufort stock cannot be estimated, and are not thought to be declining in the Chukchi stock. Although, individually, the various activities may elicit local effects on beluga whales, the area and extent of the population over which effects occur will likely increase with multiple activities occurring simultaneously or consecutively throughout much of the spring-fall range of the Arctic populations. The summary impact level of Alternative 2 on beluga whales would be considered moderate.

Type of effect	Impact Component	Effects Summary	
Behavioral disturbance	Magnitude or Intensity	**Low**	
		Medium	Behavioral harassment occurring, but likely < 30% of population disturbed
		High	
	Duration	**Temporary**	
		Interim	All activity types last more than month, but combination < 6 months
		Long-term	
	Geographic Extent	**Local**	Activities considered local
		Regional	
		State-wide	
	Context	**Common**	
		Important	Non-ESA listed, population status not well known, but thought not to be declining in Chukchi, important feeding and calving areas
		Unique	
Injury and mortality	Magnitude or Intensity	**Low**	Injury or death unlikley
		Medium	Though unlikely, cannot rule out PTS
		High	
	Duration	**Temporary**	
		Interim	Type of potential injury (though unlikely) would likely have moderate effects
		Long-term	
	Geographic Extent	**Local**	Since unlikely, any few impacts would be considered local
		Regional	
		State-wide	
	Context	**Common**	Not ESA listed, populations not thought to be decreasing
		Important	
		Unique	
Habitat alterations	Magnitude or Intensity	**Low**	
		Medium	Combination of potential habitat impacts, including acoustic habitat, are medium
		High	
	Duration	**Temporary**	
		Interim	Although other alterations shorter, acoustic habitat is altered for duration of activities
		Long-term	
	Geographic Extent	**Local**	Lower to mid-level of ativities considered regional
		Regional	
		State-wide	
	Context	**Common**	Not ESA listed, populations not thought to be decreasing
		Important	
		Unique	

4.5.2.4.11 Other Cetaceans

This section discusses the potential direct and indirect effects of Alternative 2 on Other Cetaceans, excluding bowhead and beluga whales. Bowhead whales and beluga whales are addressed individually in Section 4.5.2.4.9 and Section 4.5.2.4.10, respectively, as they are both important subsistence species and common in the EIS project area. Other Cetaceans include all other cetaceans known to frequent the EIS project area and have been combined into two groups: baleen whales and toothed whales. The baleen whales include gray, humpback, fin, and minke whales, while the toothed whales include harbor porpoise, killer whale, and narwhal. Cetaceans are a diverse group with varied life histories and migratory patterns (see Chapter 3, Section 3.2.4.2 for more information). However, they share many important traits and exhibit similar physiological and behavioral responses. Each group is analyzed collectively where appropriate, as the individual species within each group share many similar characteristics which are correlated with potential impacts from offshore oil and gas exploration activities. Where sufficient research exists for species-specific analysis, or unique effects or susceptibilities exist, individual species have been discussed separately.

4.5.2.4.11.1 Direct and Indirect Effects

In general, potential direct and indirect effects on Other Cetaceans resulting from exploration activities in the Beaufort and Chukchi seas authorized under Alternative 2 are similar to those discussed for bowhead whales (Section 4.5.2.4.9) and beluga whales (Section 4.5.2.4.10). The primary direct and indirect effects on other cetaceans would result from noise exposure. Direct and indirect effects arising from ship strikes and habitat degradation are also possible. Potential noise sources include 2D/3D seismic survey equipment (airgun arrays), echosounder and sonar devices associated with site clearance and shallow hazards surveys, support, monitoring and receiving vessels associated with these surveys, icebreaking activities, on-ice vibroseis seismic surveys (Beaufort Sea only), exploratory drilling, and helicopter and fixed wing aircraft associated with the different programs. Details of these activities and associated components can be found in Chapter 2. For a general discussion of the types of effects of oil and gas exploration activities can have on marine mammals, see Section 4.5.2.4.

Behavioral Disturbance

Anthropogenic noise from oil and gas exploration activities has been shown to elicit behavioral responses from baleen and toothed whales. These responses include subtle changes in behavior, more conspicuous changes in activities, and displacement. Observable reactions of marine mammals to sound include attraction to the sound source, increased alertness, modification to their own sounds, cessation of feeding or interacting, alteration in swimming or diving behavior (change direction or speed), short or long-term habitat abandonment (deflection, short or long-term avoidance), and, possibly, panic reactions, such as stampeding or stranding (Nowacek et al. 2007, Richardson et al. 1995, Southall et al. 2007). Most research on oil and gas exploratory activities have focused on the effects from seismic surveys. Although this research can also be applied to other activities covered in this EIS, the analyses of these other activities is therefore lacking in comparison.

2D/3D Seismic Surveys (July through November)

Baleen Whales (gray, humpback, fin, minke): Airgun arrays are the most common source of seismic-survey noise and would be employed for most exploratory activities. Baleen whales generally avoid operating airguns, but avoidance distances vary by species, locations, behavioral activities, as well as environmental conditions that influence sound propagation (Richardson et al. 1995, Gordon et al. 2004, Bain and Williams 2006). Some research has shown that airguns can interrupt feeding behavior in gray whales. Malme et al. (1986) studied the responses of feeding eastern gray whales to pulses from a single 100 in3 airgun off St. Lawrence Island in the northern Bering Sea. They estimated, based on small sample sizes, that 50 percent of feeding gray whales ceased feeding at an average received pressure level of 173 dB re 1 μPa, and that 10 percent of feeding whales interrupted feeding at received levels of

163 dB. However, findings in Russia and British Columbia have shown that gray whales have no apparent change in feeding patterns resulting from seismic surveys (Yazvenko et al. 2007, Bain and Williams 2006).

Studies examining the response of humpback whales to seismic surveys during migration and at summer feeding grounds have likewise observed very few effects. Limited avoidance is the primary reaction, with avoidance behavior first noted at distances of 4 to 8 km (2.5 mi to 5 mi) from the sound source, with stand-off ranges of 7 to 12 km (4.3 mi to 7.5 mi) noted for sensitive resting pods including cow-calf pairs (McCauley et al. 2000, Malme et al. 1986, Weir 2008). Typically, pods including females showed greater avoidance behavior than pods without. Malme et al. (1986) found that humpback whales on their summer feeding grounds in southeast Alaska did not exhibit persistent avoidance when exposed to seismic pulses from a 1.64 L (100 in^3) airgun and concluded that there was no clear evidence of avoidance, despite the possibility of subtle effects.

Fin whales have also been shown to demonstrate very little behavioral change resulting from seismic surveys. Sightings by observers on seismic vessels during many large-source seismic surveys off the U.K. from 1997 to 2000 suggest that, during times of good visibility, sighting rates for fin and sei whales were similar when large arrays of airguns were shooting versus when they were silent (Stone 2003, Stone and Tasker 2006). However, the whales did tend to exhibit localized avoidance, remaining significantly further from the airgun array during seismic operations compared with non-seismic periods and were more likely to swim away from the vessel than in any other direction while shooting (Stone and Tasker 2006). Baleen whales, as a group, were more often oriented away from the vessel while a large airgun array was shooting compared with periods of no shooting (Stone and Tasker 2006). In addition, fin and sei whales were less likely to remain submerged during periods of seismic shooting (Stone 2003). In contrast to the general trend of avoidance, minke whales have occasionally been observed to approach active airgun arrays where received sound levels were estimated to be near 170–180 dB re 1 μPa (MacLean and Haley 2004). This example highlights the variation in behavior between species and individuals within populations.

Behavioral effects on baleen whales from 2D/3D seismic surveys are therefore expected to result primarily in avoidance. Gray whales are the only baleen whale regularly observed within the EIS project area. Should any interactions occur, effects would be of low intensity, interim duration, local in extent, and important in context. The summary impact level would therefore be negligible.

Odontocetes (harbor porpoise, killer whales, narwhals): Toothed cetaceans typically display similar behavior to baleen whales in response to noise generated from seismic surveys. Various studies have shown that toothed whales head away or maintain a somewhat greater distance from the vessel, and stay further away from seismic sources, during periods of airgun operation versus silent periods (Stone and Tasker 2006, Weir 2008).

Observers' records suggested that fewer cetaceans were feeding and fewer were interacting with the survey vessel (e.g. bow-riding) during periods with airguns operating, and small odontocetes tended to swim faster during periods of shooting (Stone and Tasker 2006). For most types of small odontocetes sighted by observers on seismic vessels, the median observed distance was ≥0.5 km (≥0.3 mi) larger during airgun operations than during silent periods (Stone and Tasker 2006). Killer whales appeared to be more tolerant of seismic shooting in deeper waters.

Porpoises show variable reactions to seismic operations, and reactions depend on species. Limited available data suggests that harbor porpoises show stronger avoidance of seismic operations than Dall's porpoises (Stone 2003, Bain and Williams 2006). In Washington State waters, the harbor porpoise—despite being considered a high-frequency specialist—appeared to be the species affected by the lowest received level of airgun sound (<145 dB re 1 μParms at a distance >70 km [43.5 mi]; Bain and Williams 2006). Similarly, during seismic surveys with large airgun arrays off the U.K. in 1997–2000, there were significant differences in directions of travel by harbor porpoises during periods when the airguns were shooting vs. silent (Stone 2003, Stone and Tasker 2006). A captive harbor porpoise exposed to single sound pulses from a small airgun showed aversive behavior upon receipt of a pulse with received level above 174 dB re 1 μPapk-pk or SEL >145 dB re 1 μPa2 s (Lucke et al. 2009). In contrast, Dall's porpoises seem relatively tolerant of airgun operations (Bain and Williams 2006), although they too have been observed to avoid large arrays of operating airguns (Bain and Williams 2006). The apparent tendency for greater responsiveness in the harbor porpoise is consistent with their relative responsiveness to boat traffic and some other acoustic sources (Richardson et al. 1995, Southall et al. 2007).

Behavioral effects on toothed whales from 2D/3D seismic surveys are therefore expected to result primarily in avoidance. Due to the limited distribution of toothed whales within the EIS project area, there is a low likelihood of these encounters occurring. Should they occur, effects would be of low intensity, temporary to interim duration, local in extent, and important in context. The summary impact level would therefore be negligible.

On-ice Vibroseis Survey (January to May) and In-ice Seismic Survey (2D/3D) with Icebreaker Support (October to mid-December)

Winter exploratory activities, including on-ice vibroseis surveys, are not likely to overlap with baleen whale presence due to their southern migration for the winter months. Although toothed whales do not migrate as far as baleen whales, they are not typically associated with sea ice. Any activities occurring on or above sea ice would therefore be unlikely to impact either group. Should in-ice seismic surveys with icebreaker support overlap with whale presence, effects would be similar to those described for summer seismic survey activities, described above.

Ocean-Bottom-Cable Survey (July to October)

Ocean Bottom Cable Surveys are used to acquire seismic data in water that is too shallow for large marine vessels or too deep to have grounded ice during the winter. The areas within the EIS project area meeting this criteria are primarily the nearshore waters of the Beaufort Sea. Therefore, gray whales are the only species expected to be exposed to any effects from these types of surveys, as all other species are so rarely observed in that region. Past surveys of this type have typically not encountered any baleen whales (73 FR 40529).

Reactions to sounds from OBC surveys would be similar to those reported for 2D/3D steamer seismic surveys. Limited research has been conducted on the effects of OBC surveys on baleen whales, focusing exclusively on bowheads. Observed behavioral effects include deflection and avoidance (Miller et al. 1999, Richardson et al. 1999). The open water season of July to October, during which OBC surveys are likely to occur, coincides with summer feeding and late-summer/fall migration periods for gray whales in the Beaufort Sea. Anticipated impacts of OBC surveys, in terms of magnitude (medium), duration (temporary), extent (local), and context (unique) would be similar to those described for 2D/3D seismic surveys above. Although disturbance effects may extend 20 to 30 km (12.4 to 18.6 mi) from the sound source, with only one OBC survey anticipated in the Beaufort Sea, short-term effects would remain localized.

Site Clearance and High Resolution Shallow Hazards Survey Programs (July to November)

High-resolution shallow hazards surveys are of short duration, and the airguns generate lower energy sounds and have a smaller zone of influence than the larger airgun arrays used for 2D/3D seismic surveys (NMFS 2010b). The radii of ensonification at 120, 160, 180, and 190 dB re 1 μPa rms were calculated for sound sources proposed for use in 2010. Radii calculated for the 40 in^3 airgun were 14,000 m (45,932 ft), 1,220 m (4,003 ft), 125 m (410 ft), and 35 m (115 ft) for the respective sound source levels. Ensonified zones were not calculated for side scan sonar, single-beam or multi-beam echosounders, or for the bathymetric sonar (NMFS 2010b), as many of these sources are outside the range of best hearing for mysticetes and possibly for other marine mammals. Additionally, as mentioned above, the beam widths of these sources are quite narrow, which would only expose marine mammals to the sounds for one or two pulses at most if the animal were to swim in the direct beam width of the source.

The limited sound levels combined with the low frequency of most cetaceans within the anticipated survey area result in a low likelihood of any adverse effects occurring. Any effects would be similar to those resulting from 2D/3D seismic surveys, but likely of a lower magnitude.

Exploratory Drilling (July through October) and Associated Vessels and Aircraft

Humpbacks whales respond behaviorally to anthropogenic noises, including vessels, aircraft, and active sonar (Richardson et al. 1995, Frankel and Clark 2000). Responses include alterations of swimming speed and decreased surface blow rates. Gray whales have also been shown to deflect from their course when exposed to industrial noise. Up to 50 percent of migrating gray whales deflected from their course when the received level of industrial noise reached 116-124 dB re 1 μPa, and disturbance of feeding activity may occur at sound levels as low as 110 dB re 1 μPa (Malme et al. 1986).

Studies of behavioral reactions of whales to aircraft are limited, but indicate that whales react little, if at all, to fixed-wing aircraft operating at an altitude of 460 m (1,509 ft) and that most reactions to helicopters occur when the helicopter was at altitudes of ≤150 m (500 ft) (Patenaude et al. 2002, Richardson and Malme 1993, Richardson et al. 1991, Richardson et al. 1995).

Findings detailing the short-term responses of cetaceans to anthropogenic noises do not necessarily infer information about long-term effects. It is not known whether noises affect reproductive rates or distribution and habitat use in subsequent days or years. However, findings seem to suggest that long term impacts when taken at a population level, are mild. Despite decades of on-going seismic and vessel traffic in well-known cetacean habitats, gray whales have continued to migrate annually along the west coast of North America (Malme et al. 1986), and bowhead whales have continued to migrate in and out of the eastern Beaufort Sea each summer (Patterson et al. 2007). Furthermore, both populations have increased during this period (Allen and Angliss 2010). As the noise sources are located on moving ships, the brief exposures to sound pulses from the proposed airgun source are highly unlikely to result in prolonged effects. The history of coexistence between seismic surveys and baleen whales also suggests that brief exposures to sound pulses from any single seismic survey are unlikely to result in prolonged effects.

Hearing Impairment, Injury, and Mortality

The potential for seismic airgun pulses to cause acoustic injury in marine mammals, particularly noise induced threshold shift, is not well understood (Gedamke et al. 2011) and data on levels or properties of sound that are required to induce TTS are lacking for baleen whales. Recent simulation models, using data extrapolated from TTS in toothed whales, suggest the possibility that baleen whales 1 km (0.62 mi) or more from seismic surveys could be susceptible to TTS (Gedamke et al. 2011). Noise induced threshold shift, including TTS and PTS, is described in Section 4.5.2.4.

Because baleen whales generally respond to loud noise by moving away, they are less likely to suffer hearing loss from increased noise. They are not likely to remain close enough to a large airgun array long enough to incur PTS. The levels of successive pulses received by a marine mammal will increase and then decrease gradually as the seismic vessel approaches, passes and moves away, with periodic decreases also caused when the animal goes to the surface to breath, reducing the probability of the animal being exposed to sound levels large enough to elicit PTS. Since baleen whales appear to be more tolerant of noise when feeding, work is needed to determine potential effects of repeated exposure to loud noise at distances tolerated in feeding areas. The potential for increased noise to cause physiological stress responses should also be considered, as it is not currently known (NMFS 2011a). Obtaining data on stress responses in large free-swimming whales would require potentially disruptive invasive techniques.

Although data revealing the occurrence of acoustic injury in toothed whales is limited, some studies have found that in general, they are more sensitive than baleen whales. Acoustic testing performed on harbor porpoises have shown that the received level of airgun sound that elicited onset of TTS was lower than for baleen whales. A harbor porpoise was exposed to single pulses from a small (20 in^3) airgun, and auditory evoked potential methods were used to test the animal's hearing sensitivity at frequencies of 4, 32, or 100 kHz after each exposure (Lucke et al. 2009). Based on the measurements at 4 kHz, TTS occurred upon exposure to one airgun pulse with received level ~200 dB re 1 μPapk-pk or an SEL of 164.3 dB re 1 μPa2 s. If these results from a single animal are representative, it is inappropriate to assume that onset of TTS occurs at similar received levels in all odontocetes (toothed whales). Some cetaceans may incur TTS at lower sound exposures than are necessary to elicit TTS in beluga whales or bottlenose dolphins (Southall et al. 2007).

Assessing whether or not TTS or PTS is occurring is not currently possible. There is no information on these thresholds specific to baleen whales and the likelihood of obtaining the information is low. Hearing and hearing damage can only be readily analyzed in smaller cetaceans, primarily in captivity, or through studying ears of dead whales. Determining intensity is not possible, unless noise exposure were severe enough to result in observed mortality where cause of death could be attributed to sound impulses. The duration of impact would be temporary for TTS, but permanent if PTS were to occur. The extent of such impacts would be local and the context important.

Ship strikes are a major cause of mortality and serious injury in whales in North America (Knowlton and Kraus 2001). In a study of reported ship strikes from 1975 to 2002 (Jensen and Silber 2003), baleen whales were the most commonly struck; fin, humpback, gray, and minke whales were four of the five most commonly struck cetaceans. Toothed whales are much less commonly struck, with killer whales the only species identified from that group, in addition to being the least commonly struck of all 12 species identified.

The frequency and severity of ship strikes is influenced by vessel speed. The potential for collision increases at speeds of 15 kn and greater (Laist et al. 2001, Vanderlaan and Taggart 2007). Most source vessel speeds are relatively slow (approximately 3 to 5 kn) during oil and gas exploration activities. Transit speeds, however, are likely to be much higher. Seismic survey source vessel transit speeds are, for example, estimated at 8 to 12 kn (see Chapter 2, Alternatives for details), suggesting that, if collisions were to occur, they are more likely when vessels are in transit.

The reported incidence of ship strikes is low, but, since collisions have occurred in the past, the intensity of the effect should be considered medium. The likelihood of other types of injury arising from the described activities is low. The duration would be would be temporary to permanent for the impacted whale, depending on the injury. The extent of the effect would be local, given the infrequency of occurrence and the non-random distribution of both cetaceans and exploration activity in the EIS project area. The summary impact level resulting from hearing impairment, injury, or mortality is therefore negligible.

Habitat Alterations

Oil and gas exploration activities that may result in alteration of habitat include drill cuttings and drilling mud discharges from exploratory drilling. Drill cuttings and drilling mud discharges are regulated by the EPA NPDES General Permit. The impact of drill cuttings and drilling mud discharges would be localized and temporary. Drill cuttings and mud discharges could temporarily displace marine mammals a short distance from the drilling site. The EPA modeled a hypothetical 750 bbl/hr discharge of drilling fluids in 20 m (66 ft) of water in the Beaufort and Chukchi seas and predicted a minimum dilution of 1,326:1 at 100 m (330 ft) from the discharge point (Shell 2011a). Discharged drilling fluid should be well diluted within 100 m (330 ft) so that any impacts would be localized and temporary assuming that whales continue to swim through and past the discharge plume. If toxic contaminants are present in discharges, only a small area of potential habitat and prey base might be contaminated. Population-level effects would, therefore, be negligible.

