4 **Declarations**

5 **Funding**

6 This research was not funded by CIRES or any previous sponsors. The work did not fit into defined missions. I
7 was encouraged, but not supported.

8 **Conflicts of Interest/Competing Interests**

9 I do not have any.

10 **Availability of Data and Material**

11 The measurements were made using a PC with the Cornell Raven software and a microphone detailed in the
12 manuscript. These data are in a standard format.

13 **Code Availability**

14 The Raven software developed by Cornell is available on-line.

15 **Authors Contributions**

16 Not Applicable

17 **Acknowledgements**

18 The measurements in the vicinity of Niagara Falls presented here were enabled by Dr. and Mrs. Peter F. Regan the
19 3rd. The application of this work to avian migration was inspired by a series of papers by J. T. Hagstrum.

1 Waterfall low-frequency vibrations and infrasound: implications for avian migration and 2 hazard detection

3 Alfred. J. Bedard Jr.¹

4 Abstract

5 Many researchers have suggested that birds may use natural infrasound sources for navigation and hazard avoidance. However, there
6 is a need to define the sound levels and frequencies to characterize potential infrasound sources. This paper summarizes new
7 measurements from Niagara Falls which define a stable, powerful infrasound source that could be detected by birds on a regional scale
8 of over 400 kilometers. Measurements made in the vicinity of Niagara Falls show that exceptional infrasonic pressure levels can occur
9 in the regions of large waterfalls (>100Pa at a range of about 500 meters). This paper reviews investigator assessments of avian use of
10 infrasound. A review of the results of Cornell researchers on pigeon hearing provides a basis for estimating avian detection ranges of
11 waterfalls. It is possible that migrating birds use sounds from waterfalls as beacons- a component of their “navigation toolbox” as
12 well as infrasound for hazard avoidance.

13 **Key Words:** avian navigation · infrasound · waterfalls · weirs · hazard avoidance

14

15 Introduction

16 There have been a broad set of infrasonic sources identified in
17 the atmosphere (Bedard and Georges, 2000). Many of these
18 are quite transient, only lasting for minutes. Examples of these
19 signals are small explosions, meteors, avalanches and those
20 related to storm electrical discharges. Another transient set of
21 infrasonic signals, while of longer duration (tens of minutes to
22 hours), can involve moving sources (e.g. radiation of
23 infrasound from severe weather); as well as sounds from
24 volcanoes, earthquakes, or large explosions. In addition, there
25 are sources of infrasound of large areal extent. Most notably,
26 these sources are related to air flows interacting with terrain
27 features or originating with turbulence aloft (Bedard, 1978). In
28 addition, large areas of interacting ocean waves at sea or
29 alternatively waves abruptly stopping on shore lines can
30 provide infrasound arriving from a broad azimuth sector.
31 Chanson (2009) has documented low frequency, rumbling
32 sounds accompanying tidal bores. On the other hand, unique,
33 continuous infrasound sources could easily have gone
34 unnoticed in the midst of the detection of acoustic energy from
35 larger areas of radiation. Often, past infrasonic monitoring was
36 restricted to a specific range of frequencies. Frequently,
37 monitoring has been episodic or focused on a specific source
38 (e.g. tornado detection). This paper addresses waterfalls as
39 unique, essentially continuous geophysical sources of
40 infrasound and considers possible sound generation
41 mechanisms.

42 There are dual goals in this review paper. One goal is to
43 define the sound levels created by natural waterfalls, and
44 explore sound generation mechanisms, contrasting these with
45 sound generation by weirs and dams. A parallel goal is to
46 detail evidence for the sound pressure threshold levels and
47 capabilities of pigeons for infrasound detection and potential
48 avian uses of infrasound.

49 A significant amount of research has addressed possible avian
50 uses of infrasound. An overview is in the section entitled-
51 Studies focused on possible avian uses of infrasound. This is
52 followed by an evaluation of the potential of pigeons to use
53 infrasound from Niagara Falls and costal waves for navigation
54 in the section entitled- Possible Importance of waterfall
55 infrasound for bird migration.

65

66 Waterfall infrasound quantitative measurements

67 This section documents the exceptional infrasound levels
68 observed from Niagara Falls, as well as lower levels from San
69 Rafael Falls and Boulder Falls. The summaries and analyses of
70 processes causing powerful sounds caused by hydraulic
71 processes appear in appendices 1 and 2

72 Johnson et al. (2006) measured the infrasound associated with
73 the San Rafael Ecuadorian waterfall. They observed almost
74 continuous infrasound from the waterfall between 2 and 3 Hz.
75 To my knowledge, this was the first instrumented detection of
76 a natural waterfall.

77
78 Data at Niagara Falls were taken on 16 June 2009 for four 1-
79 minute intervals separated in time by about 5 minutes. Data
80 were displayed as time series and spectra using RAVEN (A
81 sonogram display program developed by Cornell Laboratory of
82 Ornithology). Data files were archived for additional
83 processing. Figure 1 is an example of one of the data sets
84 recorded. These levels were at a distance of about .5 kilometer
85 from the falls- Horseshoe and American.

86

87 **Fig.1** This shows data taken about 500 meters from Niagara
88 Falls. The upper trace is a time series for a one minute interval
89 of data. The lower display is a spectrogram covering a
90 frequency range from 0 to 90 Hz. The scale for the time series
91 is +/- 100 Pa. (Color online)

92 In Fig.1 the spectral energy scale is that black indicates no
93 energy and white the greatest energy. Therefore the greatest
94 energy is around 10 Hz. All four 1-minute measurement
95 intervals showed strong peaks in energy between 5 and 20 Hz,
96 much stronger than the energy in the audible range (producing
97 a continuous roaring sound). There were no winds during the
98 measurement period.

99 The amplitude scale of the Raven sonogram display is in
100 arbitrary units so there was a need to calibrate the scale. The
101 microphone used was an Avantone, large capsule/USB
102 Cardioid FET. We measured the microphone sensitivity in the
103 frequency range between 10 and 40 Hz. The sensitivity was
104 0.3 divisions/Pa between 30 and 40 Hz, falling off below 20 Hz
105 to < .03 division/Pa at about 10 Hz.

1 At Niagara Falls measured levels were above 30 divisions in
 2 the 5 to 20 Hz range, corresponding to pressures >100 Pa..
 3 Assuming an inverse range dependence for geometrical
 4 spreading, amplitude levels of 0.5 Pa and 0.05 Pa will occur at
 5 ranges of 100 and 1000 km from the source respectively.
 6 Levels of 0.1Pa are typical background amplitudes for
 7 locations with low wind conditions. Figure 2 contrasts Niagara
 8 Falls data with data taken in Colorado under low noise
 9 conditions. The constant tone at 24 Hz was from a woofer-
 10 organ pipe combination at a range of 762 meters.

25 **Fig.2** The figure was recorded at the Boulder Atmospheric
 26 Observatory (BAO) in Colorado using identical
 27 instrumentation and sensitivity settings The level at the BAO
 28 of <0.1 Pa is typical for low wind conditions The constant tone
 29 at 24 Hz is from a woofer/organ pipe combination at a range of
 30 762 meters The 24 Hz test signal pressure level shown was
 31 ~0.01 Pa (Color online)
 32
 33 Using the hardware deployed at Niagara Falls measurements
 34 were made on 11 August 2009 at a range of 30 meters from
 35 Boulder Falls, Colorado. Infrasound occurred between 10 and
 36 30 Hz at a pressure level of 3 Pa

37
38
39 **Summary of waterfall quantitative sound measurements**

40 Table 1 below summarizes key parameters for the several waterfalls for which infrasonic data were available.

41 Table 1. Waterfall infrasound measurements, including waterfall heights, frequencies in Hz, infrasound pressure levels, volume
 42 fluxes, and waterfall types.