Bottom-founded drilling units or gravel islands could impact small areas of benthic habitat that support epibenthic invertebrates that baleen whales feed on, including through increased turbidity or sediment suspension in marine waters. Exploration drilling on past and current leases would add incrementally to potential discharges into the Beaufort and Chukchi seas, but would remain localized to areas immediately surrounding exploration drilling activity.

The results of habitat alterations caused by oil and gas exploratory activities on other cetaceans would be negligible. Effects would be of low intensity, and very local in extent. Although some habitat alteration, such as those from the construction of gravel islands, would be permanent, most would be temporary, and only and affect common benthic resources.

Additionally, the acoustic habitat, within which whales use sound to communicate and detect prey, predators, and other environmental cues, can be temporarily altered by the presence of sounds in the frequency bands of the signals of interest for the whales. Depending on the level, frequency, and duration of these sounds, these acoustic habitat alterations can result in reduced ability to detect or interpret important sounds. Acoustic habitat alterations would be expected to be more of a potential issue for mysticetes and low frequency sound sources (than other taxa and sound source types) because of the long distances and times over which these species communicate combined with the physical properties of low frequency sounds, which are not absorbed nearly as quickly underwater as higher frequency sounds, and therefore travel much longer distances.

Small Fuel Spill

There is the potential for other cetaceans to be exposed to small accidental fuel spills of less than 50 bbl (see Section 4.2.7). The potential effects of a small fuel spill (<50 bbl) on other cetaceans are anticipated to be the same as those described for bowhead whales. No more than a negligible level of effect is anticipated.

4.5.2.4.11.2 Conclusion

Like in other resource sections, consideration of the effects of implementation of the required standard mitigation measures is included in the conclusion immediately below. Unlike in other resource sections, the Standard Mitigation Measure section is *not* included immediately prior to this Conclusion section, but rather, the separate section analyzing the measures themselves is included once at the end of the Marine Mammal section after all of the individual species sections because the measures apply to multiple species and including them multiple times in separate species sections would be repetitive and potentially confusing.

Many of the species in this resource group are relatively uncommon within the EIS project area, particularly in the Beaufort Sea. Although fin and humpback whales are endangered, they are very rarely seen in the Chukchi Sea and almost never in the Beaufort Sea. Gray whales are the only species with an established range spanning the entire EIS project area that are encountered with any regularity, especially in the Chukchi Sea. Therefore, the probability of interactions from oil and gas exploration activities is low.

There have been no documented impacts from previous oil and gas exploration activities within the EIS project area. The intensity and duration of the various effects and activities considered are mostly medium and interim. However, potential long-term effects from repeated disturbance are unknown. Although, individually, the various activities may elicit local effects on particular whales, the area and extent of the population over which effects occur will likely increase with multiple activities occurring simultaneously or consecutively throughout the EIS project area.

If seismic operations overlap in time, the zone of seismic influence could potentially be quite large, depending on the number, and the relative proximity of the surveys. The impact to individual gray whales would likely be related to the importance of the food source or resting area to the component of the population that would have utilized it had not the disturbance caused them to avoid the area. This is likely to remain unknown. Potential impacts to the population could be related to the numbers and types of individuals that were affected (e.g. juvenile males versus females with calves) and to the relative importance of the habitats from which they may be excluded.

The potential total adverse effects of long-term added noise, disturbance, and related avoidance of feeding and resting habitat in long-lived species such as whales are unknown. Available information does not indicate any long-term adverse effects on any of the existing cetacean populations resulting from the high level of seismic surveys and exploration drilling during the 1980s in the Beaufort and Chukchi seas. This is likely most relevant to gray whales that have used the Chukchi area, in particular, for a long time, certainly when early OCS activities occurred. Despite vessel and industrial activity throughout much of the range of eastern North Pacific gray whales, the population steadily increased to a level that warranted delisting (Rugh et al. 1999) and may even be approaching carrying capacity (Rugh et al. 2005). Many of the other baleen whales and the harbor porpoise occurrences appear to have increased in recent years and may be possible range extensions.

Sub-lethal impacts on health (such as reduced hearing or increased stress) cannot be measured. There has been no documented evidence that noise from previous OCS operations has served as a barrier to migration or any other spatial use resources within the EIS project area. Because whales respond behaviorally to loud noise, they are less likely to suffer hearing loss from increased noise. However, whales appear to be more tolerant of noise when feeding, and future work is needed to determine potential effects on hearing due to long periods over many years of exposure to loud noise at distances tolerated in feeding areas. Similarly, concern needs to be given to other potential physiological effects of loud noise, including the potential for increased noise to cause physiological stress responses.

Evaluated collectively, and with consideration given to reduced adverse impacts through the implementation of the standard and additional mitigation measures, as appropriate, the overall impact to other cetaceans, not including bowhead and beluga whales, is likely to be minor. For the most part, effects will be of low to medium magnitude, interim in duration, and local in extent. The resources affected are either common or important.

Type of effect	Impact Component	Effects Summary	
Behavioral disturbance	**Magnitude or Intensity**	**Low**	Possible that some other species may not come into contact with activities or be impacted
		Medium	If behavioral harassment occurs, would be < 30% of population disturbed
		High	
	Duration	**Temporary**	
		Interim	All activity types last more than month, but combination < 6 months
		Long-term	
	Geographic Extent	**Local**	Effects primarily considered local
		Regional	Impacts from max levels of activity might be considered regional for gray whales when consider area ensonified over 120 dB (>10% EIS area) and fact that gray whales are more likely to be encountered than other species.
		State-wide	
	Context	**Common**	
		Important	Although not ESA listed, important areas exist for gray whales.
		Unique	
Injury and mortality	**Magnitude or Intensity**	**Low**	Injury or death unlikley
		Medium	Though unlikely, cannot rule out PTS
		High	
	Duration	**Temporary**	
		Interim	Type of potential injury (though unlikely) would likely have moderate effects
		Long-term	

Type of effect	Impact Component	Effects Summary	
	Geographic Extent	Local	Since unlikely, any few impacts would be considered local
		Regional	
		State-wide	
	Context	Common	Not ESA listed species, but trends of some species not known
		Important	Not ESA listed species, but trends of some species not known
		Unique	
Habitat alterations	Magnitude or Intensity	Low	
		Medium	Combination of potential habitat impacts, including acoustic habitat, are medium
		High	
	Duration	Temporary	
		Interim	Although other alterations shorter, acoustic habitat is altered for duration of activities
		Long-term	
	Geographic Extent	Local	Lower to mid-level of ativities considered regional
		Regional	
		State-wide	
	Context	Common	
		Important	Not ESA listed species, but trends of some species not known
		Unique	ESA listed species, trends of some species not known

4.5.2.4.12 Ice Seals

4.5.2.4.12.1 Direct and Indirect Effects

This section discusses the potential direct and indirect effects of Alternative 2 on four species often collectively called “ice seals:” ringed seal; spotted seal; ribbon seal; and bearded seal. These species are all highly dependent on sea ice for critical life functions, and their seasonal distributions are heavily influenced by seasonal ice movement in Arctic waters. They are treated collectively because they share many similar characteristics which are correlated with potential impacts from offshore oil and gas exploration activities. Where unique effects or susceptibilities exist, individual species are discussed separately.

Potential direct and indirect effects on ice seals from exploration activities authorized under Alternative 2 are similar to those discussed for other cetaceans (Section 4.5.2.4.11) and Pacific walrus (Section 4.5.2.4.13). These include disturbance in water and on the surface of the ice due to sounds and physical movements of vessels and equipment, risks of injury or mortality, and changes in habitat.

Behavioral Disturbance

There are several mechanisms for potential disturbance to ice seals associated with each of the different types of exploration activities considered under Alternative 2. Most of these mechanisms are common to both the Beaufort and Chukchi seas, and these potential effects are discussed together. Where activities or mechanisms are unique to one sea or the other, they are discussed separately.

Marine vessels associated with exploration activities all introduce sounds into the marine environment (see Acoustics, Section 4.5.1.4) and have a physical presence that could affect ice seals in the water or on sea ice. Many of these vessels have carried PSOs in the past, and the data they have collected about ice seals and other marine mammals forms the basis of much of this discussion. Ice seals are by far the most commonly observed marine mammals in both the Beaufort and Chukchi seas, with ringed seals making up the majority and ribbon seals being rare (Savarese et al. 2010, Haley et al. 2010a). Seismic surveys often include PSOs on monitoring ships that are deployed at various distances from the seismic source ships, sometimes over 75 km (47 mi) away. Sightings from these ships when they are at great distance from the source vessel or when the seismic arrays are not active (non-seismic conditions) provide a measure of ice seal reactions to typical vessel traffic rather than the seismic source (discussed below). When monitoring ships are traveling under non-seismic conditions, the average closest point of approach to seals ranged from 160 to 180 m (525 to 590 ft) (Savarese et al. 2010, Haley et al. 2010a). Seismic source vessels traveling under non-seismic conditions appear to disturb seals at greater distances, perhaps in part because of their larger physical presence, with the average closest point of approach to seals ranging from 200 to 400 m (556 to 1,312 ft) (Savarese et al. 2010, Haley et al. 2010a). However, these averages are derived from seal observations that span a very wide range of distances at which the seals were first detected, which depends greatly on weather and sea conditions that determine visibility conditions. At least half of the seals observed did not swim away from an approaching vessel, and some seals actually swam toward the vessel, and a small number bow ride. There appears to be a range of sensitivities among seals to ships, including many that are not noticeably disturbed by their passing.

Icebreaking vessels, whether used for in-ice seismic surveys or for ice management near exploratory drilling ships, introduce an additional type of disturbance to ice seals than non-icebreaking vessels. These activities would take place in late fall-early winter under Alternative 2, a time period when ice seals are often on top of sea ice and in the water but not in subnivean structures. Ringed seals give birth in lairs beginning in mid-March (Smith and Stirling 1975), months after the latest time icebreakers could operate in the Arctic. The process of breaking through ice increases the amount of sound produced by the ship, primarily by increasing cavitation from props under high power but restricted motion (Richardson et al. 1995). The sounds of the ship and breaking ice likely combine with the physical presence of the ship to disturb ice seals and cause them to move away from the path of the ship. Data on how close seals allow icebreakers to approach are limited, but ringed and bearded seals on pack ice typically dove into the water within 0.93 km (0.58 mi) of the vessel. Ringed seals have also been seen feeding among overturned ice floes in the wake of icebreakers (Brewer et al. 1993), so not all disruptions may be adverse. The pack ice is a highly dynamic environment in late fall to early winter when icebreaking activities would occur. Ice seals are adapted to moving frequently to accommodate changing ice conditions so displacement due to a passing icebreaker is likely to be temporary and well within the normal range of ability for ice seals at this time of year.

The greatest concern for seals and other marine mammals from exploration activities is the potential for disturbance from seismic airgun arrays, especially the larger and more powerful 2D/3D arrays (16 to 36 airguns) which cover large areas. OBC surveys and shallow hazard/site clearance seismic surveys cover smaller geographic areas but more intensely and thus present more localized disturbance potential, although shallow hazard/site clearance surveys use much smaller seismic arrays (1 to 4 airguns). For the purposes of calculating “take by harassment” under the MMPA, NMFS considers any marine mammals exposed to pulsed sound levels at or above 160 dB to experience Level B behavioral harassment. Operators are required to monitor out to this distance for seismic surveys to record actual numbers of animals detected within the ensonified zone. They are also required to calculate how many animals may be exposed but were not detected, generally based on the density of animals in the area and the size of the ensonified zone. Because ice seals are common and widespread in the Beaufort and Chukchi seas, the numbers of seals detected and calculated to be within the 160 dB radii are quite large. However, as mentioned above, seals often do not react strongly to passing seismic ships, at least by what visual observers can detect. Seals keep further away from seismic source vessels with active arrays than they do monitoring vessels within the 160 dB zone but by about the same amount as they do when the array is not active (Savarese et al. 2010, Haley et al. 2010a). This may be due to the more imposing physical characteristics of the source vessel, which causes the seals to maintain a greater distance, or the ability of PSOs on the taller source vessels to detect seals at greater distances than PSOs on the smaller monitoring vessels, resulting in a data set more skewed to greater distances. Seals have been noted to tolerate high levels of sounds from airguns (Arnold 1996, Harris et al. 2001, Moulton and Lawson 2002). In any case, the observable behavior of seals to passing active source vessels is often to just watch it go by or swim in a neutral way relative to the ship rather than swimming away. Seals at the surface of the water would experience less powerful sounds than if they were the same distance away but in the water below the seismic source. This may also account for the apparent lack of strong reactions in ice seals.

In addition to airguns, site clearance and high resolution shallow hazards surveys utilize smaller, higher frequency sound sources. Very few data are available on the reactions of pinnipeds to echosounder sounds or other devices at frequencies similar to those used during seismic operations. Hastie and Janik (2007) conducted a series of behavioral response tests on two captive gray seals to determine their reactions to underwater operation of a 375 kHz multibeam imaging echosounder that included significant signal components down to 6 kHz. Results indicated that the two seals reacted to the signal by significantly increasing their dive durations. However, because of the brevity of exposure of pinnipeds to such sound sources, pinniped reactions are anticipated to be limited to startle or otherwise brief responses of no lasting consequence to the animals.

Any two deep penetration seismic surveys cannot be conducted concurrently from closer than 24 km (15 mi). This restriction, based on the need of the surveys not to interfere with each other to preserve the quality of the data, provides an effective limit on the intensity of disturbance effects on ice seals no matter where the activities take place. Ice seals traveling across a broad area may encounter more than one exploration activity in a season and may therefore be disturbed repeatedly by the presence of vessels or seismic survey sound or both. If exploration activities are more concentrated near the pack ice edges where seals are more common, the chances are greater that more seals would experience multiple disturbances in a season than if exploration activities were clustered away from the ice. It is not known if multiple disturbances within a certain timeframe add to the stress of an animal and, if so, what frequency and intensity may result in biologically important effects. There is likely to be a wide range of individual sensitivities to multiple disturbances, with some animals being more sensitive than others. However, given the limited potential for multiple disturbances in the same general area from the level of activity authorized under Alternative 2 and the generally minor to negligible intensity and duration of effects on ice seals from any of these activities, it is not likely that additive effects from multiple activities will become a concern for any species of ice seals.

On-ice surveys (vibroseis) are typically conducted only in the shallower, near shore waters of the Beaufort Sea and take place during the winter months. Ringed seals are the only species likely to be in these areas at the time, although bearded seals may also be present in deeper waters further offshore. At this time of year, seals excavate a series of cavities under the snow (subnivean structures), accessed from holes they maintain in the ice from below, for pupping and to provide protection from predators (Smith and Stirling 1975). Ringed seals use multiple breathing holes (Smith and Stirling 1975, Kelly and Quakenbush 1990) and are not expected to be adversely affected by the loss of one to two breathing holes within the thickened ice road. Ringed seals near BP’s Northstar Island have demonstrated an ability to open new holes and create new structures throughout the winter, and ringed seal use of landfast ice near Northstar did not appear to be much different than that of ice 1.2 to 2.2 mi away (2 to 3.5 km; Williams et al. 2002).

Vibroseis surveys involve a large number of heavy tracked vehicles, but many of them are associated with camp facilities that are established on land-fast ice that does not support ringed seals. Survey vehicles with vibrators and sensors are often deployed in shallow water areas and may disturb seals in their subnivean lairs or animals hauled out on top of the ice. Standard mitigation measures require advance scouting of routes and survey lines to minimize impacts to seals by avoiding areas more likely to have lairs (pressure ridges and deep snow accumulations). These mitigation measures also require use of various methods to detect and avoid seal lairs, thereby greatly reducing the chance of destroying an active lair from ice road construction or on-ice survey activities. If an active lair is not detected and is incidentally impacted by heavy survey equipment, the adult female could likely escape into the water but the pup could be killed by crushing or premature exposure to the water. Disturbed adults may remain in their lairs or move to other nearby lairs or swim to different breathing holes (Kelly et al. 1988). Because the survey vehicles move to new locations every few minutes, the disturbance is likely very temporary in nature and not likely to drive animals out of their normal territory.

Potential effects to pinnipeds from aircraft activity could involve both acoustic and non-acoustic effects. It is uncertain if the seals react to the sound of the helicopter or to its physical presence flying overhead. The available information describes reactions of hauled out pinnipeds and not of pinnipeds in the water. Typical reactions of hauled out pinnipeds to aircraft that have been observed include looking up at the aircraft, moving on the ice or land, entering a breathing hole or crack in the ice, or entering the water. Blackwell et al. (2004b) observed 12 ringed seals during low-altitude overflights of a Bell 212 helicopter at BP’s Northstar Island in June and July 2000 (9 observations took place concurrent with pipe-driving activities). One seal showed no reaction to the aircraft while the remaining 11 (92%) reacted, either by looking at the helicopter (n=10) or by departing from their basking site (n=1). Blackwell et al. (2004b) concluded that none of the reactions to helicopters were strong or long lasting, and that seals near Northstar in June and July 2000 probably had habituated to industrial sounds and visible activities that had occurred often during the preceding winter and spring. Born et al. (1999) determined that 49% of ringed seals escaped (i.e. left the ice) as a response to a helicopter flying at 492 ft (150 m) altitude. Seals entered the water when the helicopter was 4,101 ft (1,250 m) away if the seal was in front of the helicopter and at 1,640 ft (500 m) away if the seal was to the side of the helicopter. The authors noted that more seals reacted to helicopters than to fixed-wing aircraft. The study concluded that the risk of scaring ringed seals by small-type helicopters could be substantially reduced if they do not approach closer than 4,921 ft (1,500 m). Spotted seals hauled out on land in summer are unusually sensitive to aircraft overflights compared to other species. They often rush into the water when an aircraft flies by at altitudes up to 984 to 2,461 ft (300 to 750 m). They occasionally react to aircraft flying as high as 4,495 ft (1,370 m) and at lateral distances as far as 1.2 mi (2 km) or more (Frost and Lowry 1990, Rugh et al. 1997).

Exploratory drilling involves the establishment of a large drill ship or jackup rig in one location for some weeks and the deployment of numerous support vessels. The level of disturbance to seals is likely more intense in terms of the physical presence of the ships than any types of exploratory surveys, but the geographic area involved is much smaller. The noise generated from drilling is also not as loud as seismic airguns, but it is produced on an almost continual basis, making it more of a chronic sound source in one location. Given the mild reaction of seals to marine vessels, drilling activities are likely to deter seals from venturing too close to the rig and support vessels while it is in that particular area. This displacement would cover a very small area and be considered short-term.

Hearing Impairment, Injury, and Mortality

Although mortality of seals due to ship strikes has been reported off the coast of Scotland where numerous seals apparently died after being sucked through large ducted propellers (BBC News 2010), similar mortalities or injuries have not been observed in the Chukchi and Beaufort seas. PSOs on many vessels in both seas have logged thousands of hours monitoring vessel transit and have recorded the presence of thousands of seals, but there have been no suspected or documented cases of seals being injured or killed by the type of large vessels used in Arctic oil and gas exploration activities. These species are able to swim much faster than such ships and have been observed to easily swim away from vessels traveling at full speed. Some seals have even been observed to swim to the front of the vessels to bow ride on their wake (Reiser et al. 2011). Given these observations, the risk of ship strikes for ice seals is considered negligible.