Waterfall	Height (m)	Frequency (Hz)	Infrasound Pressure Level (Pa) At various ranges	Volume Flux (m ³ /s)	Reference/comments
Niagara Falls American	51	5-20	>100 Pa @500m	2407	Block type of waterfall
Niagara Falls Canadian	51	5-20			
Boulder Falls, Colorado	20	10-30	3Pa @ 30m	22	Cascade type of waterfall
San Rafael Falls, Ecuador	145 Tallest single drop 94 m	2-3	.05Pa @ 7.8Km	400	Johnson et al. (2006), Tiered type of waterfall with 2 drops

1 Sources and possible avian uses of infrasound

2
3 This section summarizes efforts to understand the uses birds
4 make of infrasound (and higher frequency sound). There have
5 been many investigators addressing this question. These
6 studies range from establishing that atmospheric inversions can
7 influence homing success, modification of song frequency and
8 timing in the vicinity of surf for communication success, to
9 using infrasound generation to increase communication range
10 in dense vegetation. Berthold (1999) explored the sensory
11 bases for bird's use of environmental factors in migration,
12 including their exceptional sensitivity to atmospheric pressure
13 and an ability to detect infrasound. He concluded that it is
14 likely that differences in atmospheric pressure directly
15 influence migratory behavior.

16 17 Observations

18
19 Numbers of observations address the possible role of
20 infrasound in avian navigation. Some observations indicate that
21 important sensing abilities (e.g. visual, magnetic orientation)
22 are not sufficient to explain homing skill. Other observations
23 are indirect, indicating that the state of the atmosphere is
24 important. Still other observations show evidence that homing
25 pigeons can detect infrasound, Observations are summarized
26 below, including references.

- 27
- 28 • The ability of pigeons with degraded vision to home to
29 the vicinity of their loft (Schmidt-Koenig and Schlichte
30 1972), (Beason and Wiltshko 2015)
- 31 • The existence of navigational ability during cloud cover
32 and where pigeons are equipped with magnets,
33 eliminating these options of solar and magnetic
34 orientation (Griffin 1973)
- 35 • Pigeons have enhanced sensitivity to infrasound
36 (Kreithen and Quinn 1978)
- 37 • Sonic boom disruption of pigeon races from the
38 Concord SST (Hagstrum 2000)
- 39 • For birds with degraded hearing homing abilities were
40 reduced, while under some conditions improved -
41 possibly reducing industrial noise (Schöps and
42 Wiltshko 1994)
- 43 • Correlations exist between modeling of good and poor
44 infrasound propagation conditions from loft areas and
45 homing success or failure (Hagstrum 2000, 2007,
46 2013)
- 47 • Pigeons have difficulty navigating when above a cirrus
48 cloud deck associated with a temperature inversion
49 (Griffen 1973), (Wagner 1977), (Hagstrum 2000)
- 50 • Homing performance degrades in the winter months,
51 indicating that the state of the atmosphere is an
52 important factor (Gronau and Schmidt-Koenig 1970),
53 (Hagstrum et al. 2016)
- 54 • Generation of infrasound by birds (Mack and Jones
55 2003), (Lieser et al. 2006), (Manley et al. 2011).

58 Hypotheses advanced to explain observational results and 59 additional uses of infrasound and audible sound with 60 cautionary remarks

61
62 There have been theories advanced to explain homing
63 failures, possible sources and uses of infrasound, as well as
64 audible sound. In addition, there are increasing concerns about
65 the impacts of civilization sources of low frequency sound.

- 66
- 67 • Possible explanations of homing failures

68
69 A model (e.g. see Hagstrum 2000, 2007, 2013) to explain the
70 frequent homing failures to the Cornell loft area involves the
71 existence of a local, loft centric, sources of sound caused by

74
75
76 coupling of microseism energy interacting with local terrain
77 features into the atmosphere. Poor atmospheric propagation
78 from the loft area to a release site will prevent patterned
79 infrasound signals being used. Microseisms and their
80 counterpart in the atmosphere, microbaroms, are ubiquitous
81 features of the wintertime months and are caused by interacting
82 ocean waves. These seismic and atmospheric waves typically
83 occur in a limited frequency range near 0.2 Hz and do not
84 provide a unique spectral signature, while occurring over an
85 extended region. When the homing experiments by Cornell
86 researchers occurred in the 1970's through early 1980's there
87 were no accompanying infrasound measurements and thus we
88 have no direct knowledge of the local infrasound levels or
89 frequency content at the time of their releases. There are two
90 significant waterfalls in the Cornell loft area (Ithaca Falls and
91 Taughannock Falls), but to my knowledge infrasound levels
92 and frequency content have not been documented.

- 93 • Are wind turbine sites auditory landmarks?
94 Mora et al. (2012) describe an experiment where pigeons
95 were released from a wind turbine site. They considered the
96 possibility that wind turbine noise acted as an auditory
97 landmark. They felt it was unlikely that the pigeons relied
98 solely on auditory clues in comparison with visual clues. Wind
99 turbines should be considered as local sources of sound that
100 should not mask long range infrasound navigation clues, even
101 when night time conditions can enhance wind turbine sound
102 propagation. Wind turbines produce unique spectral signatures
103 with multiple harmonic peaks radiated. Measured values at a
104 range of 1 km are typically less than 0.01 Pa (Keith et al.
105 2018).
- 106 • The use of audible sounds from the surface as
107 navigational clues

108 Griffin (1976) found the sounds of frog breeding choruses are
109 loud enough to be audible to migrating birds up to at least 1 km
110 from their source, both vertically and horizontally, provided
111 that no large obstacles intervene. During May in south-eastern
112 New York State sound pressure levels (A weighting) at
113 altitudes of 200 to 965 m and slant ranges from the frogs of
114 225 to 1020 m varied from 28 to 52 dB SP. On the other hand,
115 D'Arms and Griffin (1972) concluded that the circumstantial
116 evidence for non-visual orientation is sufficient to warrant
117 consideration of alternate sources of directional information for
118 birds navigating on overcast nights. They reviewed balloonist
119 reports of sounds aloft from the surface of the earth. One
120 example was from the observations of Wise (1873). At an
121 altitude of 10,000 feet above Niagara Falls, Wise (1873) makes
122 the following comment. "It is not a roaring, thundering,
123 dashing, tumultuous sound, but a music of sweetest cadence.
124 Like an Aeolian harp it sends up its vibrations". Jones and
125 Bedard (2015) have modeled sound propagation in an
126 atmospheric downdraft/updraft system showing that enhanced
127 propagation can occur from the surface to higher altitudes.

- 128
- 129 • Cold fronts and high winds over mountains
130 Carey and Dawson (1999) considered whether birds could
131 predict the approach of severe winter storms. The possibilities
132 reviewed were barometric pressure changes, wind speed and
133 direction changes, infrasound, clouds, and air ion changes.
134 They postulated that infrasound generated by air flow over
135 mountain ranges (Bedard, 1978) could provide clues
136 concerning approaching weather or the existence of strong
137 winds aloft. Also, they wondered if infrasound produced by
138 changes of state during snow storms could provide predictive
139 information. They concluded that there was not sufficient
140 supporting data to unravel possible predictive capabilities.
141 Infrasound related to high winds over mountains occurs
142 frequently during the winter months. At frequencies < 0.1Hz it
143 can represent a source region originating from extended lengths
144 of mountain ranges. The identification of high wind events
145 could have benefits for avian survival and also be useful for
146 navigation. A north-south source 100's of kilometers in length

1 could indicate the presence of mountainous areas and help
2 define a navigation corridor.