TTS is the mildest form of hearing impairment that can occur during exposure to loud sound (Kryter 1985). It is not considered to represent physical injury, as hearing sensitivity recovers relatively quickly after the sound ends. It is, however, an indicator that physical injury is possible if the animal is exposed to higher levels of sound. The onset of TTS is defined as a temporary elevation of the hearing threshold by at least 6 dB (Schlundt et al. 2000). Several physiological mechanisms are thought to be involved with inducing TTS. These include reduced sensitivity of sensory hair cells in the inner ear, changes in the chemical environment in the sensory cells, residual middle-ear muscular activity, displacement of inner ear membranes, increased blood flow, and post-stimulatory reduction in efferent and sensory neural output (Kryter 1994, Ward 1997).

Very few data are available regarding the sound levels and durations that are necessary to cause TTS in pinnipeds. TTS has been measured for only three pinniped species: harbor seals; California sea lions; and northern elephant seals, and only one study has examined TTS in response to exposure to underwater pulses (Finneran et al. 2003). No data are available for any free ranging marine mammals or for exposure to multiple pulses of sound during seismic surveys. Kastak et al. (1999) reported TTS of approximately 4 to 5 dB in three species of pinnipeds (harbor seal, California sea lion, and northern elephant seal) after underwater exposure for approximately 20 minutes to noise with frequencies ranging from 100 to 2,000 Hz at received levels 60 to 75 dB above hearing threshold. This approach allowed similar effective exposure conditions to each of the subjects, but resulted in variable absolute exposure values depending on subject and test frequency. Recovery to near baseline levels was reported within 24 hours of noise exposure (Kastak et al. 1999). Kastak et al. (2005) followed up on their previous work using higher sensitivity levels and longer exposure times (up to 50-min) and corroborated their previous findings. The sound exposures necessary to cause slight threshold shifts were also determined for two California sea lions and a juvenile elephant seal exposed to underwater sound for a similar duration. The sound level necessary to cause TTS in pinnipeds depends on exposure duration, as in other mammals; with longer exposure, the level necessary to elicit TTS is reduced (Schusterman et al. 2000; Kastak et al. 2005, 2007). For very short exposures (e.g. to a single sound pulse), the level necessary to cause TTS is very high (Finneran et al. 2003). For pinnipeds exposed to in-air sounds, auditory fatigue has been measured in response to single pulses and to non-pulse noise (Southall et al. 2007), although high exposure levels were required to induce TTS-onset (SEL: 129 dB re: 20 µPa2.s; Bowles et al. unpub. data).

There is the potential for seals to be exposed to small accidental spills of oils, lubricants, and other compounds used by vessels, vehicles, and equipment during exploration activities. Spills in the offshore or onshore environments could occur during normal operations (e.g. transfer of fuel, handling of lubricants and liquid products, and general maintenance of equipment). Exposure of seals to oil products could lead to irritation of eyes, mouth, lungs, and anal and urogenital surfaces (St. Aubin 1990). The effects of an oil spill on ringed or bearded seals would depend largely on the size, season, and location of the spill. If a spill were to occur during the ice free, open water season, seals may be exposed to oil through direct contact, or perhaps through contaminated food items. However, St. Aubin (1990) notes that with their keen sense of olfaction and good sense of vision ringed and bearded seals may be able to detect and avoid oil spills in the open water season (St. Aubin 1990).

Immersion studies by Smith and Geraci (1975) found ringed seals may develop mild liver injury, kidney lesions and eye injury from immersion in crude oil. The eye damage was often severe, suggesting permanent eye damage might occur with longer periods of exposure to crude oil, and the overall severity of the injuries was most likely associated with the exposure duration to crude oil. Geraci and Smith (1976a) concluded the direct effects of an oil blow-out or spill may result in transient eye damage to healthy seals in open water.

However if breathing holes, polynyas, or leads become fouled with oil, permanent damage may occur. Geraci and Smith (1976a) noted their findings pointed to stress as instrumental in their convulsive behavior and subsequent death when exposed to crude oil, suggesting exposure to crude oil was additive to pre-existing stress levels in ringed seals in their experiment where all of the test animals died. Geraci and Smith (1976a) also found ringed seals exposed to a slick of light crude oil showed no impairment in locomotion or breathing.

Ringed seal pups in their lanugo coats could be particularly vulnerable to the cold if they become oiled and have not yet established adequate fat reserves.

Reports of the effects of oil spills have shown that some mortality of seals may have occurred as a result of oil fouling; however, large-scale mortality has never been observed (St. Aubin 1990). Flippers of young harp seal pups were impeded by a coating of Bunker C fuel oil (Sergeant 1991). Oiling of both mother and pups does not appear to interfere with nursing (Lowry et al. 1994) although disturbances associated with oil spill response and clean-up may do so (Geraci and St. Aubin 1988). Jenssen (1996) reported that oil has produced few visible effects to gray seal behavior and there has been little mortality despite the fact that approximately 50% of gray seal pups at Norway's largest breeding rookery are polluted each year by oil.

Investigations into the effects of crude oil ingestion and exposure on ringed seals (Smith and Geraci 1976) indicate the probability of ringed seals accidentally ingesting large amounts of oil by way of contaminated food items is very low. Moreover, only small, transient effects were found to have occurred during necropsies of ringed seals deliberately fed potent fractions of carbon tetrachloride.

St. Aubin (1990) found ingestion of hydrocarbons can irritate and destroy epithelial cells in the stomach and intestine, affecting motility, digestion, and absorption, which may result in death or reproductive failure; however, after being returned to clean water, contaminated animals can depurate this internal oil (Engelhardt 1978; 1982; 1985). Harbor seals observed immediately after oiling appeared lethargic and disoriented, which may be attributed to lesions observed in the thalamus of the brain (Spraker et al. 1994).

Subsequent studies (Engelhardt et al. 1977, Engelhardt 1982) indicate that ringed seals may accumulate compounds from hydrocarbons in their tissues, but that they are rapidly excreted via renal pathways. Engelhardt (1983) further states that exposure studies in ringed seals revealed they have a great capability to excrete accumulated hydrocarbons via renal and biliary excretion mechanisms, clearing blood and most other tissues of the residues within seven days. Ringed seals probably have the ability to purge their bodies of some harmful oil residues, depending on the duration and extent of exposure. Based on morphological similarities, the physiological impacts in bearded seals are expected to be similar to those of ringed seals.

Direct ingestion of oil, ingestion of contaminated prey, or inhalation of volatile hydrocarbons transfers toxins to body fluids and tissues causing effects that may lead to death, as suspected in dead gray and harbor seals found with oil in their stomachs (Engelhardt et al. 1977, Engelhardt 1982, St. Aubin 1990, Frost et al. 1994, Lowry et al. 1994, Spraker et al. 1994, Jenssen 1996). Seals exposed to an oil spill and especially a blowout are unlikely to ingest enough oil to cause serious internal damage (Geraci and St. Aubin 1980; 1982) and any effects are probably reversible (Spraker et al., 1994). Zooplankton may engulf petroleum droplets when in direct contact and retain metabolized and unmetabolized petroleum for 7-10 days (Geraci and St. Aubin 1990).

Similarly, marine fish are able to metabolize hydrocarbons and are therefore not a source of hydrocarbon contamination for marine mammals during extended periods.

Bivalve molluscs however, tend to accumulate hydrocarbons from prolonged or repeated exposure, posing a threat to benthic-feeding seals. Spilled oil has caused major disruptions to benthic communities inducing substantial contamination of tissues, failed spawning, significantly lower densities, and transfer of oil through the food web from invertebrates to larger fish (Koyama et al. 2004, Elmgren et al.,1983). Ingestion of small quantities of oil through feeding is usually not harmful to ringed seals because they are able to metabolize hydrocarbons (Payne 1992).

Ice seals are commonly observed near exploratory activities during the open-water season and could be exposed to spills in the water or on ice. If a small spill did occur, cleanup efforts would begin immediately and those activities would likely include the presence of PSOs to monitor for ice seals and other marine mammals and deter them from entering the spill area if possible. Given the mitigation measures in place to prevent and clean up spills, the risk of ice seals being exposed to small spills during exploration activities is considered to be minor. The potential effects of a very large oil spill are much more serious and are discussed in Sections 4.10.6.11 and 4.10.7.11.

Habitat Alterations

There are four potential mechanisms for habitat changes that may affect ice seals: 1) disturbance/dispersion of prey species by seismic surveys; 2) disturbance of sea ice habitat from icebreakers; 3) disturbance of sea ice habitat from ice-road construction and on-ice survey activities; and 4) contamination of the marine environment from discharge of drilling muds and other waste streams from ships and support facilities.

Seismic airgun technology has been adopted in part because of its lack of substantial effects on marine invertebrates and fish (see Sections 4.5.2.1 and 4.5.2.2, respectively). Prey fields for ice seals may experience temporary disturbance due to passing ships and towed seismic equipment, much as the seals themselves, but the marine waters are not altered so fish and invertebrates are expected to resume their normal behavior and movement patterns within minutes or a few hours after seismic vessels pass. Given the wide distribution and dynamic nature of prey fields for ice seals, it is unlikely that seals would experience any changes to their foraging success as a result of seismic surveys in open water.

Icebreaking ships intentionally disrupt ice floes in order to conduct in-ice seismic surveys or to help manage ice flows around exploratory drilling equipment. These activities would take place in late fall to early winter under Alternative 2, a time period when ice seals are often on top of sea ice but not in subnivean structures. Seals have been observed to dive into the water and move out of the way well before icebreakers approach. Seals often appear in the open water/broken ice channels behind ice breakers, and some of them appear to be feeding on fish exposed by the broken ice (Haley et al. 2011). Sea ice in these seasons moves continually, opening leads and closing them very quickly at times. The channels cut by icebreakers often close up very soon after the ship passes, mimicking the natural dynamics of the ice in many respects. The effects on ice seal habitat are therefore temporary and may be reduce adverse impacts if prey becomes easier to catch.

In the Beaufort Sea, on-ice seismic surveys (vibroseis) typically take place in mid-winter to early spring (January to May) because thick ice is required to support the vehicles and to ensure personnel safety. These surveys involve the use of large tracked vehicles to pull heavy seismic equipment and associated support facilities (crew camps) across the ice. Convoy travel routes and camp locations are selected based on ice conditions (land-fast for camps) and avoidance of pressure ridges and deep snow accumulations. Sensor cables and vibrator vehicles travel along pre-surveyed and groomed routes across the ice. Ringed seals are the only species likely to be encountered by these surveys, which are conducted relatively close to shore in the shallow waters of the Beaufort Sea. Bearded seals prefer deeper waters and broken ice, which must be avoided by the heavy vehicles. The potential for habitat effects during these surveys involve the potential destruction or damage to subnivean lairs and breathing holes in the ice (disturbance effects are discussed above). The operational and safety requirements for this type of seismic survey require industry to avoid the types of areas where seals are likely to build lairs. Ringed seals typically build and maintain a series of lairs and breathing holes and move between them on a regular basis to help avoid predation and accommodate changing ice conditions (Kelly and Quakenbush 1990, Lydersen and Hammill 1993). The potential loss or displacement of a small number of lairs and breathing holes because of on-ice survey activity would be temporary and readily replaceable by ringed seals in the same way as they relocate under natural conditions, which are highly dynamic.

The discharge of drilling muds and other waste streams from drilling rigs and other exploration vessels could affect ice seal habitat by contaminating ice floes, the water column, and prey. There have been no comprehensive studies conducted on the potential distribution and persistence of the many compounds and substances that could be released accidentally or under discharge permits by the myriad exploration vehicles and vessels involved in the activities authorized under Alternative 2. The potential effects on the habitats of the different ice seal species are therefore unknown. The scope of research needed to track any one discharge compound through the Arctic marine environment and to measure its potential effects in seals would likely be prohibitive and very difficult to interpret given the many other factors that can influence an animals' health.

Additionally, the acoustic habitat, within which pinnipeds use sound to communicate and detect prey, predators, and other environmental cues, can be temporarily altered by the presence of sounds in the frequency bands of the signals of interest for the whales. Depending on the level, frequency, and duration of these sounds, these acoustic habitat alterations can result in reduced ability to detect or interpret important sounds. Acoustic habitat alterations would be expected to be more of a potential issue for mysticetes and low frequency sound sources (than other taxa and sound source types) because of the long distances and times over which these species communicate combined with the physical properties of low frequency sounds, which are not absorbed nearly as quickly underwater as higher frequency sounds, and therefore travel much longer distances.

4.5.2.4.12.2 Conclusion

Like in other resource sections, consideration of the effects of implementation of the required standard mitigation measures is included in the conclusion immediately below. Unlike in other resource sections, the Standard Mitigation Measure section is *not* included immediately prior to this Conclusion section, but rather, the separate section analyzing the measures themselves is included once at the end of the Marine Mammal section after all of the individual species sections because the measures apply to multiple species and including them multiple times in separate species sections would be repetitive and potentially confusing.

The four species of ice seals would likely not be affected to the same extent by exploration activities in the Beaufort and Chukchi seas based on their respective abundance and distribution. Ringed seals and bearded seals have been the most commonly encountered species of any marine mammals in past exploration activities, and their reactions have been recorded by PSOs onboard source vessels and monitoring vessels. These data indicate that seals do tend to avoid on-coming vessels and active seismic arrays but their behavioral responses are often neutral rather than swimming away, and they do not appear to react strongly even as ships pass fairly close with active arrays. They also do not appear to react strongly to icebreaking or on-ice surveys, keeping their distance or moving away at some point to an alternate breathing hole or haulout, but the scope of these behavioral responses appears to be within their natural abilities and responses to their naturally dynamic environment. Studies of ringed and bearded seals have noted the most common reaction to aircraft flying overhead is looking at the aircraft. Reactions become more pronounced when aircraft fly below 150 m (492 ft). However, reactions have been noted to be short-term in nature. None of the behavioral reactions observed to date indicate that any of the ice seal species would be displaced from key areas or resources for more than a few minutes or hours and would therefore be unlikely to experience any measurable effects on their reproductive success or survival. Additionally, impacts from any discharges or accidental, small fuel spills are anticipated to be negligible. Ice seals are legally protected, with ringed and bearded seals listed as threatened under the ESA, have unique ecological roles in the Arctic, and are important subsistence resources and are therefore considered to be unique resources. Given the standard and additional mitigation measures considered in this EIS, the effects of exploration activities that could be authorized under Alternative 2 on ice seals would likely be low in magnitude, distributed over a wide geographic area, and temporary to interim in duration. Reliable data with which to estimate population trends is not available. The effects of Alternative 2 would therefore be considered minor for all ice seal species according to the criteria established in Section 4.1.3.

Type of effect	Impact Component		Effects Summary
Behavioral disturbance	Magnitude or Intensity	Low	
		Medium	Behavioral harassment occurring, but likely < 30% of population disturbed for all species but ringed seals
		High	When maximum activities considered, more than 30% ringed seals may be taken
	Duration	Temporary	
		Interim	All activity types last more than month, but combination < 6 months
		Long-term	
	Geographic Extent	Local	Effects of activities considered local
		Regional	
		State-wide	
	Context	Common	
		Important	ESA-listed species, but impacts not occurring in areas specifically important for feeding/pupping, etc.
		Unique	
Injury and mortality	Magnitude or Intensity	Low	Injury or death unlikley
		Medium	Though unlikely, cannot rule out PTS
		High	
	Duration	Temporary	
		Interim	Type of potential injury (though unlikely) would likely have moderate effects
		Long-term	
	Geographic Extent	Local	Since unlikely, any few impacts would be considered local
		Regional	
		State-wide	
	Context	Common	
		Important	ESA listed species, no reliable data available to assess population trends
		Unique	
Habitat alterations	Magnitude or Intensity	Low	
		Medium	Combination of potential habitat impacts are medium
		High	
	Duration	Temporary	
		Interim	Although other alterations shorter, acoustic habitat is altered for duration of activities
		Long-term	
	Geographic Extent	Local	Lower to mid-level of ativities considered regional
		Regional	
		State-wide	
	Context	Common	
		Important	ESA listed species, population status unknown, no reliable data on trends
		Unique	

4.5.2.4.13 Pacific Walrus

4.5.2.4.13.1 Direct and Indirect Effects

This section discusses the potential direct and indirect effects of Alternative 2 on Pacific walrus. This species is highly dependent on sea ice for critical life functions, and seasonal distributions are heavily influenced by seasonal ice movement in Arctic waters. Potential direct and indirect effects on Pacific walrus from exploration activities authorized under Alternative 2 are similar to those discussed for cetaceans (Sections 4.5.2.4.9 to 4.5.2.4.11) and pinnipeds (Section 4.5.2.4.12). These include disturbance in water and on the surface of the ice due to sounds and physical movements of vessels and equipment, risks of injury or mortality, and changes in habitat. Walrus are distributed widely across the Chukchi Sea but are uncommon in the deeper offshore waters of the Beaufort Sea. Therefore activities that occur in the Beaufort Sea are not anticipated to impact Pacific walrus.

This EIS considers a number of standard and additional mitigation measures as part of each alternative that are intended to reduce adverse effects on marine mammals, especially bowhead whales and other species under the jurisdiction of NMFS, but these mitigation measures may also help to reduce adverse effects on Pacific walrus and polar bears, which are under the jurisdiction of the USFWS. In addition to the mitigation measures imposed by NMFS, the oil and gas industry operates under LOAs for incidental take of Pacific walrus and polar bears issued by the USFWS which contain mitigation measures specific to these species. A series of LOAs have been issued since 1993 for the Beaufort Sea (USFWS 2011a) and since 1991 for the Chukchi Sea (USFWS 2008a). The following mitigation measures are typically required by the USFWS for oil and gas exploration activities in the Beaufort and Chukchi seas to minimize impacts on Pacific walrus and are thus incorporated into the analysis of potential effects under Alternative 2:

- Seismic source and support vessels must be staffed with dedicated PSOs to alert the crew to the presence of Pacific walrus and initiate adaptive mitigation measures.
- Except under emergency situations, vessels must maintain the maximum distance possible from concentrations of Pacific walrus and never get closer than 805 m (0.5 mi) to Pacific walrus or 1,610 m (1 mi) from terrestrial walrus haul outs.
- Vessel operators must take every precaution to avoid harassment of concentrations of feeding walrus when a vessel is operating near these animals. Vessels should reduce speed and maintain a minimum 805 m (0.5 mi) operational exclusion zone around feeding walrus groups. Vessels may not be operated in such a way as to separate members of a group of walrus from other members of the group. When weather conditions require, such as when visibility drops, vessels should adjust speed accordingly to avoid the likelihood of injury to walrus.
- Operators of support aircraft should, at all times, conduct their activities at the maximum distance possible from concentrations of walrus.
- Under no circumstances, other than an emergency, should aircraft operate at an altitude lower than 457 m (1,500 ft) within 805 m (0.5 mi) of walrus observed on ice or land. Helicopters may not hover or circle above such areas or within 805 m (0.5 mi) of such areas. When weather conditions do not allow a 457 m (1,500 ft) flying altitude, such as during severe storms or when cloud cover is low, aircraft may be operated below the 457 m (1,500 ft) altitude stipulated above. However, when aircraft are operated at altitudes below 457 m (1,500 ft) because of weather conditions, the operator must avoid areas of known walrus concentrations and should take precautions to avoid flying directly over or within 805 m (0.5 mi) of these areas.
- All seismic surveys will establish and monitor an acoustically verified exclusion zone for walrus surrounding seismic airgun arrays or sound source where the received level would be ≥180 dB re 1 μPa and an acoustically verified walrus disturbance zone ahead of and perpendicular to the seismic vessel track where the received level would be ≥160 dB re 1 μPa.
- Immediately power-down or shut-down the seismic airgun array and/or other acoustic sources whenever any walrus are sighted approaching close to or within the area delineated by the 180 dB re 1 μPa walrus exclusion zone. If the power-down operation cannot reduce the received sound pressure level to 180 dB re 1 μPa the operator must immediately shut-down the seismic sound sources.
- Whenever an aggregation of 12 or more walrus is detected within the 160 dB re 1 μPa disturbance zone ahead of or perpendicular to the seismic vessel track, the holder of an LOA must: (A) Ensure sound pressure levels at the shortest distance to the aggregation do not exceed 160 dB re 1 μPa by powering down the seismic airgun array and/or other acoustic sources or by altering vessel course; and (B) Not proceed with powering up the seismic airgun array and/or other seismic sound sources, or resuming the original course, until it can be established that there

are no walrus aggregations within the 160 dB re 1 μPa walrus disturbance zone based upon ship course, direction and distance from last sighting.