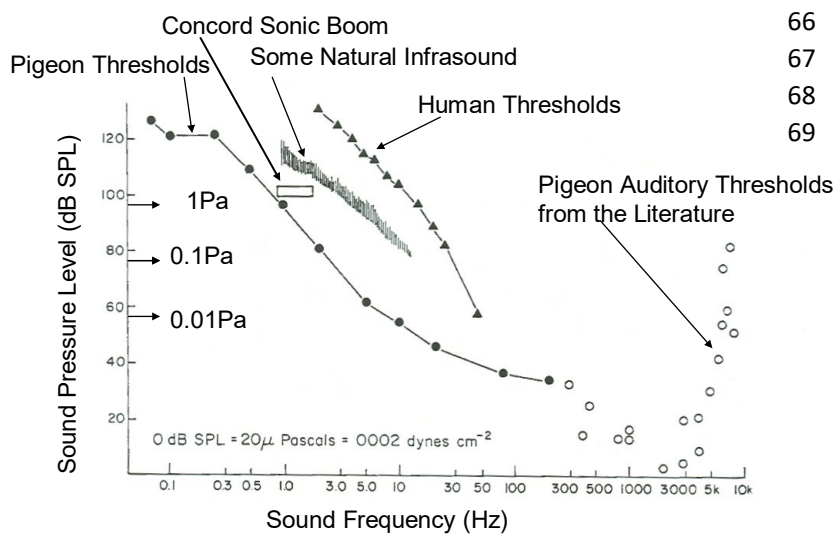

- 3 • Potential of industrial sources masking infrasound
4 valuable for navigation

5 For example, there are a large number of gas compressors
6 operating in North America. Habib et al. (2007) and Ludlow et
7 al. (2015) document the large numbers of gas compressor
8 stations in the boreal forests of Alberta (13,555 as of 2008) and
9 effects upon birds. Ortega (2012) recommended that resulting
10 impacts on birds also be evaluated at low sound frequencies.

11
12

13 **Possible importance of waterfall infrasound for**
14 **homing pigeons**

15 There is a history establishing that pigeons and other creatures
16 are exceptionally sensitive to low frequency sound. Griffin
17 (1969) first suggested the possibility that birds may use
18 infrasound for navigation. Figure 3 indicates that the pigeon
19 thresholds of detectability of low frequency sound can be 40
20 dB below humans.

21
22

23 **Fig.3** Sound pressure level as a function of frequency with key
24 measurements annotated (after Kreithen and Quine 1979)

25 Kreithen and Quine (1979) postulated that this sensitivity may
26 have survival value in terms of navigation. They further
27 postulated that pigeons could detect Doppler shifted
28 frequencies to determine sound source locations (Also Quine
29 and Kreithen 1979, 1981). The horn from an approaching train
30 has a higher frequency, followed by a lower frequency as it
31 recedes. Similarly, birds will detect a higher or lower
32 frequency depending upon whether they are approaching or
33 leaving a stationary sound source. But how pigeons exploit
34 their enhanced infrasonic hearing has remained to large extent
35 a mystery. The previous section reviews efforts to understand
36 how birds use infrasound. These results and the laboratory
37 measurements of Kreithen and Quine (1979) and others
38 indicate that homing pigeons can detect infrasound.

39 To explore the frequency discrimination capability of pigeons
40 to determine the direction from which a sound is originating
41 the following estimate was made. The flight speed necessary
42 to exceed a discrimination threshold of 5% of the frequency is
43 shown in Fig.4. As pointed out by Griffin (1969), the distances
44 between ears is not great enough to use phase shifts at
45 infrasonic frequencies, so that some other explanation is
46 required. The flight speeds of many migrating birds exceed
47 this threshold (e.g. Pennycuik 2001). Pigeon flight speeds
48 measured in wind tunnels exceeded 20 m/s (Tobalske and Dial
49 1996) in agreement with pigeon race flight speeds and there are
50 numerous reports of flight speeds greater than this (up to 50
51 m/s). Once a waterfall has been identified as the target source,
52 a flight azimuth will either deviate to higher or lower
53 frequencies with any deviations from the target direction.
54 Birds will surely depend upon each other for guidance.

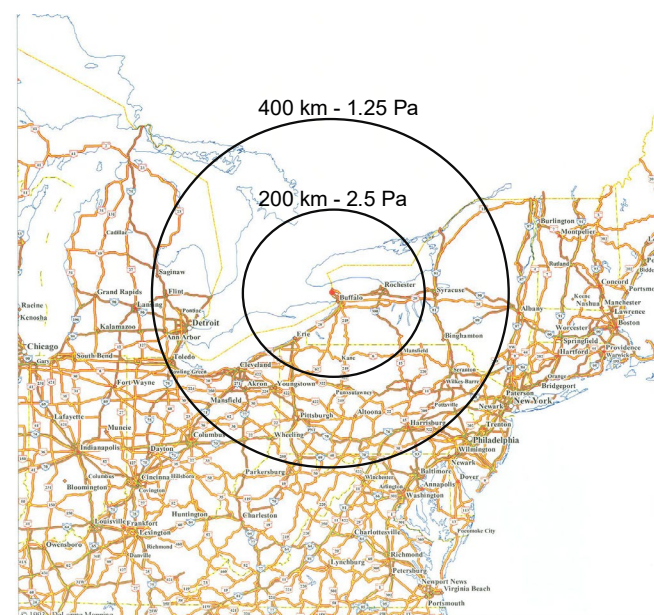

55

56
57

58 **Fig.4** Percentage shift in frequency as a function of flight
59 speed. The fact that major waterfalls can have distinct
60 dominant frequencies could optimize navigation by Doppler
61 shifts permitting triangulation, localizing multiple falls (Color
62 online)

63 Continuous, concentrated, robust natural sources of low
64 frequency are possible “beacons” that could be exploited by
65 navigating birds in “VFR” (visual flight rule) conditions as
66 well as “IFR” (instrument flight rule) conditions. This follows
67 on a recent paper by Hagstrum (2013) that provides evidence
68 that homing capabilities are dependent upon atmospheric wind
69 and temperature structure.