- Ramp-up Procedures - (A) Prior to commencing ramp-up, the exclusion zone for walrus must be visible and observed by a MMO watch for at least 30 minutes when: At the commencement of operations using airguns or sound sources; a complete shut-down has occurred; any time operation of the airgun array or sound source(s) is discontinued for a period of 10 minutes or more; or the MMO watch has been suspended; (B) If the exclusion zones are not completely visible for at least 30 minutes prior to ramp-up in either daylight or nighttime, ramp up may commence following established procedures which must include: Ramp-up airgun arrays slowly over a period of at least 30 minutes, start with one airgun or sound source in the array and then gradually add additional guns or sound sources, until the full array is firing.
- Poor Visibility Conditions - (A) During poor visibility conditions (fog, rain, snow, darkness, etc.), if the entire 180 dB re 1 μPa walrus exclusion zone is visible using vessel lights and/or night vision devices, then ramp-up procedures of airguns or sound sources may occur following a 30 minute period of observation by MMOs with no sighting of walrus in their exclusion zone; (B) If during poor visibility conditions, the full exclusion zone is not visible, the airguns cannot commence a ramp-up procedure from a full shutdown; (C) If, however, one or more airguns have been operational since before the onset of poor visibility conditions, they may continue to operate under the assumption that walrus will have been alerted by the sounds from the single airgun and have moved away.

In addition to these mitigation measures designed to reduce impacts on walrus, the MMPA contains provisions to protect subsistence hunting of walrus by requiring plans of cooperation and communication channels between industry and subsistence communities when activities have the potential to impact subsistence hunting. Industry is also required to participate in monitoring programs intended to measure the effectiveness of mitigation measures and advance knowledge about the species. LOAs also have established protocols for reporting interactions with walrus and the results of monitoring programs.

Behavioral Disturbance

There are several mechanisms for potential disturbance to Pacific walrus associated with each of the different types of exploration activities that would be authorized under Alternative 2.

Marine Vessels

Marine vessels associated with exploration activities all introduce sounds into the marine environment (see Section 4.5.1.4 on Acoustics) and have a physical presence that could affect Pacific walrus in the water or on sea ice. Many of these vessels have carried PSOs in the past and the data they have collected about walrus and other marine mammals forms the basis of much of this discussion. Walrus are frequently observed from exploration ships in the Chukchi Sea but they are rarely observed in the Beaufort Sea. The majorities of all sightings are of animals in the water rather than on ice but sightings were more common the closer the vessel was to the pack ice. In the Beaufort Sea from 2006 through the 2008 open-water season, PSOs recorded only six sightings of Pacific walrus with a total of 10 individual walrus (Savarese et al. 2010). Five of these sightings occurred in 2007. In the Chukchi Sea from 2006 through the 2008 open-water season, PSOs recorded 575 Pacific walrus sightings comprised of 4821 individual walrus (Haley et al. 2010a). There were many more walrus sightings in the Chukchi in 2007 (n=351) than in other years, with about 40 percent of these being sighted in one day (24 August). This concentration of walrus was suspected of abandoning the ice pack after it retreated beyond the shelf break and heading to haulouts on the coasts of Alaska and Russia (Savarese et al. 2010). This situation may occur more frequently in the future as the ice pack thins and recedes further due to warming temperatures in the Arctic.

Seismic surveys often include PSOs on monitoring ships that are deployed at various distances from the seismic source ships, sometimes over 75 km (47 mi) away. Sightings from these ships when they are at great distance from the source vessel or when the seismic arrays are not active (non-seismic conditions, <120 dB rms) provide a measure of walrus reactions to typical vessel traffic rather than the seismic source (discussed below). When monitoring ships are traveling under non-seismic conditions, the average closest point of approach to walrus was 265 m (869 ft) (Haley et al. 2010a). Seismic source vessels traveling under non-seismic conditions appear to disturb walrus at greater distances, perhaps in part because of their larger physical presence, with the average closest point of approach to walrus being 822 m (2,700 ft) (Haley et al. 2010a). However, these averages are derived from walrus observations that span a very wide range of distances at which they were first detected, and detection distances were greater from source ships probably because of their larger size and higher observation platforms above the sea surface relative to monitoring ships. Another measure of walrus reactions to vessels is their movements relative to an approaching vessel under non-seismic conditions. About half of the walrus observed showed no obvious movement pattern relative to a passing ship. Of those animals that did move, more than twice as many swam away from the vessel than swam toward the vessel (Haley et al. 2010a). This data indicates that there is a range of sensitivities among walrus to ships, including many that are not noticeably disturbed by their passing at some distance. Because they can easily swim faster than exploration vessels, it is likely that more sensitive walrus move away from approaching ships before they react more strongly to the disturbance. Disturbance of walrus in the water from passing vessels would be temporary and unlikely to cause meaningful displacement.

Icebreaking

Icebreaking vessels, whether used for in-ice seismic surveys or for ice management near exploratory drilling ships, introduce an additional type of disturbance to walrus than non-icebreaking vessels. These activities would take place in late fall to early winter under Alternative 2, a time period when walrus are often closely associated with the pack ice edge or are hauled out on coastal shores. Walrus resting on ice floes may also be disturbed by ice management vessels if the floe is too close to an exploratory drilling rig and needs to be moved. Past monitoring efforts indicated that most groups of hauled out walrus showed little reaction to icebreaking activities beyond 805 m (0.5 mi), although some walrus groups may be disturbed up to several kilometers away (Brueggeman et al. 1990). Given the dispersed distribution of walrus on the ice and the short time period and limited geographic extent of icebreaking activities authorized under Alternative 2, it is unlikely that many walrus would be affected in the Chukchi Sea and unlikely that any would be affected in the Beaufort Sea. Such disturbance would be temporary as the icebreaker moved through an area and the ice reformed relatively quickly. Only one in-ice seismic survey could be authorized in the Chukchi Sea under Alternative 2 so there would be no potential for multiple in-ice surveys to affect the same group of walrus.

Seismic Surveys

The greatest concern for most marine mammals from exploration work has been the potential for disturbance from seismic airgun arrays, especially the larger and more powerful 2D/3D surveys (16 to 36 airgun arrays) which cover large areas. Walrus hear sounds both in air and in water. Kastelein et al. (1996) tested the in-air hearing of a walrus from 125 Hz to 8 kHz and determined the best sensitivity was between 250 Hz and 2 kHz. Walrus were able to hear at all frequency ranges tested. Kastelein et al. (2002) tested the underwater hearing and determined that the best sensitivity was at 12 kHz. Their best range of hearing was between 1 and 12 kHz. Most of the noise sources discussed, other than the very high frequency seismic profiling, would be audible to walrus.

During the 2006 to 2008 open-water seasons, 10 walrus were observed in the water from seismic source or monitoring vessels in the Beaufort Sea. None of these animals were detected within the 180 dB re 1 µPa rms safety radius for walrus (Savarese et al. 2010). In the Chukchi Sea, 32 walrus were detected within this safety radius in 2006 and 53 walrus were seen within this radius in 2007 (Haley et al. 2010a). These situations triggered power-down responses of the seismic arrays. These data represent the minimum number of animals that were exposed to these sound levels because some animals detected outside of this radius could have moved away before being detected and some animals may not have been detected by observers. The great majority of observable behavioral reactions of walrus to passing active source vessels was either no reaction or to just watch it go by rather than swimming away (Haley et al. 2010a). Walrus at the surface of the water would experience less powerful sounds than if they were the same distance away but in the water below the seismic source. This may also account for the apparent lack of strong reactions in walrus that were visible to observers. Given the short time period in which seismic vessels would be operating in any one area, potential disturbance of walrus by seismic surveys would likely be temporary and affect very small numbers of animals.

Aircraft Traffic

The behavioral response of walrus to aircraft traffic varies with distance, type of aircraft, flight pattern, age, sex, and group size. Richardson et al. (1995) reviewed responses of walrus to aircraft and summarized that individual responses to aircraft can range from orientation (i.e. looking at the aircraft) to leaving a haulout. In general, small herds on haulout sites (terrestrial and pack ice) seem more easily disturbed than large groups, and adult females with calves are more likely to enter the water during an aircraft disturbance. Stronger reactions occur when the aircraft is flying low, passes overhead, or causes abrupt changes in sound. The greatest potential impact of aircraft is when the disturbance causes walrus at a haulout site to stampede into the water, which may result in the crushing of calves. However, flight restrictions imposed by USFWS LOAs greatly reduce the risk of aircraft disturbance to walrus hauled out on ice or on land. Given the limited amount of activities likely to require over-ice aircraft support under Alternative 2, the numbers of walrus potentially affected would be very small.

On-ice Vibroseis Survey

On-ice vibroseis surveys only take place in the shallow near-shore waters of the Beaufort Sea in the winter when Pacific walrus are not present in the area. Therefore, no impacts to Pacific walrus from this activity are anticipated to occur.

Exploratory Drilling

Exploratory drilling involves the establishment of a large drill ship in one location for some weeks and the deployment of numerous support vessels. The physical presence and chronic noise from multiple ships in the same area may result in displacement of walrus from a small geographic area. The importance of that displacement would depend on the quality of the benthic habitat for feeding walrus and its proximity to the ice pack or haulouts on land. Potential displacements would be short-term, lasting a few weeks to a few months.

Hearing Impairment, Injury, and Mortality

The noise levels required to cause TTS or PTS have not been determined for walrus. NMFS and USFWS have adopted a 180 dB re 1 µPa rms safety radius for walrus as a precautionary measure to reduce the risk of seismic sounds on walrus in lieu of actual data on TTS and PTS levels.

PSOs on many vessels in both seas have logged thousands of hours monitoring vessel transit and have recorded thousands of walrus in the water. There have been no suspected or documented cases of walrus being injured or killed by the type of large vessels used in Arctic oil and gas exploration activities. Given this historical record, the risk of ship strikes for walrus is considered negligible. It is also unlikely that any walrus would be exposed to very loud sounds from seismic operations to the point where they might be injured.

There is a potentially dangerous situation with walrus on land-based haulouts. Due to pack ice receding beyond the shelf break in low-ice years, thousands of walrus have been using haulouts on land in recent years, primarily on the Chukchi coast from Point Lay to Barrow. If they are strongly disturbed by polar bears or low-flying aircraft or nearby vessels, the herd may stampede into the water. Walrus may be injured during stampedes, and injuries may be severe enough to result in mortalities. Juveniles and calves are particularly susceptible, but adults may be injured or killed as well. USFWS LOA mitigation measures for exploration aircraft and vessels are intended to monitor and avoid such haulouts to avoid causing such deadly disturbance.

There is the potential for walrus to be exposed to small accidental spills of oils, lubricants, and other compounds used by vessels, vehicles, and equipment during exploration activities. Spills in the offshore or onshore environments could occur during normal operations (e.g. transfer of fuel, handling of lubricants and liquid products, and general maintenance of equipment). The direct effect of oil on walrus is probably similar to other pinnipeds. This includes irritation of eyes, mouth, lungs, and anal and urogenital surfaces (St. Aubin 1990). Kidney and liver damage could occur from ingestion of petroleum products while feeding (Cornelius and Kaneko 1963, Geraci and Smith 1977, Holden 1978). Because walrus are gregarious, any one animal that is exposed to a spill could spread that contact to other walrus. Walrus could also be affected through damage to their benthic food sources. If a small spill did occur, cleanup efforts would begin immediately, and those activities would likely include the presence of PSOs to monitor for walrus and other marine mammals and deter them from entering the spill area if possible. Given the occurrence of walrus primarily on or near the pack ice rather than swimming in open water where most exploration activities take place and the mitigation measures in place to prevent and clean up spills, the risk of walrus being exposed to small spills during exploration activities is considered to be minor. The potential effects of a very large oil spill are much more serious and are discussed in Sections 4.10.6.11 and 4.10.7.11.

Habitat Alterations

There are three potential mechanisms for habitat changes that may affect walrus: disturbance/mortality of prey species by exploration activities; disturbance of sea ice habitat from icebreakers; and contamination of the marine environment from discharge of drilling cuttings and other waste streams from ships and support facilities.

Benthic prey of walrus may experience disturbance/mortality from bottom-contact equipment used in exploration activities such as ocean bottom cable surveys, vessel anchors, and exploratory drilling. All of these activities could displace benthic mollusks and crustaceans temporarily and may cause small amounts of mortality. Given the wide distribution and dynamic nature of prey fields for walrus, these activities would be unlikely to affect the availability of prey to walrus. In addition, ocean bottom cable surveys would only occur in the Beaufort Sea where few walrus feed.

Icebreaking ships intentionally disrupt pack ice in order to conduct seismic surveys or to help manage ice floes around exploratory drilling equipment. These activities would take place in late fall to early winter under Alternative 2, a time period when walrus are on the pack ice or on shore waiting for the ice to return. Sea ice in these seasons moves continually, opening leads and closing them very quickly at times. The channels cut by icebreakers often close up very soon after the ship passes, mimicking the natural dynamics of the ice in many respects, and would not offer any hindrance to walrus movement.

The discharge of drilling cuttings and other waste streams (such as ballast water, waste water, and sewage) from drilling rigs and other exploration vessels could affect walrus habitat by contaminating benthic prey and fouling ice floes. Exploration wells generally include digging a large mud line cellar (MLC) and the release of cuttings onto the seafloor. Benthic prey items, such as bivalves and other invertebrates, would be buried during this process. This may result in the loss of several acres of benthic feeding habitat until the area is recolonized. The size of the area covered by the MLC and cuttings would depend upon the depth of the well and the deposition pattern.

4.5.2.4.13.2 Conclusion

Walrus have been regularly encountered during vessel-based exploration activities in the past, primarily in late summer as the pack ice recedes, as recorded by PSOs on board seismic source vessels and monitoring vessels. These data indicate that walrus do not react strongly to vessels and active seismic arrays and their behavioral responses are often neutral rather than swimming away. They tend to dive into the water as icebreaking ships approach from some distance and are therefore not exposed to the loudest of sounds generated by the ships. Mitigation measures required for walrus by USFWS LOAs since the early 1990s have reduced the risk of close encounters with seismic and other exploration vessels and have reduced the risk of accidental spills that may affect walrus or their prey. None of the data collected to date on walrus reactions to exploration activities indicate that they would be displaced from key areas or resources for more than a few minutes or hours. Careful avoidance of vessel and aircraft traffic around walrus haulouts on land would minimize the risk of mortality from stampedes. Walrus are legally protected, fulfill an important ecological role in the Arctic, and are an important subsistence resource and are therefore considered to be a unique resource for NEPA purposes. For the level and type of exploration activities that would be authorized under Alternative 2, given the mitigation measures that would be required by USFWS LOAs and NMFS as considered in this EIS, the effects on Pacific walrus would likely be low in magnitude, distributed over a wide geographic area, and temporary in duration. The effects of Alternative 2 would therefore be considered minor for walrus according to the criteria established in Section 4.1.3.

4.5.2.4.14 Polar Bears

4.5.2.4.14.1 Direct and Indirect Effects

This section discusses the potential direct and indirect effects of Alternative 2 on polar bears. Polar bears were listed as a threatened species under the ESA in 2008 (73 FR 28211, 15 May 2008), primarily on the basis of concerns about shrinking ice cover in Arctic seas due to climate change. Polar bears depend on pack ice for much of their denning habitat and for hunting seals. Thinning and receding ice cover threatens to greatly reduce suitable habitat for polar bears and could have serious population-level effects.

This EIS considers a number of standard and additional mitigation measures as part of each alternative that are intended to reduce adverse effects on marine mammals, especially bowhead whales and other species under the jurisdiction of NMFS, but these mitigation measures may also help to reduce adverse effects on polar bears and Pacific walrus, which are under the jurisdiction of the USFWS. In addition to the mitigation measures imposed by NMFS, the oil and gas industry operates under LOAs for incidental take of polar bears and Pacific walrus issued by the USFWS which contain mitigation measures specific to these species. A series of LOAs have been issued since 1993 for the Beaufort Sea (USFWS 2011a) and since 1991 for the Chukchi Sea (USFWS 2008a). The following mitigation measures are typically required by the USFWS for oil and gas exploration activities in the Beaufort and Chukchi seas to minimize impacts on polar bears and are thus incorporated into the analysis of potential effects under Alternative 2:

- Seismic source and support vessels must be staffed with dedicated PSOs to alert the crew to the presence of polar bears and initiate adaptive mitigation measures.
- Except under emergency situations, vessels must maintain the maximum distance possible from polar bears and never get closer than 805 m (0.5 mi) from polar bears.
- Operators of support aircraft should, at all times, conduct their activities at the maximum distance possible from polar bears.
- Under no circumstances, other than an emergency, should aircraft operate at an altitude lower than 457 m (1,500 ft) within 805 m (0.5 mi) of polar bears observed on ice or land. Helicopters may not hover or circle above such areas or within 805 m (0.5 mi) of such areas. When weather conditions do not allow a 457 m (1,500 ft) flying altitude, such as during severe storms or when cloud cover is low, aircraft may be operated below the 457 m (1,500 ft) altitude stipulated above. However, when aircraft are operated at altitudes below 457 m (1,500 ft) because of weather conditions, the operator must avoid areas of known polar bear concentrations and should take precautions to avoid flying directly over or within 805 m (0.5 mi) of these areas.

- All seismic surveys will establish and monitor an acoustically verified exclusion zone for polar bears surrounding seismic airgun arrays or sound source where the received level would be ≥190 dB re 1 μPa.
- Immediately power-down or shut-down the seismic airgun array and/or other acoustic sources whenever any polar bears are sighted approaching close to or within the area delineated by the 190 dB re 1 μPa polar bear exclusion zone. If the power-down operation cannot reduce the received sound pressure level to 190 dB re 1 μPa the operator must immediately shut-down the seismic sound sources.
- Ramp-up Procedures - (A) Prior to commencing ramp-up, the exclusion zone for polar bears must be visible and observed by a PSO watch for at least 30 minutes when: at the commencement of operations using airguns or sound sources; a complete shut-down has occurred; any time operation of the airgun array or sound source(s) is discontinued for a period of 10 minutes or more, or the PSO watch has been suspended; (B) If the exclusion zones are not completely visible for at least 30 minutes prior to ramp-up in either daylight or nighttime, ramp up may commence following established procedures which must include: Ramp-up airgun arrays slowly over a period of at least 30 minutes, start with one airgun or sound source in the array and then gradually add additional guns or sound sources, until the full array is firing.
- Poor Visibility Conditions - (A) During poor visibility conditions (fog, rain, snow, darkness, etc.), if the entire 190 dB re 1 μPa polar bear exclusion zone is visible using vessel lights and/or night vision devices, then ramp-up procedures of airguns or sound sources may occur following a 30 minute period of observation by PSOs with no sighting of polar bears in their exclusion zone; (B) If during poor visibility conditions, the full exclusion zone is not visible, the airguns cannot commence a ramp-up procedure from a full shutdown; (C) If, however, one or more airguns have been operational since before the onset of poor visibility conditions, they may continue to operate under the assumption that walrus will have been alerted by the sounds from the single airgun and have moved away.
- Holders of LOAs will be required to develop and implement an approved, site-specific polar bear interaction plan for on-shore and on-ice exploration activities. Polar bear awareness training will also be required of certain personnel. For on-ice surveys, trained polar bear monitors are often required to alert crew of the presence of polar bears and initiate adaptive mitigation responses.
- Activities in known or suspected polar bear denning habitat during the denning season (November to April) must include efforts to locate occupied polar bear dens within and near proposed areas of operation with FLIR imagery and/or polar bear scent-trained dogs.
- Operators must observe a 1.6 km (1 mi) operational exclusion zone around all known polar bear dens during the denning season. Should previously unknown occupied dens be discovered within one mile of activities, work in the immediate area must cease. The USFWS will evaluate these instances on a case-by-case basis to determine the appropriate action. Potential actions range from cessation or modification of work to conducting additional monitoring, and the holder of the authorization must comply with any additional measures specified.