70
71

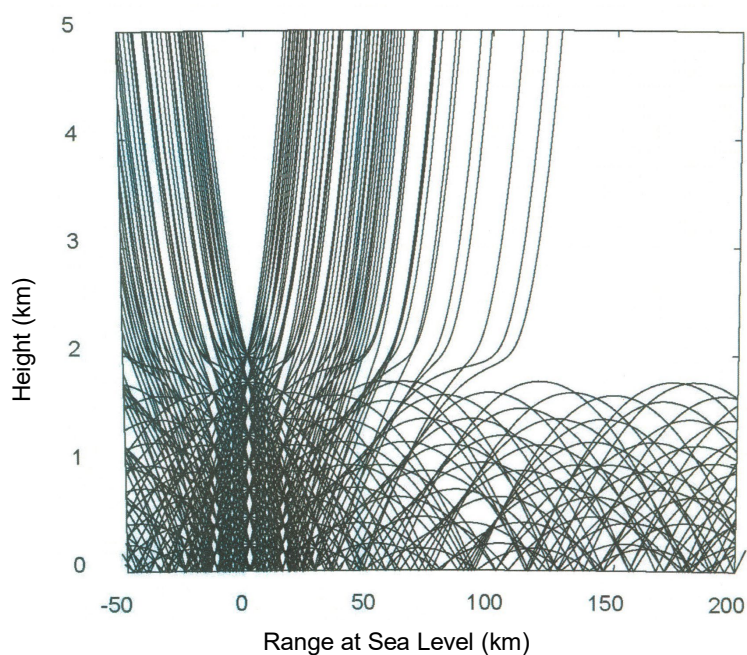

72 **Fig.5** Range rings at 200 and 400 km centered on Niagara
73 Falls with the pressure levels extrapolated assuming an inverse
74 range decrease in amplitude. The levels corrected
75 for the response of the microphone at 10 Hz are indicated in
76 parenthesis. (Color online)

77 The pressure levels shown in Fig.5 are higher than the
78 minimum threshold capability measured for pigeons. 1.25 Pa
79 at 400 Km is almost 2 orders of magnitude larger than the
80 hearing threshold of pigeons shown in Fig.3. Infrasound
81 documented at ranges up to and in excess of 1000 km from the
82 source is influenced by geometric spreading causing the
83 pressure levels to decrease inversely as a function of range.
84 Even smaller reductions can occur because of atmospheric
85 wave guides (Bedard 2005). Attenuation because of absorption
86 is of much less importance at infrasonic frequencies.

87 However, there is a “zone of silence” from about 20 to 200
88 kilometers for a standard atmosphere. The temperature
89 decreasing with height causes sound to be refracted upward.
90 This effect can be mitigated by nocturnal inversions which
91 permit robust propagation out to 200 kilometers. Figure 6 after
92 Jones et al. (2004) shows how a low-level inversion can
93 prevent a zone of silence from forming at low altitudes.
94 Conversely, such an inversion layer can prevent sounds from
95 the surface from being detected at altitudes above the inversion
96 layer. The pressure amplitudes of infrasound, although not

1 significantly absorbed by the atmosphere, are affected by
 2 temperature structure and winds. The temperature (e.g. Fig.6)
 3 and wind structure (e.g. Bedard and Georges 2000) can either
 4 enhance or suppress detected sound pressure levels.

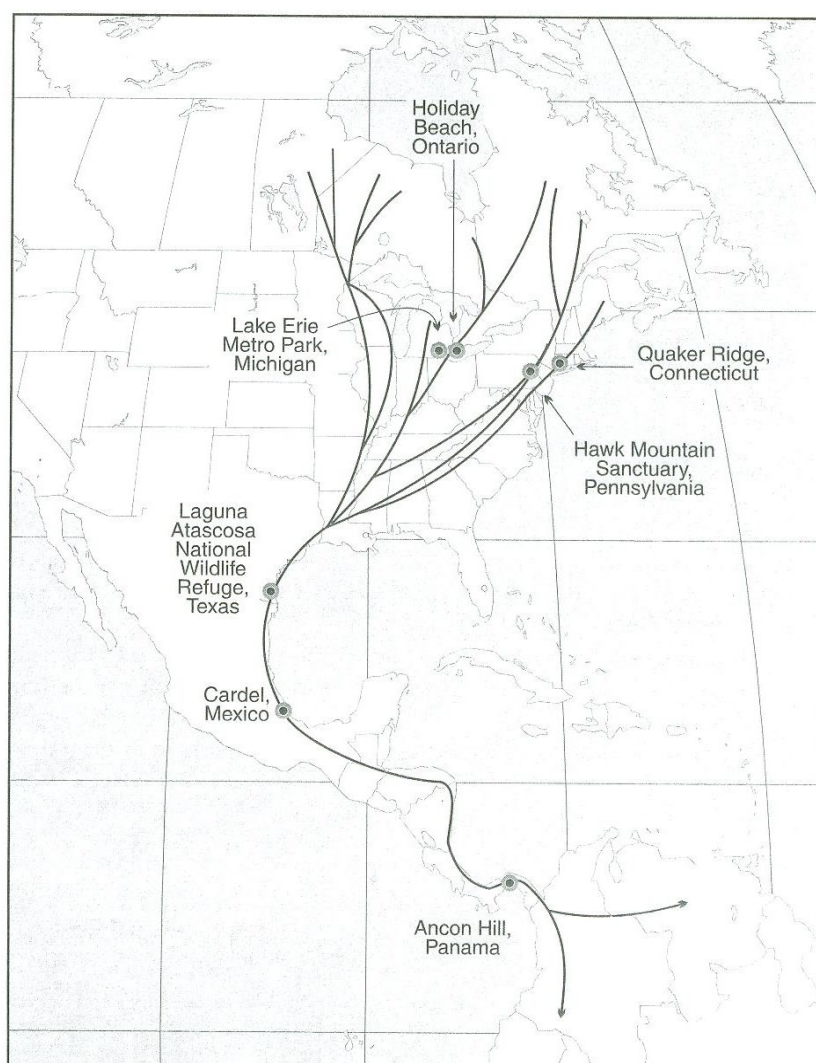

5

6

7

8 **Fig.6** Ray trace simulation showing the propagation from a
 9 vertically extended source region as a function of range in the
 10 presence of an inversion at 2 kilometers in altitude with an
 11 isothermal region below (After Jones et al., 2004)

12

13 **Fig.7** The southbound migration route of broad winged
 14 hawks in eastern North America (after Bildstein 1999 his
 15 figure 6.1)

16 Bildstein (1999) shows a map with the fall southbound
 17 migration routes in Eastern North America of the broad wing
 18 hawk. It shows a convergence from an area including the great
 19 lakes. This region is within the infrasound detectability range
 20 to Niagara Falls.

21

22

23 In addition to the work of Bildstein (1999) shown in Fig.7, La
 24 Sotta et al. (2016) show examples of flyways within the eastern
 25 portion of North America. They estimate the migration
 26 trajectories in the Western Hemisphere for 119 long-distance
 27 migration bird species. Guillaumet et al. (2011) show the
 28 migration tracks of 119 cormorants equipped with satellite
 29 tracking devices. Most of these nested in the area of the great
 30 lakes. Many of the tracks converge in a region east of Lake
 31 Ontario.

32 **Comments concerning shore line flyways**

33 The sub-routes in Fig.7 show some signs of convergence in
 34 the region of Niagara Falls. The route following the coastline
 35 will provide reference sound from wave breaking action at
 36 shore lines. Even the audio components of wave breaking
 37 could easily be detected at altitudes of several kilometers and
 38 provide a reference in the presence of low-level clouds or fog.
 39 There are a number of potential sources of sound involved with
 40 waves impacting a beach:

- 41 • Audible sounds involved with the wave creation of bubble
 42 plumes (e.g. Bolin, K. and M. Abom 2010) They found
 43 that wave heights below 1.5 meters have a peak
 44 frequency at 1 KHz and higher wave heights have
 45 spectra dominated by frequencies below 1 KHz. The
 46 sound pressure levels at a range of 250 meters were
 47 about 50 dB.
- 48 • Infrasound in the 1-7 Hz range generated by wave
 49 breaking processes (LePichon et al. 2004, Garces et al.
 50 2003). Infrasonic surf noise can occur in the 1 to 7 Hz
 51 frequency range with the level proportional to wave
 52 height.
- 53 • Infrasound at the ocean wave frequency associated with
 54 waves abruptly stopping at a beach (Cook (1963 1969).
 55 Evidence for the existence of such waves is provided by
 56 Barruol et al. (2006). They found a relationship between
 57 infrasonic amplitude and swell height. Also, observed
 58 single frequency (near 0.1 Hz) as well as double
 59 frequency peaks (conventional microbaroms near 0.2
 60 Hz).

61

62 Shorebird species use a window for sound transmission and
 63 reception (Douglas and Conner (1999)). A comparative study
 64 of the eastern and western willet showed that the eastern willet
 65 has songs of shorter duration and higher frequency than the
 66 western willet. This permits more information to be transferred
 67 during the periods between bursts of surf noise. They showed
 68 an example of a call of a migratory shore bird near 3 kHz
 69 occurring in the 3 second interval between bursts of surf noise
 70 (< 1kHz to 7 kHz). Katayama (2003) measured surf noise with
 71 most acoustic energy occurring between 250Hz and 4 kHz.
 72 Shorebirds are quite sensitive to surf noise, which they could
 73 also detect at typical migration altitudes. Infrasonic surf
 74 components could also be present (especially in the 1 to 5 Hz
 75 range) as indicated by Garces et al. (2003), and LePichon et al.
 76 (2004).

77

78 **Concluding remarks**

79 This section indicates observational efforts valuable for
 80 defining infrasonic and low frequency sound environments.
 81 Also, outlining possibilities for avian uses of infrasound for
 82 navigation and hazard avoidance.

83 Figure 7 in Appendix 1 summarizes significant waterfalls in
 84 the United States producing significant earth vibrations and by
 85 inference infrasound. These are an important set of waterfalls
 86 that will be worth documenting in terms of the sound pressure
 87 levels and frequencies measured as a function of the waterfall
 88 parameters (waterfall type, height, and volume flux).
 89 Observations to date suggest that the waterfall type may be a
 90 critical factor in determining acoustic efficiencies, with the
 91 cascading and tiered waterfalls being less efficient than the

1 block or plunging types. Although the volume flux is an
2 important factor, the efficiencies of the sound generation
3 mechanisms involved may dominate the sound pressure levels
4 emitted.

5 In addition to making observations of environmentally
6 important waterfall related infrasound, there should also be
7 parallel observations of low frequency sound from industrial
8 processes detectable at long ranges. Since there is no Federal
9 Communications Commission equivalent monitoring acoustic
10 energy or assigning bands at low acoustic frequencies, there
11 could be a potential that future, episodic industrial or other
12 processes could produce sound masking important geophysical
13 sources. The addition of a dam at a critical river point
14 involving a natural waterfall could possibly have impacts on
15 avian navigation guidance.

16 Conversely, robust, continuous civilization sound sources
17 could possibly be exploited for avian navigation or perhaps by
18 other creatures as well. A possible example of this is the
19 infrasound radiated by a bridge as vehicles pass over (Donn et
20 al. 1974). Could birds be “encouraged” to not populate aviation
21 flight routes? There is an important need to define the
22 characteristics and roles of acoustic sources potentially used in
23 avian navigation.

24 Possibilities for hazard avoidance

25 Streby et al. (2015) presented the first documentation of
26 obligate long-distance migrant birds undertaking a facultative
27 migration, wherein breeding golden-winged warblers
28 (*Vermivora chrysoptera*) carrying light-level geolocators
29 performed a >1,500 km 5-day circumvention of a severe
30 tornadic storm. The birds evacuated their breeding territories
31 >24 hr before the arrival of the storm and atmospheric hazards
32 associated with it. The probable cue, they postulated was
33 infrasound radiating >1,000 km from tornadic storms perceived
34 by birds and influencing bird behavior and movements.

35 Wiedenfeld and Wiedenfeld (1995) describe a tornadic storm
36 that killed an estimated 40,000 birds of 45 species in Grand
37 Island Louisiana in April 1993. A key factor was that the
38 storm arrived at the time when large numbers of birds were
39 arriving after migrating all night across the Gulf. McClure
40 (1945) describes an impact of a tornado that hit Portsmouth,
41 Iowa at 3 AM on 9 July 1940 with about 1000 birds killed.
42 From the damage description (no one was killed and homes
43 were damaged but not destroyed) the tornado was apparently
44 short-lived and did not affect nearby towns.

45 The observations of Streby et al. (2015) suggest that birds
46 need to have recovered from migration and encounter longer-
47 lived tornadic systems to make optimum use of infrasound
48 weather warning clues. Bedard et al. (2004) have detected
49 infrasound at long range from tornadic storms. Some of these
50 storms radiated infrasound continuously for long periods, while
51 cyclically producing tornadoes. It may be possible to use
52 archived infrasound measurements for comparisons with
53 homing or migration anomalies.

54 Measurements made using co-located seismic and infrasound
55 sensors 38 meters from the channel in the Grand Canyon
56 identified three distinct seismic sources. An infrasonic sensor
57 measured a 6.25 Hz peak corresponding to one of the seismic
58 peaks (Schmandt et al (2013). The peak discharge for the
59 controlled flood was 1300 m³/s. They interpret the 6.25 Hz
60 peak as related to fluid/air interactions involving breaking
61 waves. The infrasound increased to 18dB above the
62 background level. The sound level estimated at 500 meters
63 based upon the measurements at 38 meters was 0.6 microbars,
64 less by a factor of 10 than the levels for waterfalls summarized
65 in Figure 11 of this paper. Nevertheless, birds could detect
66 nearby rivers or follow the course using radiated infrasound.

67

68 In summary, there is a range of potential avian uses of
69 infrasound for navigation as well as hazard awareness and
70 avoidance.

71 These include:

- 72 • Triangulation on fixed sound sources for navigation
73 (Major waterfalls are a continuous source of high-level
74 infrasound.)
- 75 • Following coast lines in the presence of obscuring
76 cloud cover
- 77 • Detecting and following rapidly flowing streams and
78 rivers (Schmandt et al. 2013)
- 79 • Tornado avoidance (Streby et al. 2015), (Bedard et al.
80 2004)
- 81 • Cyclone avoidance behavior by foraging seabirds
82 (Weimerskirch et al. 2019), (Thielbot et al. 2020)
- 83 • Turbulence and high wind avoidance (Bedard 1978),
84 (Schermuly and Klinke, 1990)
- 85 • Warnings of regional fires (Jones et al. 2004), (Bedard
86 and Nishiyama 2002)

88 Atmospheric turbulence has significant effects on bird flight
89 (Nisbet, 1955). The burden produced when maximum flight
90 speed falls below the level of turbulent velocity fluctuations
91 means birds will not be able to fly safely in winds. "In high
92 winds birds are often reluctant to fly at all". Measurements of
93 infrasound from turbulence, regions of high wind, and fires
94 produce sound pressure levels greater than the pigeon
95 thresholds shown in Fig.3. It will remain a challenge to
96 understand the extent to which these potential uses of
97 infrasound are actually applied in nature.

98

99

100 Acknowledgements

101 The measurements in the vicinity of Niagara Falls presented
102 here were enabled by Dr. and Mrs. Peter F. Regan the 3rd. The
103 application of this work to avian migration was inspired by a
104 series of papers by J. T. Hagstrum.