In addition to these mitigation measures designed to reduce impacts on polar bears, the MMPA contains provisions to protect subsistence hunting of polar bears by requiring plans of cooperation and communication channels between industry and subsistence communities when the activities have the potential to impact subsistence hunting. Industry is also required to participate in monitoring programs intended to measure the effectiveness of mitigation measures and advance knowledge about the species. LOAs have also established protocols for reporting interactions with polar bears and the results of monitoring programs.

Behavioral Disturbance

There are several mechanisms for potential disturbance to polar bears associated with each of the different types of exploration activities that would be authorized under Alternative 2. Most of these mechanisms are common to both the Beaufort and Chukchi seas, and these potential effects are discussed together. Where activities or mechanisms are unique to one sea or the other, they are discussed separately.

Marine Vessels

Exploration activities during the open water season are limited to vessel-based exploration activities. Because most polar bears tend to remain on the ice pack as it moves north, there is a limited potential for exploration vessels to encounter polar bears on ice floes or swimming in open water. The physical presence of a vessel is more likely to cause disturbance to a polar bear rather than the airborne noise generated by the vessel but observer data indicates that bears generally do not react strongly to the presence of vessels, with most animals exhibiting neutral or ambiguous movements in relation to the ship (Savarese et al. 2010). In the Beaufort Sea, polar bear sightings from exploration vessels are uncommon and most of these have been of polar bears on or near barrier islands in the fall (Savarese et al. 2010). In the Chukchi Sea, polar bear sightings from vessels have been relatively rare (Haley et al. 2010a). About half of the sightings have been of bears in the water.

Icebreaking

Icebreaking vessels, whether used for in-ice seismic surveys or for ice management near exploratory drilling ships, introduce an additional type of disturbance to polar bears than non-icebreaking vessels. These activities would take place in late fall to early winter under Alternative 2, a time period when polar bears are often hunting seals along leads in the ice and in broken ice. Bears resting on ice floes may also be disturbed by ice management vessels if the floe is too close to an exploratory drilling rig (USFWS 2008b). However, given the dispersed distribution of bears on the ice and the short time period and limited geographic extent of icebreaking activities, it is unlikely that more than a few bears would be affected in either of the Arctic seas and such disturbance would be temporary to both the bears and their ice seal prey.

Seismic Surveys

There is limited information on the hearing of polar bears. Polar bears are not known to communicate underwater and studies have not been conducted to determine the effects, if any, on polar bears from underwater noise. The greatest concern for most marine mammals from exploration work has been the potential for disturbance from seismic airgun arrays, especially the larger and more powerful 2D/3D arrays (16 to 36 airguns) which cover large areas. During the 2006 to 2008 open-water seasons, 15 polar bears were observed in the water from exploration vessels in the Beaufort Sea (n=11) and the Chukchi Sea (n=4). Of these animals, one was observed within the 170 dB re 1 µPa rms safety radius (which initiated a power-down situation as a precaution before the bear potentially entered the 190 dB re 1 µPa rms safety radius) and the rest were outside the 160 dB re 1 µPa rms safety radius (Savarese et al. 2010, Haley et al. 2010a). Most of these animals exhibited neutral or ambiguous behavior rather than clear avoidance behavior (moving away from the exploration vessel). Given the short time period in which seismic vessels would be operating in any one area, potential behavioral reactions of bears to seismic surveys would likely be temporary.

Aircraft Traffic

Behavioral reactions of polar bears to aircraft depend on distance and type of aircraft. Polar bears may run away from aircraft passing at low altitudes. Most polar bears in dens continue to occupy the dens after close approaches by aircraft (Amstrup 1993). Although the snow attenuates some aircraft noise (Blix and Lentfer 1992), it is possible that repeated overflights may cause polar bears to abandon or depart their dens. However, minimum flight altitudes and flight restrictions around known polar bear dens would reduce the potential for bears to be disturbed by aircraft. Given the limited amount of activities likely to require over-ice aircraft support under Alternative 2, the numbers of bears potentially affected would be very small.

On-ice Vibroseis Survey (January to May)

On-ice vibroseis surveys are typically conducted only in the shallower, near shore waters of the Beaufort Sea and take place during the winter. This type of survey is the only type of exploratory activity authorized under Alternative 2 that has a realistic potential for direct bear-human encounters. The noise produced by on-ice activities such as ice-road construction and vibroseis surveys could attract curious bears rather than deter them. Encounters with humans can be dangerous for both polar bears and humans and are the subject of polar bear interaction plans developed in collaboration with and approved by the USFWS. The plans provide guidance for minimizing polar bear encounters through personnel training, polar bear guards, lighting, snow clearance, waste management and garbage control, agency communication, site clearance, and site-specific safety briefings for polar bear awareness. Employee training programs are designed to educate field personnel about the dangers of human-bear encounters and to implement safety procedures in the event of a bear sighting. Personnel are instructed to leave an area when bears are seen in the vicinity. As described in the LOA mitigation measures above, special emphasis is placed on finding and protecting polar bear dens with a 1.6 km (1 mi) buffer zone from all exploration activities. These efforts involve radio-collaring female bears, FLIR surveys, scent-trained dogs, and cooperative GIS efforts among the USFWS and all companies covered under exploratory and development LOAs.

Noise and vibrations produced by vibroseis activities could potentially result in impacts on denning and non-denning polar bears. The best available scientific information indicates that female polar bears entering dens, or females in dens with cubs, are more sensitive than other age and sex groups to noises. The proactive and adaptive nature of the LOA mitigation measures regarding den sites are designed to avoid and minimize the potential adverse effects on denning polar bears. Given the limited number and extent of the on-ice activities authorized under Alternative 2, the number of bears potentially affected would be very small.

Exploratory Drilling

Exploratory drilling involves the establishment of a large drill ship or ice island in one location for some weeks and the deployment of numerous support vessels. The physical presence of multiple ships in the same area may result in a greater potential for disturbance to polar bears than seismic surveys but the geographic area involved is much smaller. The noise generated from drilling is also not as loud as seismic airguns but it is produced on an almost continual basis, making it more of a chronic sound source in one location. Given the mild reaction of polar bears to marine vessels, drilling activities are unlikely to be a source of more than temporary displacement. (Polar bears are curious and will approach vessels and drilling vessels but do not appear to be particularly disturbed by their presence in most instances.) This displacement would be temporary and would not involve loss of feeding opportunity since bears typically do not hunt from the water.

Hearing Impairment, Injury, and Mortality

The noise levels required to cause TTS or PTS have not been determined for polar bears. However, polar bears typically swim with their heads above water or encounter exploration vessels while on ice or land, where sound levels from seismic surveys would be greatly reduced and they are unlikely to experience injurious sound levels.

PSOs on many vessels in both seas have logged thousands of hours monitoring vessel transit and have recorded only a few dozen polar bears in the water. There have been no suspected or documented cases of polar bears being injured or killed by the type of large vessels used in Arctic oil and gas exploration activities. Given the infrequency of polar bear observations at sea and the presence of observers on board, the risk of ship strikes for polar bears is considered negligible. It is also very unlikely that any polar bears would be exposed to very loud sounds from seismic operations to the point where they might be injured.

There is the potential for polar bears to be exposed to small accidental spills of oils, lubricants, and other compounds used by vessels, vehicles, and equipment during exploration activities. Spills in the offshore or onshore environments could occur during normal operations (e.g. transfer of fuel, handling of lubricants and liquid products, and general maintenance of equipment). The USFWS has determined that, based upon the reported effects of crude oil and refined oil products exposure on polar bears, any bear that makes contact with such a spill would probably die (USFWS 2008b). However, few polar bears are likely to be near exploratory activities during the open-water season, and the spatial separation that vessels and on-ice vehicles are required to maintain between themselves and bears should minimize the potential for close contact. In addition, if a small spill did occur, cleanup efforts would begin immediately and, if it occurred on land or on ice, would require the presence of PSOs to monitor for polar bears and to deter them from a dangerous situation by means of approved hazing methods. The risk of polar bears being exposed to small spills during exploration activities is therefore considered to be minor. The potential effects of a very large oil spill are much more serious and are discussed in Sections 4.10.6.11 and 4.10.7.11.

The main concern for the safety of polar bears during exploration activities is to minimize the risk of bear-human encounters and to manage encounters appropriately so neither bears nor humans suffer injury or death. Oil industry encounters with polar bears in Alaska that have resulted in mortality of bears have been rare, with one case in the winter of 1968 to 1969 and another in 1990 (USFWS 2008b). More recently, a female polar bear was shot and killed by a security guard near employee housing at the Endicott oil field (Reuters 2011). The USFWS began issuing LOAs for exploratory activities on the North Slope in the early 1990s that included mitigation measures and polar bear safety/interaction plans. Polar bears are curious about new things in their environment, however, so there is always the potential for bear-human interactions during oil and gas exploration in the Arctic, even if the activities are temporary. Continual preparation, training, and vigilance are required to maintain the excellent record of avoiding lethal encounters with polar bears, especially as more bears spend more time on shore as the ice pack recedes due to climate change and bears have to fast for longer time periods. It is in the industry's best interest to place a high priority on safety regarding polar bears and it is likely they will continue to work closely with the USFWS to improve and update their procedures to maintain the safest possible working conditions for the sake of people and bears.

Habitat Alterations

There are three potential mechanisms for habitat changes that may affect polar bears: disturbance/dispersion of prey species (ice seals) by seismic surveys or other industry activities; disturbance of sea ice habitat from icebreakers; and ice-road construction and on-ice survey activities.

The analysis of effects on ice seals (Section 4.5.2.4.12) indicates that most of the effects on these species from seismic surveys, icebreaking, and vessel traffic under Alternative 2 would be temporary and would not have population-level effects. None of the effects are likely to displace ice seals for more than a few hours and typically much less. It is therefore unlikely that the availability of seals to polar bears would be affected at all and would continue to be determined primarily by ice conditions and distribution, which are not affected by exploration activities.

Icebreaking ships intentionally disrupt ice floes in order to conduct seismic surveys or to help manage ice flows around exploratory drilling equipment. These activities would take place in late fall to early winter under Alternative 2, a time period when polar bears are on the pack ice or on shore waiting for the ice to return. Sea ice in these seasons moves continually, opening leads and closing them very quickly at times. The channels cut by icebreakers often close up very soon after the ship passes, mimicking the natural dynamics of the ice in many respects, and would not offer any hindrance to polar bear movement. On-ice seismic surveys in the Beaufort Sea require the construction of ice-roads on shore-fast ice and the removal of snow in some places to prepare for vibroseis equipment but these activities would not affect the abundance of seal breathing holes or dens, which polar bears seek out for hunting purposes. The effects on polar bear habitat are therefore temporary and of low intensity.

4.5.2.4.14.2 Conclusion

Polar bears have been infrequently encountered during vessel-based exploration activities in the past, as recorded by PSOs on board source vessels and monitoring vessels. These sparse data indicate that polar bears do not react strongly to vessels and active seismic arrays and their behavioral responses are often neutral rather than running or swimming away. They also do not appear to react strongly to icebreaking or on-ice surveys. Some bears keep their distance or move away at some point but others may approach vehicles and equipment out of curiosity. The types of effects of most concern for polar bears during exploration activities involve the risk of bear-human encounters. Mitigation measures and polar bear safety/interaction plans required by USFWS LOAs since the early 1990s have reduced the risk of these encounters for both people and bears. None of the data collected to date on polar bear reactions to exploration activities indicate that polar bears would be displaced from key areas or resources for more than a few minutes or hours and they are unlikely to experience any measurable effects on their reproductive success or survival as a result. Polar bears are legally protected, have a unique ecological role in the Arctic, and are an important subsistence resource and are therefore considered a unique resource. Given the mitigation measures that would be required by USFWS LOAs and NMFS as considered in this EIS, the effects of exploration activities that could be authorized under Alternative 2 on polar bears would likely be low in magnitude, distributed over a wide geographic area, and temporary in duration. The effects of Alternative 2 would therefore be considered minor for polar bears according to the criteria established in Section 4.1.3.

4.5.2.4.15 Standard Mitigation Measures for Marine Mammals

Standard Mitigation Measures are outlined in Section 2.4.10 and described in detail in Appendix A. These measures are required by all permits and authorizations issued under Alternative 2 for the noted activities. Many of them are similar or identical to mitigation measures required by the USFWS in the LOAs for polar bears and walrus. Therefore, while the measures considered by NMFS would only be included in authorizations for species under NMFS' jurisdiction, there is the potential for these measures to reduce impacts to polar bears and walrus, which are species under the jurisdiction of the USFWS. The following standard mitigation measures could be implemented to reduce adverse effects of oil and gas exploration activities on marine mammals.

Additionally, as noted above in the Conclusion sections for several species, because they are required under this alternative, the anticipated effects of the implementation of these Standard Mitigation Measures are included in the conclusions.

A1. Establishment and execution of 180 & 190-dB shutdown/power down radius for cetaceans & ice seals, respectively. The indicated radius is established, and monitored by PSOs, and the airguns are either powered down or shutdown if an animal approaches or comes within the distance associated with received levels of 180 or 190 dB rms (which is established based through acoustic modeling or on-site verification tests).

Applicable Activities: 2D/3D, in-ice, and OBC seismic surveys, site clearance and high resolution shallow hazards surveys

Purpose: The purpose of this measure is to avoid the injury of marine mammals through PTS and to reduce the likelihood of TTS or more intense behavioral responses that might be expected to occur as a result of exposures at these higher levels.

Science, Support for Reduction of Impacts, and Likely Effectiveness: Section 4.2.6 discusses NMFS' current acoustic critera and references upcoming revisions to the criteria based on Southall et al. (2007), as well as Finneran and Jenkins (2012). Additionally, the sections above include more information regarding the levels above which and durations beyond which animals would be expected to incur acoustic injury. NMFS does not expect that every animal exposed to this level of sound would experience PTS, especially from periodic pulsed sounds that move through an area such as occur from seismic surveys. However, as noted above, hearing impairment can also result from exposure to lower levels over a longer time.

The 180-dB rms zone should contain the area of potential injury for cetaceans, with the possible exception of high-frequency cetaceans – for which the area may be slightly larger. For phocid seals, the 190-dB rms zone likely contains the majority of the area in which injury could occur, but the area could be slightly larger based on the draft revised acoustic criteria (see Section 4.2.6 of this EIS). Because the metrics are different (cSEL vs. SPL rms), allowing for an accumulation of sound over time, and because frequency weighting should be applied to the specific sound source, it is difficult to pre-determine exactly how big the area of conern will be in advance of modeling for any particular source, but preliminary calculations suggest that the areas would not far exceed the 180 or 190-dB isopleths.

The safety radius serves to provide a basis for reducing the level of sound exposure before PTS occurs. Associated mitigation measures, e.g. ramp up and PSO requirements, are intended to either give marine mammalss a chance to swim away from potentially harmful sound sources or to minimize their risk of accidental exposure to such sounds. Data from PSOs indicate that most seals tend to move out of the way before they enter this safety radius, and others do not appear to be disturbed to any noticeable extent as active seismic vessels approach close by, even as these close approaches require power-down/shutdown procedures.

The majority of marine mammals likely avoid the source at these distances. The majority of animals entering these zones are likely detected before they have been exposed above 180 or 190 dB for significant amounts of time, and then further continued exposure at those levels is avoided by power-down or shutdown.

The ability of PSOs to effectively monitor these radii depends on their experience, state of alertness, and visibility/sea conditions, all of which vary over time, as well as the size of the zone. Distances out to which observers can detect marine mammals also depend on the height of the observation platform above water. For example, Haley et al. (2010b) calculated an effective strip half-width (the distance from the centerline of the transect outside of which the number of animals detected equals the number not detected inside) of 1,618 to 3,136 m (1,767 to 3,430 yds) for vessels higher than 11 m (12 yds) and 1,191 to 1,893 m (1,302 to 2,070 yds) for those lower than 11 m (12 yds). Additionally, although the 190-dB zone is smaller than the 180-dB zone, pinnipeds are often more difficult to detect visually than cetaceans.

One limitation and concern regarding monitoring of the exclusion radii is that the 180-dB zone may extend beyond the detection limits of the PSOs, so that cetaceans may enter within the exclusion radii and be exposed to sound sources ≥180 dB rms. Funk et al. (2010) found that the size of ≥180 dB rms exclusion radius around the seismic vessel *Gilavar* in the Chukchi Sea 2007 and 2008 approached the limit of the distance to which PSOs could reliably detect marine mammals. A protocol utilizing additional monitoring vessels was, therefore, employed to observe the exclusion zone. However, there is also the possibility of marine mammals avoiding or being disturbed by the presence of additional vessels, as noted earlier in this document.

For pinnipeds, the 190 dB radius for 2D/3D seismic arrays (24 airguns) in the Beaufort Sea is 860 to 920 m (2,821 to 3,018 ft) (Savarese et al. 2010). In the Chukchi Sea, the typical range for the 190 dB radius for 2D/3D seismic arrays (16 to 36 airguns) is 460 to 610 m (1,509 to 2,001 ft) (Haley et al. 2010a). For site clearance and high resolution shallow hazards surveys (1 to 4 airguns) this radius typically ranges from 5 to 50 m (16 to 164 ft) (Savarese et al. 2010, Haley et al. 2010a). Ice seals are the most common marine mammals sighted by PSOs, and the detection of seals within the 190 dB exclusion zone radius has resulted in numerous powerdown/shut down situations in both the Beaufort and Chukchi seas. During the most active years for seismic work in recent years, 35 seals were detected within the

190 dB radius in the Beaufort Sea in 2008 (Savarese et al. 2010) and 65 seals were detected within the radius in the Chukchi Sea in 2006 (Haley et al. 2010a). These numbers are likely underestimates of the number of seals exposed to these sound levels because some animals may have moved away before coming into the range of visual observers and others could have been underwater or otherwise escaped detection by PSOs.

Frequency of implementation of shutdown and powerdown zones varies but appears generally higher for pinnipeds (190 dB radius) than cetaceans. In 2008, 41 of 44 power downs requested during seismic surveys in the Beaufort Sea were for pinnipeds; the remainder was for one bowhead whale and two unidentified mysticetes (Ireland et al. 2009).

Despite observer effort to mitigate exposure to sounds ≥180 dB re 1 μPa rms, some cetaceans may enter within the exclusion radii. In the Chukchi Sea in 2006 to 2007, 13 cetaceans were sighted within the ≥180 dB re 1 μPa rms radius and exposed to noise levels above that range before appropriate mitigation measures could be implemented (Haley et al. 2010b). Acoustic impairment or injury is, therefore, unlikely for the cetaceans that briefly enter within the 180 dB exposure radius before the mitigation measure can be implemented.

History of Implementation: Power-down and shutdown procedures are currently used, and have been consistently used for years, during exploration activities in the Beaufort and Chukchi seas.

Practicability: To date, this measure has proven practicable to industry operators, as it has been implememted consistently for years.

Recommendation: Based on the feasibility and likely avoidance of injury or more severe behavioral impacts, it makes sense to continue requiring this measure of industry operators.