105

106 Appendix 1: A summary of past observations of 107 waterfalls, weirs, and dams

108 This summary provides information on sounds from falling
109 water, distinguishing between systems of large horizontal
110 extent and those for which the heights are greater than the
111 widths. This summary provided valuable insights helping to
112 interpret measurements made in the vicinity of Niagara Falls.
113 Whereas a horizontal organ pipe model explains sounds
114 radiated by dams and weirs, this model does not apply to major
115 waterfalls.

116 A compilation of the works of John Muir by Diadem Books
117 (1992) provides an important resource of observations from
118 this early conservationist, who died in 1914. He wrote vividly
119 of the Yosemite waterfall in California. “At the top of the fall
120 they seem to burst forth in irregular spurts from some grand,
121 throbbing mountain heart”. “This noble fall has far the richest,
122 as well as the most powerful voice of all the falls of the
123 valley”. “The low bass, booming, reverberating tones heard,
124 under favorable conditions, five to six miles away”. His
125 complete descriptions suggest the possibility of a variety of
126 sound source mechanisms.

127 Heim (1874) documented tones associated with a series of
128 waterfalls, as noted by Charlie (1998). Trained musicians were
129 able to identify tonal acoustic energy and made estimates of the
130 musical notes corresponding to the tones. Perforce, the tones
131 detected were in the audible and could have been harmonics of
132 lower frequency energy. They noted the following
133 observations:

- 1 • There was a striking similarity of tonal structure for a
- 2 variety of waterfalls
- 3 • The more the fall of the water mass the stronger the tone
- 4 • The lower frequencies were heard behind various barriers
- 5 and at longer ranges than the higher frequency tones.
- 6 • Tones were purist and clearest when the free water
- 7 crashes into a pool below
- 8 • No tones were heard when there was only rushing stream
- 9 of water
- 10 • They documented the tones detected for 14 waterfalls.
- 11 Some waterfalls had lower frequency components (e.g.
- 12 2-87 Hz), while others showed mostly higher
- 13 frequencies (>3-174 Hz).
- 14

15 Unfortunately there is not enough information to relate the
 16 details of these waterfalls (e.g. height, volume flow) to the
 17 frequencies documented. Nonetheless, the work documented
 18 was a pioneering effort in the area of waterfall acoustics.

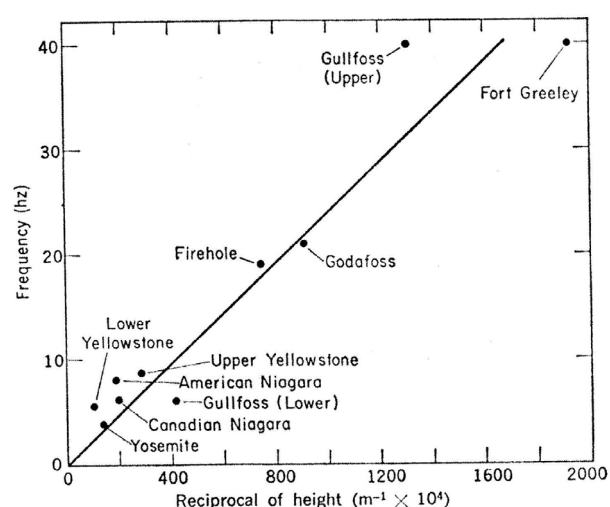

19 Many persons with high musical dictation, score very well on
 20 tests for absolute pitch (Dooley and Deutsch 2010 their Figure
 21 2). Bachem (1955) observed professional violinists obtaining
 22 accuracies to 1/16 of a semi-tone. Leite et al. (2016) found a
 23 high correlation between advanced musical skill and absolute
 24 pitch for Brazilian musicians.

25 The observations of waterfall sound frequencies (Heim 1874)
 26 represent the consensus of a number of trained musicians. The
 27 studies of individuals with absolute pitch indicate that the
 28 waterfall musician observations should be considered accurate,
 29 in spite of the lack of electronic spectrum analyses in the
 30 1800s.

31

32 A summary of ground vibrations from waterfalls 33 and their possible interpretation

34 Reinhart (1969a) used geophones to measure earth vibrations
 35 from a number of waterfalls. Figure 8 is from his paper
 36 showing that the dominant frequency measured is inversely
 37 proportional to the height of the waterfall.

38

39 **Fig.8** Predominant vibrational frequency as a function of the
 40 reciprocal of waterfall height (after Reinhart, 1969a)

41
 42

43 **Fig.9** Plot of the dominant frequency data of Reinhart (1969a)
 44 as a function of waterfall height The line superimposed on the
 45 figure was determined assuming the frequency was equal to the
 46 speed of sound in air divided by the waterfall height (Color
 47 online)

48
 49 The fairly good agreement shown in Fig. 9 suggests that the
 50 time it takes a sound wave to propagate from the waterfall base
 51 to the top controls the frequency, indicating that an acoustical
 52 feedback mechanism is present. An energetic sound wave
 53 emitted from the impact of water at the base could propagate in
 54 air to the top and modulate the water discharge. This also
 55 implies that atmospheric sound measured in the vicinity of
 56 waterfalls will tend to follow the earth vibrations measured by
 57 Reinhart.

58

59 Weir/Dam acoustics

60

61 A weir is an overflow type of dam commonly used to raise the
 62 level of a river or stream. A nappe is a sheet of water flowing
 63 over a weir. Weirs have a history of being sources of annoying
 64 vibrations and evidence of this is often visible in the nappes.
 65 Loomis (1843) summarized observations of 6 sets of dams, all
 66 associated with the generation of vibrations and annoying
 67 effects such as vibrating windows and doors. The dams
 68 involved similar effects:

- 69 • The vibrations occurred for a restricted range of water
- 70 heights above the dam
- 71 • Gentle breezes can enhance the vibrations, while strong
- 72 winds destroy the vibrations
- 73 • Obstacles at the top of the dam impede the effect
- 74 • The effect is great when the water falls in an unbroken
- 75 sheet
- 76 • Window vibrations have been induced at ranges of 2.5
- 77 miles from a dam.

78 There were 3 cases where estimates were made of the
 79 vibration frequency. A Cuyahoga Falls, Ohio dam was 27.4
 80 feet long, producing frequencies between 12 and 15 Hz. An
 81 East Windsor, Conn dam was a 100 foot long, straight dam
 82 with an estimated frequency of 5 Hz. A dam at Springfield,
 83 MA was a 450 foot, straight dam with an estimated frequency
 84 of 1 Hz. These dams produced frequencies consistent with an
 85 organ pipe mechanism, open at both ends.

86 Loomis suggested alternate methods for estimating the
 87 frequencies observed. For frequencies below about 4-5 Hz he
 88 recommended counting the number of beats over a fixed time.
 89 For higher frequencies he suggested creating a reference with a
 90 calculable frequency (e.g. Use a string of variable length with a
 91 weight and match observed frequency vibrations). documented

92

93 Sound and earth vibration from a Ringwood, New Jersey dam
 94 was documented by Blade and Blade (1969). The dam was
 95 about 20 meters long, 5 meters high and produced a strong

1 frequency at flood time at about 10 Hz, in disagreement with
 2 the observations of Rinehart (1969a). Rinehart (1969b)
 3 suggested that, in this case, the frequency may be controlled by
 4 the dam length rather than the height from which the water
 5 falls.