***Walrus* –** USFWS adopted this safety radius for walrus as a precautionary measure *in lieu* of direct evidence regarding sound source characteristics that would cause TTS (NMFS 2000). NMFS does not expect that every animal exposed to this level of sound would experience TTS, especially from periodic pulsed sounds that move through an area such as occur from seismic surveys. The safety radius serves to provide a basis for reducing the level of sound exposure before TTS occurs. Associated mitigation measures, e.g. ramp up and PSO requirements, are intended to either give walrus a chance to swim away from potentially harmful sound sources or to minimize their risk of accidental exposure to such sounds. The 180 dB radius is established through acoustic modeling or on-site verification tests, which have become routine operational practices for the industry, and is monitored by PSOs on board the sound source vessels and sometimes on support vessels. This measure has been implemented many times in the past due to the presence of walrus in the water near seismic vessels, primarily in the Chukchi Sea.

***Polar Bears* –**USFWS adopted this safety radius for polar bears as a precautionary measure *in lieu* of direct evidence regarding sound source characteristics that would cause TTS in polar bears. The 190 dB radius is established through acoustic modeling or on-site verification tests, which have become routine operational practices for the industry, and is monitored by PSOs on board the sound source vessels and sometimes on support vessels. There are no records of polar bears being exposed to this intensity of sound from seismic surveys.

A2. Specified ramp-up procedures for airgun arrays. This technique involves the gradual increase (usually approximately 5-6 dB per 5-minute increment) in emitted sound levels, beginning with firing a single airgun and gradually adding airguns over a period of 20 to 40 minutes, until the desired operating level of the full array is obtained.

Applicable Activities: 2D/3D seismic surveys, including in-ice surveys, and site clearance and high resolution shallow hazards surveys.

Purpose: The purpose of a ramp-up (soft-start) procedure when starting airgun operations is to provide a gradually (from low levels) increasing sound (vs. sudden high level sound) so that marine mammals near the vessel have the opportunity to move away before being exposed to sound levels that might be strong enough to cause injury. The 180- and 190-dB exclusion zones described in the previous measure are used for the ramp-up procedures as well. The means by which this mitigates injury is by causing deflection from or avoidance of the sound source so, in effect, causing disturbance to mitigate harm.

Science, Support for Reduction of Impacts, and Likely Effectiveness: There have been no documented cases where cetaceans have been observed to move away from a survey vessel during ramp-up. Efficacy is assumed, based on studies of effects of airgun sounds on marine mammals, although the degree to which ramp-up protects marine mammals from exposure to intense noises is unknown (75 FR 49760, August 13, 2010).

Single-airgun experiments show that bowheads typically move away when a single airgun starts firing nearby (Richardson et al. 1986, Ljungblad et al. 1988). Startup of a single airgun is equivalent to the start of a ramp-up, suggesting that bowhead whales would begin to move away during the initial stages of a ramp-up. Hannay et al. (2011b) conducted a model-based assessment of underwater noise from a soft-start operation. In shallow water (50 m (164 ft) depth), the cumulative SEL levels for steps one through three (30 shots into the 230 shot ramp-up procedure) were below the proposed injury criteria for cetaceans at 100 m (328 ft) to the side of the sound source. Any bowhead whales in the vicinity would presumably move away during these early steps in the ramp-up procedure. NMFS requires that ramp-up of acoustic sources occur at a rate of no more than 6 dB per 5 min. This ramp-up rate would prevent marine mammals from being exposed to high levels of noise without warning (75 FR 49760, August 13, 2010). The entire procedure generally takes 20 to 40 minutes to accomplish, depending on the size of the array, and is therefore easy to implement.

Mitigation Measure A2 could impact other cetaceans the same as it would bowhead whales. Single-airgun experiments with three species of baleen whales (gray, humpback, and bowhead) have shown that they tend to move away when a single airgun starts firing nearby, which simulates the onset of a ramp up (Malme et al. 1984, 1985, 1986, 1988; Richardson et al. 1986, Ljungblad et al. 1988, McCauley et al. 2000). Since startup of a single airgun is equivalent to the start of a ramp-up, this strongly suggests that many baleen whales will begin to move away during the initial stages of a ramp-up. It is assumed that toothed whales would react similarly. However, there have been no documented cases where ice seals have been observed to move away from a survey vessel during ramp up. The effectiveness of the measure and its reduction of adverse effects on ice seals are therefore unknown. NMFS has required this measure as a conservative approach to conservation based on its potential for reducing adverse effects on a variety of species and its ease of application.

As noted above, logic and our understanding of how most marine mammals avoid loud sound would suggest that ramp up procedures would likely be effective to some degree in preventing the sudden exposure of marine mammals to injurious sounds. As noted above, cetaceans have been detected moving away from the sound source during a ramp up, but pinnipeds have not. Typically, though, not enough animals are detected during ramp ups of actual seismic surveys to perform a meaningful evaluation of the full effectiveness of the measure.

History of Implementation: Ramp-up procedures have been consistently required for years during exploration activities in the Beaufort and Chukchi seas.

Practicability: To date, this measure has proven practicable to industry operators, as it has been implememted consistently for years.

Recommendation: Based on the feasibility and potential reduction of injury or more severe behavioral impacts, it makes sense to continue requiring this measure of industry operators.

Walrus – This standard mitigation measure applies to all seismic surveys and is the same as the USFWS LOA measures. The rationale for this measure is that walrus in the vicinity of a seismic survey would hear the low sound levels during ramp up and have a chance to move away before potentially damaging sound levels are reached. This procedure may take 20 to 40 minutes to accomplish depending on the size of the array, and is therefore easy to implement. There have been no documented cases where walrus have been observed to move away from a survey vessel during ramp up. The effectiveness of the measure and its reduction of adverse effects on walrus are therefore unknown.

***Polar Bears* –** This standard mitigation measure applies to all seismic surveys and is the same as the USFWS LOA measures. The rationale for this measure is that polar bears in the vicinity of a seismic survey would hear the low sound levels during ramp up and have a chance to move away before potentially damaging sound levels are reached. This procedure may take 20 to 40 minutes to accomplish depending on the size of the array, and is therefore easy to implement. There have been no documented cases where polar bears have been observed to move away from a survey vessel during ramp up. The effectiveness of the measure and its reduction of adverse effects on polar bears are therefore unknown.

A3. PSOs required on all seismic source vessels and icebreakers, as well as on dedicated monitoring vessels.

Applicable Activities: 2D/3D seismic surveys, including in-ice surveys, and site clearance and high resolution shallow hazards surveys.

Purpose: Presence of and observations by PSOs on the source vessels are crucial for implementing many of the other mitigation measures, such as the shutdown and power down measures, and for estimating potential impacts (see Measure A1 above). PSOs are also sometimes used to collect required monitoring information from sources vessels, although this requirement is separate and may be executed from a separate platform. PSOs are trained in species identification and many other operational and data recording procedures. Data collected during visual observations include species identification, bearing and distance to the initial sightings, estimated closest point of approach of animals relative to source vessels or support vessels, movement of animals relative to vessel movements, and behavioral reactions of animals in response to vessel movements. Behavioral data are often limited by the brief time most marine mammals are at the surface where they can be observed and by distance from the vessel (Haley et al. 2010b). Crew members of all vessels are also instructed to watch for marine mammals and to notify the PSOs immediately if any are sighted. While it is not a job requirement, many PSOs are Iñupiat or Yupik hunters that live in Arctic coastal communities and bring a wealth of experience and traditional knowledge to the position.

Science, Support of Reduction of Impacts, and Likely Effectiveness: Distance out to which observers can detect marine mammals depends on the height of the observation platform above water. For example, Haley et al. (2010b) calculated an effective strip half-width (the distance from the centerline of the transect outside of which the number of animals detected equaled the number not detected inside) of 1,618 to 3,136 m (1,767 to 3,430 yds) for vessels higher than 11 m (12 yds) and 1,191 to 1,893 m (1,302 to 2,070 yds) for those lower than 11 m (12 yds).

Visually detecting marine mammals during periods of low to poor visibility, including fog and darkness, may also be challenging. Extensive ice cover, particularly during icebreaking activities, could hinder detectability of marine mammals in water. However, despite limitations, PSOs are invaluable for the purposes of mitigation and data collection aboard industry vessels.

History of Implementation: PSOs on source vessels have been consistently required for years during exploration activities in the Beaufort and Chukchi seas.

Praacticability: To date, this measure has proven practicable to industry operators, as it has been implememted consistently for years.

Recommendation: Based on the feasibility and likely reduction of injury or more severe behavioral impacts, it makes sense to continue requiring this measure of industry operators.

***Walrus* –** The use of the phrase PSOs is synonymous with the term MMOs in the USFWS LOAs. This mitigation measure applies to seismic surveys and icebreaking. PSOs are trained in species identification and many other operational and data recording procedures. Their presence and observations are crucial for implementing many of the other mitigation measures. Crew members of all vessels are also instructed to watch for marine mammals and to notify the PSOs immediately if any are sighted. While it is not a job requirement, many PSOs are Iñupiat or Yupik hunters that live in Arctic coastal communities and bring a wealth of experience and traditional knowledge to the position.

***Polar Bears* –** The use of the phrase PSOs is synonymous with the term MMOs in the USFWS LOAs. This standard mitigation measure applies to seismic surveys and icebreaking. PSOs are trained in species identification and many other operational and data recording procedures. Their presence and observations are crucial for implementing many of the other mitigation measures. Crew members of all vessels are also instructed to watch for marine mammals and to notify the PSOs immediately if any are sighted. While it is not a job requirement, many PSOs are Iñupiat or Yupik hunters that live in Arctic coastal communities and bring a wealth of experience and traditional knowledge to the position.

A4. All activities must be conducted at least 152 m (500 ft) from any observed ringed seal lair. This measure requires survey crews to be trained in seal detection and to search for ringed seal lairs around intended seismic survey operation sites and prohibits seismic activities within a 152 m (500 ft) radius of ringed seal lairs. Additionally, while traveling on ice roads, the area shall be monitored for marine mammals, especially ringed seal lairs.

Applicable Activities: on-ice seismic surveys

Purpose: The purpose of this measure is to avoid disturbing ice seals when they are in their lairs. Additionally, this requirement helps to ensure that machinery is not placed directly over a lair, thereby crushing the lair. If a lair is crushed, an animal inside the lair could be injured or killed. If the animal survives, it could be forced into the water. Pups are more susceptible to hypothermia, so forcing them into the water before their insulation layers are fully formed could result in mortality. This measure is meant to reduce both disturbance and the potential for injury or mortality of ringed seals.

Science, Support of Reduction of Impacts, and Likely Effectiveness: At this 152 m (500 ft) distance, sound source levels from vibroseis gear are not likely to appreciably affect ringed seals (Burns and Kelly 1982, Kelly et al. 1988). Crew at BP's Northstar Island have searched for and marked ringed seal lairs over the last decade prior to ice road construction activities.

History of Implementation: Avoidance of ringed seal lairs has been consistently required for years during on-ice exploration activities in the Beaufort Sea.

Practicability: To date, this measure has proven practicable to industry operators, as it has been implememted consistently for years.

Recommendation: Based on the feasibility and likely reduction of injury or more severe behavioral impacts to ringed seals, it makes sense to continue requiring this measure of industry operators.

***Polar Bears* –** This standard mitigation measure applies only to on-ice surveys and requires survey crews to be trained in seal detection and to search for ringed seal lairs around intended seismic survey operation sites and to prohibit seismic activities within a 152 m (500 ft) radius of ringed seal lairs. This measure helps reduce potential effects on the main prey of polar bears in the Beaufort Sea.

A5. No energy source may be placed over a ringed seal lair. A 152 m (500 ft) exclusion zone must be established around all located active subnivean seal structures, within which no seismic or impact work may be conducted.

Applicable Activities: On-ice seismic surveys

Purpose: The purpose is to avoid injury or severe disturbance of ringed seals.

Science, Support of Reduction of Impacts, and Likely Effectiveness: See the discussion for standard mitigation measure A4 above.

History of Implementation: Avoidance of ringed seal lairs has been consistently required for years during exploration activities in the Beaufort Sea.

Feasibility: To date, this measure has proven feasible to industry operators, as it has been implememted consistently for years (usually in conjunction with the pre-survey scouting for ice-seal structures).

Recommendation: Based on the feasibility and likely reduction of injury or more severe behavioral impacts to ringed seals, it makes sense to continue requiring this measure of industry operators.

***Polar Bears* –** This measure applies only to on-ice surveys and also helps reduce potential effects on the main prey of polar bears in the Beaufort Sea.

A6. PSOs required on all drill ships and ice management vessels.

Applicable Activities: exploratory drilling and in-ice seismic surveys

Purpose: The purpose is the same as standard mitigation measure A3, described above, to implement the mitigation measures and collect data for monitoring requirements.

Science, Support of Reduction of Impacts, and Likely Effectiveness: See discussion in standard mitigation measure A3, above. PSOs on the ice-breaking vessels associated with seismic vessels are in a good position to detect marine mammals in front of, or near, the source vessel and implement mitigation measures. However, for drilling ships, historically the source level has been low enough that it has not been necessary to have power-down and shutdown zones to avoid injury (i.e., at no distance would a marine mammal be close enough to incur PTS). As noted in Section 4.2.6, if the acoustic criteria are modified as outlined, this distance may increase and necessitate the implementation of shutdowns.

History of Implementation: Use of PSOs on drillships and ice-breaking vessels has been consistently required for years during exploration activities in the Beaufort and Chukchi Seas.

Practicability: To date, this measure has proven practicable to industry operators, as it has been implememted consistently for years.

Recommendation: Based on the practicability and likely reduction of injury or more severe behavioral impacts to marine mammals, it makes sense to continue requiring this measure of industry operators for ice-breaking vessels. For drilling vessels, depending on the distance from the vessel to where injurious effects might be expected, the utility of PSOs for implementing mitigation may be limited, however, their value in collecting important monitoring information likely still remains.

B1. Specified flight altitudes for all support aircraft except for take-off, landing, and emergency situations.

Applicable Activities: 2D/3D seismic, including in-ice, surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities

Purpose: Aircraft flight paths and altitudes are restricted to reduce the chance of disturbing marine mammals in the water or hauled out on the ice or land. There are exceptions for landing, takeoff, emergency situations, and unsafe flying conditions (such as poor weather or low visibility).

Science, Support of Reduction of Impacts, and Likely Effectiveness: Studies of behavioral reactions of bowhead whales to aircraft are limited but indicate that whales react little, if at all, to fixed-wing aircraft operating at an altitude of 460 m (1,509 ft) and that most reactions to helicopters occur when the helicopter was at altitudes of ≤150 m (500 ft) (Patenaude et al. 2002, Richardson and Malme 1993). NMFS requires that marine mammal monitoring survey flights be conducted at 305 m (1,000 ft) or greater to avoid adverse impacts to bowhead whales (and other marine mammal species). USFWS requires a minimum altitude of 457 m (1,500 ft) in the LBCHU and when flying over walrus and polar bears on ice or land. In the LBCHU and when over walrus or polar bear, the oil and gas industry conducting operations under MMPA ITAs from both NMFS and the USFWS would be required to implement the more stringent flight altitude. The altitude restrictions associated with this mitigation measure should, therefore, adequately reduce most adverse impacts from aircraft overflights.

Reactions of beluga whales to aircraft vary. Richardson et al. (1991) reported no overt response of beluga whales, even when the aircraft was 100 to 200 m (328 to 656 ft); other responses included looking up, diving abruptly, or turning sharply away from the aircraft. As summarized in Richardson et al. (1995), beluga whales often react to aircraft by swimming or diving. The altitude restrictions associated with this mitigation measure should, therefore, adequately reduce most adverse impacts from aircraft fly overs.

History of Implementation: Altitude restrictions have been consistently required for years during exploration activities in the Beaufort and Chukchi seas.

Practicability: To date, this measure has proven practicable to industry operators, as it has been implememted consistently for years. The flight stipulations are standard operating procedures and coincide with normal safety considerations for air support of offshore activities so they generally do not "cost" more to implement.

Recommendation: Based on the practicability and likely reduction of behavioral impacts to marine mammals, it makes sense to continue requiring this measure.

***Walrus* –** This standard mitigation measure applies to all exploration activities and is the same as the USFWS LOA measures. Aircraft flight paths and altitudes are restricted to reduce the chance of disturbing walrus and other marine mammals in the water or on the ice or land. This restriction would be especially important for avoiding walrus concentrations hauled out on land or on ice where panic reactions could cause injuries or mortality of animals. There are exceptions for landing, takeoff, emergency situations, and unsafe flying conditions. There is no direct evidence about how effective this mitigation measure has been for reducing disturbance to walrus but the flight stipulations are standard operating procedures and coincide with normal safety considerations for air support of offshore activities.

***Polar Bears* –** This standard mitigation measure applies to all exploration activities and is the same as the USFWS LOA measures. Aircraft flight paths and altitudes are restricted to reduce the chance of disturbing polar bears and other marine mammals in the water or on the ice or land. There are exceptions for landing, takeoff, emergency situations, and unsafe flying conditions. There is no direct evidence about how effective this mitigation measure has been for reducing disturbance to polar bears but the flight stipulations are standard operating procedures and coincide with normal safety considerations for air support of offshore activities. NMFS has required this measure as a conservative approach based on its potential for reducing adverse effects on a variety of species and its ease of application.

C1. Specified procedures for changing vessel speed and/or direction to avoid collisions with marine mammals.

Applicable Activities: 2D/3D seismic including in-ice surveys, site clearance and high resolution shallow hazards surveys, exploratory drilling activities, and all associated support vessels

Purpose: This measure is primarily designed specifically to mitigate vessel collision, although it may also indirectly reduce the risk of disturbance to whales.

Science, Support of Reduction of Impacts, and Likely Effectiveness: The circumstances under which the few reported ship strikes and vessel injuries to bowhead whales occurred are unknown, but, given that speeds above 15 kn are known to increase the likelihood of vessel collisions elsewhere for other species (Laist et al. 2001, Vanderlaan and Taggart 2007), this mitigation measure should prove effective. Recent modeling of speed restriction impacts to lethality of vessel collision found that a speed restriction of 10 kn reduced the predicted probability of lethality by 56.7 percent (Wiley et al. 2011). The effectiveness of this measure is, however, partly dependent on the ability of PSOs to adequately detect whales at the distance within which these measures apply and the vessels can adequately reduce speed.

Reducing sudden or multiple changes in vessel direction and requiring vessels to slow down under conditions of poor visibility would also reduce noise levels and the sudden appearance of fast vessels approaching whales in poor visibility. There are no data by which to determine the effectiveness of this measure to indirectly reduce adverse effects of vessel disturbance on bowhead whales, but bowheads appear to be less reactive to and tolerant of slow-moving vessels (Richardson and Malme 1993).

Beluga whale reactions to vessels are highly variable and depend on the habitat, type and behavior of boat, the whales' previous experience with vessels, and the behavioral activities of the whales during the vessel interaction. It is not known whether there have been any ship strikes involving beluga whales and exploration vessels in the Arctic, but given that speeds above 15 kn are known to increase the likelihood of vessel collisions elsewhere (Laist et al. 2001, Vanderlaan and Taggart 2007), this mitigation measure should prove effective and impact belugas whales as it would bowhead whales (see Section 4.5.2.4.9).

While ship strikes are known to affect most of the cetaceans within the EIS project area, it is difficult to draw conclusions regarding causes. Behavior varies within and among species, and there is an overall lack of quality data surrounding ship strikes (Jensen and Silbur 2003). However, this measure would be expected to be as helpful in avoiding ship strikes to other species as to bowheads and belugas.

The risk of vessel collisions with seals is much less than for slower moving whales. There is no evidence that any ice seals have been struck by any vessels associated with exploration activities in the Arctic.

History of Implementation: Use of speed or direction changes in the presence of marine mammals has been consistently required for years during exploration activities in the Beaufort and Chukchi Seas.

Practicability: To date, this measure has proven practicable to industry operators, as it has been implemented consistently for years. Additionally, it is in the best interest of any vessel not to hit a marine mammal or any other object in the water.

Recommendation: Based on the practicability and likely reduction of injury or death of marine mammals, it makes sense to continue requiring this measure of industry operators.

***Walrus* –** This standard mitigation measure applies to seismic surveys, icebreaking, and exploratory drilling. Although this mitigation measure is intended to reduce the risk of collisions with whales, it may also indirectly reduce the risk of disturbance to walrus by reducing sudden changes in vessel direction and requiring vessels to slow down under conditions of poor visibility, thereby reducing noise levels and the sudden appearance of vessels fast approaching walrus in the dark or obscured conditions.

***Polar Bears* –** This standard mitigation measure applies to seismic surveys, icebreaking, and exploratory drilling. Although this mitigation measure is intended to reduce the risk of collisions with whales, it may also indirectly reduce the risk of disturbance to polar bears by reducing sudden changes in vessel direction and requiring vessels to slow down under conditions of poor visibility, thereby reducing noise levels and the sudden appearance of vessels fast approaching bears in the dark or obscured conditions.

4.5.2.4.15.1 Standard Mitigation Measures Summary for Marine Mammals

The incorporation of all of these standard mitigation measures discussed above into future permits and authorizations would work to reduce any adverse impacts to marine mammals that could result from oil and gas exploration activities. Measures to reduce impacts to subsistence uses of marine mammals are discussed in detail in Section 4.5.3.2.3. Several measures are designed with a particular species in mind, but could result in a reduction of adverse indirect impacts to an additional marine mammal species as well. As noted above, the requirement of Standard Mitigation Measures is considered in the conclusion sections of the marine mammal impact analyses included above.

4.5.2.4.16 Additional Mitigation Measures for Marine Mammals

Additional mitigation measures are outlined in Section 2.4.11 and described in detail in Appendix A. These measures may, or may not, be incorporated in future permits and authorizations, depending on the specific activity and the analysis conducted pursuant to the MMPA and the OCS Lands Act. See Sections 2.4.2 and 4.3 for an explanation of how specific measures would be chosen for inclusion in any future permits or authorizations. The following are applicable to mitigating effects of oil and gas exploration activities on marine mammals.

Additional Mitigation Measure A1. Prior to conducting the authorized survey, the seismic array operator shall conduct sound source verification (SSV) tests for their airgun array configurations in the area in which the survey is proposed to occur and report the broadband received levels of 190 dB, 180 dB, 160 dB, and 120 dB radii from the array to the authorizing entity within 5-10 days of completion.

Applicable Activities: 2D/3D seismic including in-ice surveys, site clearance and high resolution shallow hazards surveys

Purpose: The purpose of this mitigation measure is to accurately establish the distances from the airguns that a marine mammal will receive certain sound levels instead of relying on modeling and extrapolation from different known source levels or datasets. These measurements would be used to:

- refine the shutdown zone for that season, which would ensure that animals are not exposed to received levels associated with PTS (injury);
- allow for a more accurate post-operation estimate of the number of animals exposed to levels associated with Level B Harassment in that season; and
- help systematically populate a body of similar estimates (for different airgun array sizes/types, different areas, and different seasons) that could bound the likely propagation ranges and eventually allow for more reasonable and defensible estimates of shutdown and harassment zones in the future for surveys similar to those previously measured, so that SSVs need not be conducted prior to every survey.

Science, Support for Reduction of Impacts, and Likely Effectiveness: Estimating underwater sound levels at different distances from the airgun source should be based on empirical measurement where practicable. The radii of the monitoring zones will vary in size based on the characteristics of the arrays and environmental features, such as bathymetry, bottom type, and the temperature and salinity of the water.

It is generally acknowledged that modeled received levels will be more accurate if they are based on measurements taken of the given source in the same environment and season. However, the accuracy of predictions can vary based on the technology and methods used, so acoustic experts should be consulted. Although larger shut down zones may be considered more conservative by theoretically increasing the area at which animals may not be exposed to sound, these larger zones are often difficult to monitor due to the extent of the area, poor visibility conditions, and difficulty in observing animals such as bowhead whales because of the amount of time they spend underwater. This measure is not required throughout the season but rather at the beginning of the exploration activity and often gives industry a more useful zone for monitoring that season.

SSV measurements have been conducted for several years now with similar types of vessels and sound sources in the same general locations. Over time, it may be possible to collect a broad set of sound source measurements that cover the range of variability in sound source and environmental characteristics (location, depth, bottom type, ice, etc.), which can then be applied in appropriate scenarios in the future without needing to collect new data prior to every survey. NMFS is keeping records of the sound source verification measurements that have been taken and will use it to evaluate the need for source specific measurements in future authorizations.

Because of the high variability in measured isopleths for seismic vessels, it is not clear whether there is consistently a practical reduction of adverse effects to marine mammals. However, we have noted that as more SSVs have been conducted, and more measurements are available for reference, the difference between pre-season modeled/estimated isopleths and field measurements has decreased, allowing for better industry planning and a reduced likely of injurious take as a result of underestimated injury isopleths.

History of Implementation: This mitigation measure has been required in the recent past for most oil and gas exploration projects in the Arctic. However, a 2011 University of Alaska Seismic survey did not require an SSV. The previously required measure required results to be provided to NMFS within five days. However, because of an incident during the 2012 season where rushing the results caused an error in the data analysis, NMFS is considering that applicants would have 5-10 days to submit the results.

Practicability: While this mitigation measure would not be difficult to implement because there is existing expertise and adequate equipment, there are significant costs and planning associated.

Recommendation: Our current analysis suggests that SSVs should be required of authorization-holders unless pre-existing SSVs in the same area/time and for the same array configuration have adequately characterized the expected propagation. If implemented in this manner, it would be necessary to make a case-specific decision regarding whether to require an SSV based on the the airgun configuration of that survey, the area, and the time of year. Once an appropriate representation of the likely propagation of a particular airgun configuration has been estimated in a given region and season (which will take more than one measurement), additional measurements of that airgun configuration will likely not be needed. To support this measure, BOEM and the industry should develop a systematic plan that identifies the categories of airgun configuration, area, and time that need to be populated with SSVs and indicates where data have already been gathered or still need to be collected

Walrus – The effects of this additional mitigation measure on walrus would be the same as described for pinnipeds in Section 4.5.2.4.12.

Polar Bears – The effects of this additional mitigation measure on polar bears would be the same as described for pinnipeds in Section 4.5.2.4.12.

Additional Mitigation Measure A2. All PSOs shall be provided with and use appropriate night-vision devices (e.g. Forward Looking Infrared [FLIR] imaging devices, 360° thermal imaging devices), Big Eyes, and reticulated and/or laser range finding binoculars in order to detect marine mammals within the exclusion zones.

Applicable Activities: All activities requiring PSOs

Purpose: The purpose of this measure is to improve the ability of a PSO to observe marine mammals in safety zones during poor visibility (darkness or inclement weather), which would in turn result in shutdowns for a higher percentage of exposed animals and increased protection from injury (if effective).

Science, Support of Reduction of Impacts, and Likely Effectiveness: One FLIR system was tested by ION in summer of 2012. Monitoring results suggest that the system was fairly good at detecting animals on the ice (i.e., pinnipeds), but less useful at detecting animals in the water (Beland et al. 2013). In 2011, this technology was tested by industry for additional measures to improve detection capabilities but has not yet proven to be successful.

In 2010, Statoil tested the use of an infrared camera to detect marine mammals and found that the usable view was 280 degrees, with blows of large whales visible out to 2,000 m (6,562 ft) and smaller blows (porpoise) out to 500 m (1,640 ft) (NMFS 2011b). Its effectiveness is weather dependent, with fog and poor sea state hampering visibility (white caps caused false positives). However, NMFS encourages industry to continue testing the use of such technologies. George (1999) reports that the surface of bowheads' skin is roughly the same temperature as the surrounding water, so only the blow would be useful – and that would only be useful under conditions with very little wind or if the animal is relatively close the monitoring vessel. Smaller blows of beluga whales would not be detected at as great a distance as those of bowhead whales.

Discussions at the 2012 Open-water Meeting (March 6-8, 2012 in Anchorage, Alaska) suggest these devices can hamper near-source monitoring (the area of greatest radiated sound) because the PSO is attempting to observe more distant areas. Several methods have been attempted but none have been shown to be effective. Plus, the efficacy of these various pieces of equipment in detecting marine mammals would likely vary substantially under different sets of conditions and with the experience of PSOs in operating them.

History of Implementation: NMFS has previously issued a few IHAs that required the authorization holder to use and evaluate the effectiveness of FLIR but has not yet required it as a mitigation measure that assumes effectiveness.

Practicability: Can be expensive, and the technologies are still developing.

Recommendation: Infrared technologies appear to be continuing to improve. Because of the limitations to otherwise detecting marine mammals in low-light situations, companies should continue to test these technologies and target their use to augment other methods of detection, where practicable, especially on ice.

***Walrus* –** The effects of this additional mitigation measure on walrus would be the same as described for pinnipeds in Section 4.5.2.4.12.

***Polar Bears* –** This measure is designed to better protect marine mammals in the water, especially cetaceans, and may improve the capacity of observers to detect polar bears in the water. However, polar bears are rarely encountered in the open water where most seismic surveys would occur and they swim at the surface of the water so they are less likely to be exposed to loud seismic sounds. The USFWS has required the use of FLIR through the LOA process during in-ice seismic surveys to test its utility in identifying polar bears in water or on ice in low light and low visibility conditions. Polar bears are more likely to be encountered during in-ice seismic surveys. However, few seismic surveys occur in ice covered waters. As FLIR systems become better, this measure may have some utility in decreasing the potential for interactions with polar bears during in-ice seismic surveys.

Additional Mitigation Measure A3. Operators shall limit seismic airgun operations in situations of low visibility when the entire safety radius cannot be observed (e.g., nighttime or bad weather). These limitations could mean cease airgun operations entirely, reduce the time that operations are conducted in this limited visibility situation, or reduce the number of airguns operating so that the exclusion radius is entirely visible.

Applicable Activities: 2D/3D seismic including in-ice surveys, CSEM surveys, site clearance and high resolution shallow hazards surveys

Purpose: The purpose of this measure is to limit airgun operations when darkness or inclement weather hampers PSO observations of marine mammals in exclusion zones, thus reducing the likelihood that a marine mammal would enter the exclusion radius unobserved, which could potentially result in an injury if the animal were exposed to high sound levels over a period of time.

Science, Support of Reduction of Adverse Impacts, and Likelihood of Effectiveness: Although studies show that many marine mammals avoid close-approaches of seismic airguns (Richardson et al. 1999), studies also show that some subset of marine mammals have sometimes approached operating ariguns at distances that may be within the exclusion zone, and previous IHA monitoring reports indicate that marine mammals have occassionally been detected within the exclusion zone (Savarese et al. 2010, Haley et al. 2010a, b). Additionally, although the relationship is not entirely linear, studies suggest that marine mammals are also more likely to have a more severe behavioral response if exposed to higer levels such as those within the safety zone.

While implementing this additional measure may prevent some number of marine mammals from being exposed to higher sound levels for longer times, it may also result in seismic surveys taking longer, requiring multiple seasons, or requiring some operators to work during periods where marine mammals are more common or sensitive. If a survey effort is delayed because of poor visibility due to light or weather conditions, some vessels may have to maintain their position until conditions improve. While reducing some types, implementation of this measure could also increase other types of adverse effects to marine mammals.

History of Implementation: Because of the consideration of practicability in the mitigation requirements, measures of this sort have been applied differently in different situations. For example, nighttime operations have been prohibited entirely, prohibited unless accompanied be PAM detection capabailiities (or FLIR or other nighttime enhancing devices), or allowed (with no PAM or other device) as long as they were initiated when the entire safety radius was visible.

Practicability: In the beginning of the open water season (July/August), light conditions are usually sufficient to monitor a large area because the sun does not set. However, in the latter parts of the open water season (September to October), daylight is decreasing rapidly, which would reduce the amount of time for the activities. This measure would likely be expensive to implement and could cause logistical complications that affect survey completion.

Recommendation: As noted above, this measure could result in some protection of marine mammals from exposure to higher levels of sound, but could also potentially result in exposure to sounds over longer total periods of time or in periods of time of particular importance. Additionally, the continuing development of technologies to aid in the detection of marine mammals in low visibility influences how this measure can be implemented. The decision of how to best manage times of low visibility should be made on a case-by-case basis, and based on factors such as the total length of the survey, history of observations within the safety zone in the area, temporal and spatial habitat use of the area by the species being impacted, and whether supplemental equipment is available to assist with nighttime detections.

***Walrus* –** The effects of this additional mitigation measure on walrus would be the same as described for pinnipeds in Section 4.5.2.4.12.

***Polar Bears* –** The effects of this additional mitigation measure on polar bears would be the same as described for pinnipeds in Section 4.5.2.4.12.

Additional Mitigation Measure A4. Seismic operators shall use passive (or active) acoustic monitoring systems, in addition to visual monitoring, to detect marine mammals approaching or within the exclusion zone and trigger the shutdown of airguns.

Applicable Activities: 2D/3D seismic including in-ice surveys, CSEM surveys, site clearance and high resolution shallow hazards surveys

Purpose: The purpose of this mitigation measure is to improve the ability of a PSO to detect marine mammals within the safety zone in times of low visibility (e.g., darkness or inclement weather), thus ensuring shutdowns as appropriate and further minimizing their exposure to higher levels of sound potentially associated with injury or more severe behavioral responses

Science, Support of Reduction of Adverse Impacts, and Likelihood of Effectiveness: Three key components are necessary in order for a PAM system to be able to function as a mitigation aid by triggering the shutdown: detection, localization, and classification. Certain hardware and software are needed in order to support realtime localization, and a regional call library is needed to support species classification (lack of an extensive library can be offset by experienced PAM operators). Also, depending on the sound sources in use in the vicinity of the PAM, it may be challenging to sort out marine mammal vocalizations real-time.

The efficacy of real-time passive acoustic monitoring (PAM) in the Arctic depends on species, frequency and source level of calls, how often the marine mammals call, and choosing the right array and software to match these variables. PAM has been successful at detecting higher frequency clicks of toothed whales where the frequency is well above that of the seismic and tow ship. In the Arctic, most of the calls are low frequency calls, such as from bowheads, which overlap with the seismic sounds (NMFS 2011b – JASCO). Bearded seals often vocalize and can be detected during the spring-summer breeding season but other seals do not vocalize frequently and could be missed even if present. These technologies have the potential to improve the detection of marine mammals, particularly in such a large area where visual sightings are often limited. However, there are significant technical challenges for using this system from moving vessels with their own noise source within the frequency range of the bowhead whales. There has been success in detecting bowhead whale calls from long-term passive acoustic recording devices that are placed on the seafloor bottom for a certain amount of time. However, these devices are not monitored in real-time.

In the Gulf of Mexico, the industry has successfully utilized systems with hardware and software that allow for real-time detection, localization (PAMGUARD), and classification such that shutdowns can be implemented as a result of realtime detections. Monitoring reports for oil and gas vessels in the Gulf, as well as the R/V *Langseth* in different regions, show that PAM sometimes detects marine mammals that were not otherwise detected by visual observers. However, real time PAM was tried in the Arctic by ION in 2006 and Statoil in 2010 and was not found to be effective in detecting bowhead whales because the frequency range of bowhead vocalizations was the same as that of the ship engines. For this reason, unless the technology or methodology is improved, this method may be less effective in areas where bowhead is the target species.

PAM systems only work if an animal produces a sound that can be detected by the system. An active acoustic monitoring (AAM) system circumvents this limitation, as it can detect animals that are not producing sounds. To do so, however, requires introducing sound into the environment, which can cause behavioral disturbances. Additional limitations include only being able to detect a whale ≥7 m (23 ft in length) out to a distance of about 1 km (0.62 mi), difficulty detecting whales at depth when their lungs are collapsed and at the surface when there is interference from signal reflections off of surface waves. Use of AAM remains in the realm of research and development (Bingham 2011).

The Sound and Marine Life Joint Industry Programme (JIP) is currently funding ongoing research on the use of real-time acoustic identification of cetaceans and the use of active acoustics technologies for use in mitigation and monitoring marine mammals during offshore exploration activities (JIP 2009). The technology, although not yet proven in Arctic conditions, has the potential for future application, pending continued research and modifications.

History of Implementation: PAM has been previously required, in a few cases, by NMFS for real-time use with seismic surveys both in the Arctic and in other areas (Langseth), although it has been used to augment visual detections and not to directly trigger shutdowns. AAM has not previously been required with the use of seismic airguns, rather, only in combination with the use of the US Navy's tactical low frequency active sonar, and separately considered in situations where physical injury might occur (fisheries gear entanglement).

Practicability: As discussed at the 2012 Open-water Meeting (March 6-8, 2012 in Anchorage, Alaska;

University of Alaska 2011 seismic survey 90-day report: http://www.nmfs.noaa.gov/pr/pdfs/permits/uagi_90day_report2011.pdf, Statoil 2011 marine survey program 90-day report: http://www.nmfs.noaa.gov/pr/pdfs/permits/statoil_90day_report2011.pdf) these techniques have proven feasible, although in those two casesbut have not achieved the anticipated mitigation benefits.

Recommendation: For PAM, the decision of whether to require realtime use of PAM or AAM systems to trigger shutdown should be made on a case by case basis in consideration of the continuing development of PAM systems and their ability to detect bowhead whales during operation, the specific environment/habitat that the airguns are operating in and its importance to particular species, and the availability and cost of the necessary equipment. For AAM, until more is known about the potential added impacts on marine mammals of using AAM, we recommend not requiring its use with seismic airgun operation.

***Walrus* –** The effects of this additional mitigation measure on walrus would be the same as described for pinnipeds in Section 4.5.2.4.12.

***Polar Bears* –** The effects of this additional mitigation measure on polar bears would be the same as described for pinnipeds in Section 4.5.2.4.12.

Additional Mitigation Measure A5. Enhancement of monitoring protocols and mitigation shutdown zones to minimize impacts in specific biologic situations (e.g. expansion of shutdown zone to 120 dB or 160 dB when cow/calf groups and feeding or resting aggregations are detected, respectively).

Applicable Activities: Any activity that implements standard shutdown zones

Purpose: These additional measures were originally designed with the intent of detecting bowhead whales in feeding or social aggregations or with calves and then ceasing seismic airgun operations until the animals leave the area, potentially reducing the likelihood of interfering with cow/calf social interactions or incurring additional energetic costs during an important time period.

Science, Support of Reduction of Adverse Impacts, and Likelihood of Effectiveness: Disturbance that causes behavioral reactions that affect life functions, such as migration, feeding, and nurturing or parental care, can affect vital rates (e.g. survival and reproduction), which could, ultimately, lead to population level effects (NRC 2005). Disruption of cow-calf pairs, possibly through physical separation of dependent young from their mothers, or of feeding aggregations during late summer and fall when bowheads are building fat and energy reserves prior to migrating could, therefore, be considered effects with potential biological significance.

However, during the few times that these types of measures were implemented in the Beaufort Sea beginning in 2006, there were no shutdowns of operations, as bowhead whales have not been detected in the groupings that would trigger the implementation of these measures. In particular, the 120 dB zone is often so large (>20 km [12.4 mi] radius, 126-km circumference, and an area of 1256 km^2) from the source, monitoring this large of an area from one or two aircraft is ineffective, if not impossible. Although much smaller than the 120 dB zone, the average distance to the 160 dB sound level threshold can be >10 km (6.2 mi) (Table 4.5-11). The aircraft or additional monitoring vessels are sources of potential disturbance themselves, particularly when attempting to identify calves or feeding whales, when behavioral disturbance is more likely and potentially more biologically significant. If this measure has not been previously triggered during the necessary monitoring, then it did not reduce impacts to the species.