6 Some weirs and dams can produce a horizontal, hollow
 7 column of air that, as will be shown, functions as a horizontal
 8 organ pipe. In this set of water features, the heights of water
 9 column fall distances are less than the lengths (widths). For
 10 some dams the flow release can be a spillway, underwater or
 11 above water jets with no resonant column involved. The
 12 purpose of studying infrasound observations from weirs and
 13 dams is to provide a context and help understand sound
 14 generation by natural waterfalls.

15

16 Table 2 summarizes well documented measurements from
 17 dams and weirs. These data provide valuable insight into a
 18 hydrodynamic process producing significant infrasound. These
 19 data are plotted in Fig.10, indicating that a model of an organ
 20 pipe open at both ends fits the observations.

14

Fig.10 Dominant observed frequencies for weirs as a function of weir length. These data are compared with calculations of the fundamental frequencies of organ pipes as a function of length (Color online)

15 However, in addition to the evidence for a horizontal organ
16 pipe mechanism shown in Fig.10, there could be more than one
17 sound generation process possible. For example, Casperson
18 (1993, 1993, 1994) developed a model involving small
19 displacements of the water sheet being amplified by a
20 Helmholtz mechanism as the sheet moves downward. The
21 large amplitude motions at the base in turn compress the air
22 trapped behind the nappe and affect the water surface at the
23 top. The combination of amplification and feedback can lead
24 to the formation of sustained oscillations. Liszka (1974)
25 identified hydroelectric power plants as a source of infrasound
26 theorizing that the sound was radiated by oscillating masses of
27 water.

29 Appendix 2: Relationships between waterfall 30 hydrodynamic and acoustic powers

31 The goal of this section is to relate the waterfall
32 hydrodynamics to the sounds emitted. Even if the absolute
33 magnitudes of relationships are not obtained, it will be valuable
34 to identify important relationships.

35 The pressure, dP , produced by the impact of the flux of water
36 is:

$$dP = \frac{1}{2} \rho_w U^2$$

(1)

37 where U is the flow speed and, ρ_w , is the water density.

38 The work, W , performed in moving a distance dx is:

39 Where V is the volume and A is the area

40

$$W = Fdx = dpAdx = \frac{1}{2} \rho_w U^2 dx A$$

$$= \frac{1}{2} \rho_w U^2 V$$

46

47

(2)

48

49 The hydrodynamic power is:

50

$$P_h = W / t = dpAdx / t = \frac{1}{2} \rho_w U^2 \frac{dx}{t} A$$

$$= \frac{1}{2} \rho_w U^3 A = \frac{1}{2} \rho_w U^2 Q$$

51

52

(3)

53

54 where Q is the volume flux.

55

56 The acoustic power P_{ac} is:

57

58

$$P_{ac} = 4\pi R^2 dp^2 / \rho_a c$$

59

(4)

60

61 Where R is the distance from the source, dp is the sound
62 pressure level, ρ_a is the density of air, and c is the speed of
63 sound in air.

64

65 The efficiency of the production of acoustic power from
66 hydrodynamic power, ε , is the ratio of the expressions

67

68

69

$$\varepsilon = \frac{P_{ca}}{P_h} = \frac{8\pi R^2 dp^2}{\rho_w \rho_a c U^2 Q}$$

70

71

72

(5)

73

74

75 Now an expression may be found for the sound pressure level
76 dp

77

$$dp = \left[\frac{\varepsilon \rho_w \rho_a c w h}{8\pi} \right]^{1/2} \frac{U^{3/2}}{R} = \left[\frac{\varepsilon \rho_w \rho_a c Q}{8\pi} \right]^{1/2} \frac{U}{R},$$

78

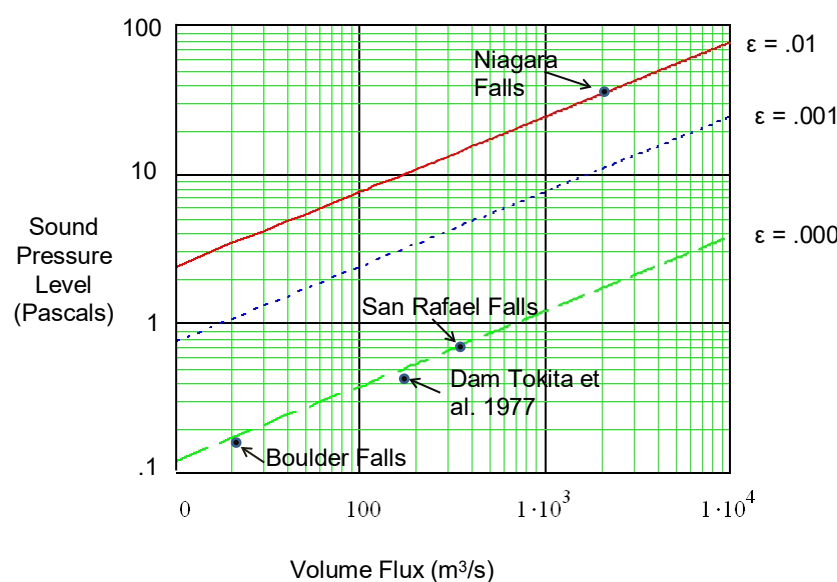

79

(6)

80 where w and h are the width and the depth of the water
81 respectively, ε is the ratio of acoustic to hydrodynamic power,

10

1 ρ_a and ρ_w are the air and water densities, c is the speed of sound
 2 in air, U is the stream flow speed, R is the source-receiver
 3 distance, and Q is the volume flux. This relationship provides
 4 guidance for organizing data sets that include information on
 5 waterfall sound pressure level and flow volume flux as
 6 presented in Fig.11.

7
 8
 9

10 **Fig.11** Plot of the sound pressure level as a function of volume
 11 flux for efficiencies of 0.01, .001, and .000025 All data were
 12 adjusted to a range of 500 meters (Color online)

13

14 Figure 11 indicates that there are great differences in the
 15 efficiencies of waterfall sound generation processes with $\epsilon =$
 16 .01 for Niagara Falls compared with $\epsilon = .000025$ for Boulder
 17 Falls, San Rafael Falls (Johnson et al. 2006), and a spill way
 18 dam. Niagara Falls is more efficient by a factor of 400 or
 19 almost 3 orders of magnitude, suggesting great differences in
 20 the sound generation processes. For example, Boulder Falls is
 21 a cascade type of waterfall with no clear resonances involved
 22 and an ensemble of incoherent sound sources including flow
 23 interactions with obstacles as well as eddy structures and
 24 bubble plumes, all at relatively small scales. The San Rafael
 25 Falls is a tiered type of falls. A video of this waterfall shows
 26 the lowest level to be highly turbulent before striking the pool
 27 of water at the base. The dam details described by (Tokita et
 28 al. 1977) indicated two sound generation processes. One of
 29 these was highly turbulent like a cascade falls. It is not
 30 surprising that these latter sources are relatively inefficient.
 31 More detail from the research of Tokita et al. (1977) is shown
 32 in Fig.12.

33
 34

35 **Fig.12** Data points obtained at a distance of 500 meters from a
 36 dam (Tokita et al. 1977) and levels predicted for an efficiency
 37 of 0.000025 (Color online)

38 A best fit to their observations (Figure 12) is $dp = 0.025 Q^{.56}$.
 39 These data of Tokita et al. (1977) indicate good agreement with
 40 the predicted $Q^{.5}$ relationship. However, their measurements
 41 also indicated that at higher discharge rates (above 200 meters
 42 cubed per second), the sound levels flattened off and slightly
 43 decreased. This suggests a reduced acoustic efficiency,
 44 possibly as a result of an increase in flow turbulence.