History of Implementation: Measures of this nature (specifically shutting down for 4 cow/calf pairs within the 120-dB isopleths, and shutting down for ro aggregations of feeding whales within the 160-dB isopleths) were required a couple of times in 2006 and 2007, but have not been required since.

Practicability: The 120 dB zone is often so large that monitoring by one or two aircraft is ineffective, if not impossible. Additionally, industry has often noted that implementation of this measure is not practicable, as they have serious concerns regarding the overall safety of conducting fixed-wing aircraft monitoring flights in the Arctic, especially in the Chukchi Sea, where the nearest landing field can be quite distant from the location of the source vessel.

Recommendation: The two examples of this type of measure cited above have been shown to not be effective and should not be considered further. However, there could be other specific measures of this nature (highlighting different biological situations) that could be proposed by the public during the MMPA process that could be worthy of case-by-case consideration.

Other Cetaceans – This additional measure was designed with the intent of detecting bowhead whales in aggregations or with calves and could indirectly affect other cetaceans in the vicinity of these groups. However, groupings that would trigger implementation of these measures have not been detected in the Beaufort Sea since this was first required in 2006. In addition, the 120 dB zone is often so large (>20 km [>12.4 mi]) from the source, monitoring this large of an area from one or two aircraft is extremely difficult, if not impossible. The aircraft or additional monitoring vessels are sources of potential disturbance themselves, particularly when attempting to identifying calves or feeding whales, when behavioral disturbance is more likely and potentially more biologically important. The effectiveness of this mitigation measure for reducing potential adverse impacts on other cetaceans is questionable, given the infrequency with which large groups occur. Refer to Section 4.5.2.4.9 for a more thorough description and analysis of the efficacy and practicability of this mitigation measure.

Ice Seals – This additional mitigation measure is oriented primarily at avoiding impacts on groups of whales. Ice seals in the vicinity of these whale groups may have some indirect reduction of adverse impacts if nearby seismic surveys are halted or delayed. However, this situation is similar to that described for Additional Mitigation Measure A3 in that overall seismic efforts could remain the same but be stretched out over time. The indirect effects of the measure on ice seals cannot be determined ahead of time nor is it likely they could ever be measured in the field. This measure could necessitate additional aerial and/or vessel surveys which may be costly and would be potential sources of disturbance themselves.

Walrus – The effects of this additional mitigation measure on walrus would be the same as described for ice seals in Section 4.5.2.4.12.

Polar Bears – The effects of this additional mitigation measure on polar bears would be the same as described for ice seals in Section 4.5.2.4.12.

Additional Mitigation Measure B1. Temporal/spatial limitations to minimize impacts in particular important habitats, including Kaktovik, Barrow Canyon, Hanna Shoal, the shelf break of the Beaufort Sea, Kasegaluk Lagoon, and Ledyard Bay. All, or a subset of, oil and gas activities would be limited (e.g., either completely prohibited, or the overall time reduced) in the areas specified here during the listed timeframes. Additionally, buffer zones around these time/area closures could potentially be included. Buffer zones would require that activities emitting pulsed sounds would need to operate far enough away from these closure areas so that sounds at 160 dB do not propagate into the area or that activities emitting continuous sounds would need to operate far enough away from these closure areas so that sounds at 120 dB do not propagate into the area. In the event that a buffer zone of this size was impracticable, a buffer zone avoiding the ensonification of the important habitat above 180 dB could be used.

Applicable Activities: All activities that occur during the open-water season (i.e. 2D/3D seismic surveys including in-ice seismic, CSEM surveys, site clearance and high resolution shallow hazards surveys, and exploratory drilling activities, as well as all support vessels and minimum flight altitudes for aircraft activity)

Purpose: These mitigation areas are each designed to achieve one or both of the following purposes:1) to minimize the effects of acoustic disturbances on marine mammals by reducing either the *number* of individuals (in higher density areas) exposed to sound levels above certain thresholds or by reducing the duration or levels of sound that individuals are exposed to during times when they may be more susceptible to adverse impacts (such as when inter-species communication is especially critical or when they are utilizing a preferred habitat and the inability to do so as a result of temporary displacement could result in adverse energetic impacts), or 2) to avoid or minimize adverse impacts to subsitence uses of marine mammals. Table 4.5-21 outlines the proposed dates for these time/area closure locations, as well as the reasons for the proposed closures (i.e. minimize effects on marine mammals or to avoid or minimize adverse impacts to subsistence uses of marine mammals.

Table 4.5-21 Proposed Time/Area closure locations under Additional Mitigation Measure B1. This table identifies the species and subsistence hunts that would be mitigated by implementing these closures.

	Kaktovik	Barrow Canyon and the Western Beaufort Sea	Beaufort Sea Shelf Break	Hanna Shoal	Kasegaluk Lagoon and Ledyard Bay
Proposed closure period	August 25 - September 15	Mid-July - October	Mid-July - late September	September 15 - early October	Mid-June - mid-July for the Lagoon and July 1 – November 15 for the LBCHU
Bowhead Whale	Migrating and feeding: late August - October	Migrating and feeding: late August - October	Migrating: late August - October	Part of migratory corridor: September - October	Do not occur (migrate offshore)
Beluga Whale	Uncommon	Migrating and feeding: mid-July - late August	Feeding: mid-July - late September	Unknown	Feeding, molting, calving: June and July
Spotted Seal	Present	Present	Present	Present	Present; Some feeding habitat
Walrus	Not present	Not present	Not Present	Feeding: July - August	Resting habitat: Spring and early winter
Whaling Hunts	bowheads: late August - mid-September	bowheads: September - October	Uncommon	None	belugas: mid-June - mid-July in the Lagoon only
Sealing Hunts	Mostly October - June	Mostly November - January and spring	Uncommon	None	Mostly October - June

Science, Support of Reduction of Adverse Impacts, and Likelihood of Effectiveness:

Kaktovik: Data collected during ASAMM surveys in the Beaufort Sea from 2008-2011 noted feeding groups of bowhead whales in September most of those years (Clarke et al. 2011b, c, 2012). Additionally, hunters from Kaktovik traditionally conduct hunts in the nearshore waters from the community in the fall. Hunts typically begin in late August/early September and continue until mid- to late September, depending on upon migration patterns, weather and ice conditions, etc. Although subsistence seal hunts could occur yearround, they are most commonly conducted in this area from October-June. Closing the area to oil and gas activities during this time period would reduce adverse impacts, particularly those associated with noise disturbance (e.g. displacement and avoidance), on bowhead whales feeding, resting, or migrating through this area. Reducing impacts on concentrations of bowhead whales in an important feeding area could be energetically beneficial to the whales. Prohibiting activities in this area during the period of highest use by bowheads could result in a decreased intensity of effects during the closure period. Reduced adverse impacts on bowhead whales would, however, be limited to the closure area. Noise effects of activities occurring outside of this closure area could continue to impact bowhead whales in the vicinity that are either outside the closure zone or within the zone, but at a distance from the sound source within which behavioral reactions are still possible. However, the implementation of buffer zones around the closure area would help to reduce further impacts from occurring within this important location.

Barrow Canyon and Western Beaufort Sea: Due to sub-sea topography and the ocean currents, Barrow Canyon is one of the two primary concentration areas for bowhead whales in the Beaufort Sea, particularly as a staging/feeding area during the fall migration of bowheads out of the Beaufort Sea. Physical and oceanographic features of Barrow Canyon promote a bowhead whale feeding “hotspot” here during late-summer and fall. Bowhead whales congregate in the area to exploit dense prey concentrations (Ashjian et al. 2010, Moore et al. 2010, Okkonen et al. 2011). Barrow Canyon is also an important feeding area for beluga whales (Clarke et al. 2011b, 2011c, Moore et al. 2000). Time/Area closures for this area are to mitigate effects on bowhead whales (late August to early October), belugas (mid-July to late August), and the fall bowhead whale subsistence hunt out of Barrow (September 15 to close of the hunt). Barrow Canyon may also serve as feeding habitat for ringed, bearded, and ribbon seals. Subsistence seal hunts typically occur in this area from November-January and then again in the spring. Closing the area to oil and gas activities during these time periods would reduce adverse impacts, particularly those associated with noise disturbance (e.g. displacement and avoidance), on bowhead whales feeding, resting, or migrating through this area, as well as for belugas. Reducing impacts on concentrations of whales in an important feeding area could be energetically beneficial to the whales. Prohibiting activities in this area during the period of highest use by bowheads and belugas could result in a decreased intensity of effects during the closure period. Reduced adverse impacts on whales would, however, be limited to the closure area. Noise effects of activities occurring outside of this closure area could continue to impact whales in the vicinity that are either outside the closure zone or within the zone, but at a distance from the sound source within which behavioral reactions are still possible. However, the implementation of the buffer zones around the closure area would help to reduce further impacts from occurring within these biologically important areas.

Beaufort Sea Shelf: The shelf break of the Beaufort Sea is an important feeding habitat for beluga whales. Active leases in the Beaufort Sea are generally on the shelf, inshore of the shelf break; drilling activities would, therefore, not be impacted through this closure. Seismic activities and associated vessel traffic would be affected, thereby reducing potential adverse impacts on beluga whales, particularly those associated with noise disturbance. The time and location of reduced adverse impacts would be limited to the area defined by the shelf break. Implementing buffer zones around the closure area could further reduce impacts of noise on the closure area generated by activities occurring in areas adjacent to the closure.

Hanna Shoal: Hanna Shoal is an important feeding area for Pacific walrus (USGS 2011) and was historically important as a feeding area for gray whales (Moore et al. 2000, Nelson et al. 1994). Additionally, the area is used as part of the bowhead whale fall migratory corridor. Hanna Shoal is also known as an important feeding area for ice seals, especially bearded seals, since polynya systems typically develop there during winter months. These polynya systems then support higher numbers of ringed and bearded seals. Closure of Hanna Shoal is primarily to mitigate potential impacts on subsistence hunters during the fall bowhead whale hunt (September 15 to close of the hunt). Barrow and Wainwright conduct fall subsistence hunts for bowhead whales in the northeast Chukchi Sea where they could be impacted by vessels transiting between the coast and Hanna Shoal. Harvested whales are generally taken well inshore of Hanna Shoal (Ashjian et al. 2010). Closure of the area to all oil and gas exploration activities during September and October could reduce adverse effects of these activities, especially those associated with noise disturbance, such as displacement, on marine mammals migrating across the area. There are no leases within Hanna Shoal, therefore, there would be no impacts to drilling operations. However, the requirement to maintain a buffer zone around the area could reduce impacts from seismic surveys.

Kasegaluk Lagoon and Ledyard Bay: Kasegaluk Lagoon provides important habitat for beluga whales and spotted seals. Belugas of the eastern Chukchi Sea stock congregate in Kasegaluk Lagoon in June and July (Frost et al.1993, Huntington et al. 1999). Omalik Lagoon, south of Kasegaluk Lagoon, is also an important gathering area for belugas in June, except in years when there is heavy ice along the shore (Huntington et al. 1999). Kasegaluk Lagoon hosts the largest concentrations of spotted seals north of Point Hope, and, consequently, Ledyard Bay can be expected to be an important feeding area for spotted seals by virtue of its proximity to Kasegaluk Lagoon and its nearshore habitat. Subsistence seal hunts can occur in this area yearround but are most common from October to June. This closure area does not contain any lease areas, and leases in the Chukchi Sea occur dozens of miles away; therefore, actual on-lease seismic or drilling operations would not be affected by the closure. Off-lease seismic surveys and associated vessel and aircraft traffic would, except in emergency situations, be required to divert around the closure area. This could decrease disturbance effects of vessel activity within these important habitats and closure areas, while shifting vessel activity further offshore. The buffer zone would require all components of the activities to occur at least some distance from these locations.

History of Implementation: NMFS has consistently required a shutdown of activities in the Beaufort Sea in the vicinity of Kaktovik on August 25 until the close of the fall bowhead whale hunt by the community (as well as for the community of Nuiqsut conducting its fall bowhead hunt from Cross Island) in IHAs. Temporary cessation of activities near the other locations noted in this mitigation measure has not been required in the last few years and has never been included in IHAs for all of these areas. Shutdowns near Barrow have also been required in IHAs in the past to accommodate the fall bowhead whale hunt. Although never required in NMFS IHAs, BOEM and USFWS require cessation of oil and gas exploration activities from July 1 to November 15 in the LBCHU in G&G permits and LOAs, respectively.

Practicability: Avoidance of these time/area closure locations may be costly to industry, as many of the proposed closure periods occur at the same time as proposed industry operations. Moreover, federal lease sales within some of these proposed closure areas have already occurred, and companies have purchased leases in these areas. The Hanna Shoal time/area closure overlaps with ten lease blocks (four of which are completely inside the proposed time/area closure location and six of which are partially inside the proposed time/area closure location). However, some of these areas would be easier to avoid, such as Kasegaluk Lagoon and the LBCHU, since there are no active leases in that area.

Recommendation: At this time, it is difficult to weigh the costs and benefits of requiring this mitigation measure without more specific information, such as the proximity of the proposed activities to these proposed time/area closure locations. NMFS would aim to limit oil and gas exploration activities in these locations through the use of these time/area closures during times when marine mammals may be present to perform specific biologic life functions or during times when subsistence hunts occur when making decisions on individual MMPA ITA requests. However, we would need to weigh the practicability for implementation against the reduction of adverse impacts to marine mammals and subsistence uses of marine mammals on a case-by-case basis.

***Walrus* –** Additional Mitigation Measures B1 and B2 apply to all exploration activities that occur during open-water season. The important areas designated in this mitigation measure are primarily meant to protect whale habitat and to avoid conflicts with subsistence whaling. The reduction of exploration activity at the designated sites in the Beaufort Sea would have little mitigative value for walrus since they infrequently occur in those areas. However, Hanna Shoal is an important habitat for feeding walrus and any reduction in exploration activity in this area would reduce the potential for disturbance of walrus. This mitigation measure is not intended to reduce overall exploration activities so any reduction in impacts in one location and time could be displaced to another location and time and the total number of animals affected by exploration activities may not change with the implementation of this mitigation measure.

***Polar Bears* –** The important areas designated in this mitigation measure are primarily meant to protect whale habitat during open-water season and to avoid conflicts with subsistence whaling. This measure would theoretically reduce disturbance impacts on polar bears by reducing seismic activities but there would likely be very few bears affected to any extent by open-water seismic surveys even without these additional restrictions. The time/area closures could be important to polar bears when pack ice is present but not during the open-water season. It is therefore unlikely that this measure would appreciably reduce the potential effects of seismic surveys on polar bears.

Additional Mitigation Measure B2. Restriction of number of surveys (of same level of detail) that can be conducted in the same area in a given amount of time (i.e. to avoid needless collection of identical data). Require industry to organize a way to interact with one another to identify when and if duplicative surveys are likely to occur (survey type to gather same type of data within five years) and outline efforts to avoid or describe justification.

Applicable Activities: 2D/3D seismic surveys

Purpose: This measure is intended to reduce disturbance of marine mammals through the reduction in the total amount of sound energy put in the water by alleviating duplicative seismic operations that would collect data already collected by another source.

Science, Support for Reduction of Effects, Likely Effectiveness: There is no specific science to support this mitigation measure. Rather, it is reasonable to expect that preventing or minimizing repeated perturbations in specific areas could reduce avoidance behavior, potential hearing injuries, and other sensitivities resulting from multiple exposures to disturbances. By lessening or removing chronic effects in the environment, fish and marine mammal species would not be subjected to harassment in the same area on multiple occasions. It is not clear how much this measure would reduce overall effort, if at all, but would appear to only affect area-wide surveys on non-lease sale areas. There is the potential for this measure to reduce repeated disturbance to bowhead whales in a particular area. However, Alternative 2 (and the other action alternatives) has a specified level of exploration activity that could be authorized, even with restrictions. Both BOEM and industry representatives have suggested that it is unlikely that much duplication of effort is occurring, as it would not likely be a profitable endeavor.

History of Implementation: Neither NMFS nor BOEM have ever restricted activities in this manner. However, it is also unclear what degree of duplication (if any) is currently occurring.

Practicability: In order to implement this measure, it would be necessary to closely track existing and proposed surveys and the willingness of industry to share what may be considered proprietary information, which could potentially create business advantages for other companies. Legal issues would also likely prohibit implementation of this measure by BOEM or NMFS. NMFS is mandated to issue or not issue an ITA based on findings pursuant to the specific proposed action. Section 101(a)(5) of the MMPA does not allow NMFS to deny an ITA for a particular action prior to the case-specific analysis. BOEM does not have the authority under OCS Lands Act to impose such a restriction either.

Recommendation: Due to the lack of evidence that duplicative surveys are occurring, the logistical effort that would be needed by industry and the Federal Agencies to implement such a measure, and the fact that neither MMPA nor OCS Lands Act seem to allow for this type of restriction through thte sections contemplated in this EIS, this measure should not be considered further.

***Walrus* –** The effects of this additional mitigation measure on walrus would be the same as described for ice seals in Section 4.5.2.4.12. Additional Mitigation Measures B2 and B3 would impose further spatial restrictions on seismic surveys during open-water season. These measures would theoretically reduce disturbance impacts on walrus by reducing seismic activities but there would likely be few walrus affected to any extent by open-water seismic surveys even without these additional restrictions. The temporal/spatial restrictions on exploration activities in the Chukchi could appreciably reduce the potential effects of exploration on walrus at Hanna Shoal.

***Polar Bears* –** The effects of this additional mitigation measure on polar bears would be the same as described for ice seals in Section 4.5.2.4.12.

Additional Mitigation Measure B3. Separate seismic surveys are prohibited from operating within 145 km (90 mi) of one another.

Applicable Activities: 2D/3D seismic surveys, including in-ice surveys

Purpose: The intended purpose of this measure, as put forth by the public in comment letters, is to avoid creating a large ensonified area between two surveys through which marine mammals are reluctant to pass (potentially barring them from areas they need to get to, or imposing additional energetic costs) and/or impacts are intensified. The 145 km (90 mi) separation appears to be loosely based on avoiding the overlap of the 120-dB isopleths of two seismic arrays.

Science, Support for Reduction of Impacts, and Likelihood of Effectiveness: Currently, standard operational requirements for seismic arrays include a separation distance of 24 km (15 mi). There is no evidence to support the idea that widening this gap to 145 km (90 mi) will result in a reduction of impacts to marine mammals, either in number or severity. Although the body of literature is growing, there are limited field data clearly illustrating how marine mammals respond to single sound sources, far less information indicating how marine mammals would likely respond when exposed to multiple sound sources simultaneously, and none that we are aware of comparing responses to different configurations of multiple concurrent sound sources. Separating seismic surveys by farther distances decreases the overlap of ensonified space, increasing the total ensonified area, and potentially the likely effects.

History of Implementation: This measure has not previously been required by NMFS or BOEM.

Practicability: In the Arctic, the Beaufort lease areas cover an area that is about 240 km (149 mi) from east to west and about out to 80 km (50 mi) off shore. The Chucki leases cover an area that is about 240 km (149 mi) east to west and 80 km (50 mi) north to south. Due to available open water and subsistence limitations, almost all seismic surveys conducted in the Arctic will overlap in time to some degree. Separating two concurrent surveys within either the Beaufort or the Chukchi creates serious logistical issues. Separating more than two surveys in this manner would be nearly impossible.

Recommendation: Due to the lack of any evidence supporting that this measure will result in a reduction of adverse impacts, this measure should be removed from future consideration.

***Walrus* –** The effects of this additional mitigation measure on walrus would be the same as described for ice seals in Section 4.5.2.4.12.

Polar Bears – The effects of this additional mitigation measure on polar bears would be the same as described for ice seals in Section 4.5.2.4.12.