45 Major waterfalls with high volume rates may enhance the
 46 efficiencies of sound generation processes. Measuring acoustic
 47 energy near Niagara Falls involves a complex sound generation
 48 environment with both the American and Canadian Falls
 49 nearby. There has been historical documentation of unusual
 50 physical effects involving Niagara Falls. For example, Barlow
 51 (1877) describes jets of water which were projected vertically
 52 from the base of the falls. These frequently rose from 10 to 30
 53 feet above the top of the falls. These jets were apparently
 54 related to observations of doors and windows being vibrated
 55 one quarter to one half of a mile away.

56 Doi and Kaku (2004) exposed windows to a variety of
 57 infrasonic waveforms. They found that the window response
 58 was a complex function of the details of the infrasonic signals
 59 used. For hinged windows exposed to a triangle wave the
 60 threshold of rattling was between -18 Pa and 92 Pa.

61 Naka et al. (2008) experimentally studied the response of
 62 windows to sonic booms. They found that typical sonic boom
 63 N-waves with durations of 100 and 200 milliseconds and
 64 pressure amplitudes of 1 PSF (47.9 Pa) and 2 PSF (95.7 Pa)
 65 can induce significant window vibrations. These pressure
 66 levels are in the range of the >100 Pa measured at a range of
 67 about .5 km from Niagara Falls.

68 In comparison to waterfalls having orders of magnitude
 69 smaller volume flow rates and complex descents to the base of
 70 the falls (e.g. involving a more gently sloping fall interacting
 71 strongly with terrain), it is probable that greatly differing
 72 acoustic efficiencies and sound generation processes may
 73 occur. Ostrovsky and Bedard (2002) estimated the sound
 74 pressure levels produced by large objects falling into water and
 75 estimated the sound production efficiencies involved. This
 76 work was focused on estimating the possibility of infrasonic
 77 detection of ice calving. They estimated a wide range of
 78 efficiencies depending upon the source type and object size.
 79 Using an efficiency of 8×10^{-4} corresponding to a monopole
 80 source they estimated a sound pressure level of 5 Pa at a range
 81 of 1 km from a 100 meter radius object. Richardson et al.
 82 (2010) documented an infrasonic signal of 2 Pa associated with
 83 ice calving at a range of about 3 km. The details of the sound
 84 production process for this case were not observed.

85 Bubble plumes as sound sources

86 Kolaini et al. (1993, 1994) described a series of experiments
 87 where various heights of water in cylindrical containers were
 88 released to impact liquid surfaces. Hahn et al. (2003) and
 89 Carey et al. (1993) also studied the sounds produced by falling
 90 jets of water. Kolaini et al. found a correlation between the
 91 total low frequency acoustic energy radiated under water from
 92 the resulting bubble plume and the potential energy of the
 93 water jets. The plumes generated were bubble clouds that
 94 oscillated collectively. They found the radiation efficiency (a
 95 ratio of total radiated acoustic energy to the initial potential
 96 energy) was within the range of 10^{-6} to 10^{-7} . They noted a
 97 sharp increase in efficiency at higher potential energies,
 98 possibly resulting from an increased production of bubbles. In
 99 addition, the laboratory measurements of Kolaini et al. (1994)
 100 examined the acoustic energy as a function of potential energy
 101 of the impacting fluid elements (Their Fig.9). They observed a
 102 discrete change in acoustic efficiency as the potential energy
 103 increased above a threshold point, the acoustic energy
 104 increased an order of magnitude for an increase of 2 in

1 potential energy. Prior to this threshold being crossed there
2 was a linear relationship and quite low efficiencies.

3 Kolaini et al. (1993, 1994) also studied the dominant
4 frequencies produced by the resulting bubble plumes. They
5 obtained an expression for the frequency as a function of plume
6 radius, which agreed well with experimental data at low
7 frequencies. The frequency depended on the plume radius a ,
8 ambient pressure P_0 , the water density ρ_w , and the void
9 fraction β . The expression they found was

$$F = \frac{\left(\frac{3P_0}{\rho_w \beta}\right)^{.5}}{2\pi a} \quad (6)$$

12 This expression predicts frequencies between 10 and 20 Hz
13 corresponding to bubble plume radii between 40 and 20
14 centimeters. This estimate was made for a void fraction, β of
15 about 50%. A model used by Chanson (2016) to explain the
16 dominant acoustic frequency range generated by a tidal bore
17 (57 to 131 Hz) is the collective oscillations of bubble clouds.

18 Unlike organ pipes with solid walls, a waterfall can produce a
19 vertical cavity with one side the rock face of the falls and the
20 other the surface of the falling water. A key question is
21 whether this closed tube resonance can modulate the falling
22 water sheet and produce pulses of fluid producing sound from
23 resonating bubble clouds when impacting the base of the falls
24 and/or act to increase the sound pressure level through
25 resonance.

26 The left panel of Fig.13 shows times series of pressure from
27 the laboratory measurements of Kolanai et al. (1994) their
28 Fig.7. The upper plot (a) shows the pressure levels for a fairly
29 continuous stream of 3.66 liters impacting the water. The lower
30 plot (b) is for an impulsive impact of a volume of 3.66 liters of
31 water. Note that the impulsive impact produced about an order
32 of magnitude greater sound pressure level than the more
33 continuous stream. The form of the time series was in this case
34 a number of sinusoidal waves at a constant frequency followed
35 by a decay to the background level. Other runs could best be
36 described as damped sine waves. The right hand panel of
37 Fig.13 shows a view of a segment of the Niagara Falls sound
38 measurements shown in Fig.1. This is for a 1 second interval
39 focused on one of a series of impulses that occurred throughout
40 the complete interval shown in Fig.1. The expanded time
41 series shows a series of about 4 waves at about 10 Hz before
42 being lost in the background of other sounds related to the falls.
43 This time series expansion is typical of other impulses
44 examined for the complete 1 minute time period (Figure 1) as
45 well as other intervals recorded.

After Kolanai et al.(1994) their Figure 7 showing sound from release of 3.66 liters of water (a) as a continuous flow (b) as an impulsive release

Expansion of a segment of the 60 second time series of sound waves measured in the vicinity of Niagara Falls (Figure 1) from 45 to 46 seconds

46
47

48 **Fig.13** Comparison of the sound generated by the laboratory
49 experiments of Kolanai et al. (1994) and an expanded view of

50 one of the impulses of infrasound measured from Niagara Falls
51 shown in Fig.1 (color online)

52

53 Niagara Falls height ranges from 21 to 34 meters (70 to 110
54 feet) from the top of the falls to the top of the rock pile at the
55 base. Photographs of the base of the falls show large rocks
56 inter-dispersed with pools of water. For these waterfall
57 conditions a vertically oriented organ pipe model with both
58 ends closed is considered to estimate the dominant frequencies
59 radiated. The fundamental frequency for these conditions
60 ranges from 8.1 to 5 Hz. The 1st harmonic ranges from 16.2 to
61 10 Hz. The 1st harmonic pressure field is depicted in the
62 schematic view shown in Fig.14. As shown in the schematic
63 (Fig.14) there will be antinodes created at the top and bottom
64 of the column with strong pressure gradients along the height.

65 Estimating the sound pressure level dp at the base of the
66 impacting sheet of water to be 1000 Pa, we can calculate the
67 particle velocities induced by the sound wave. For a particle
68 velocity v , and air density ρ , and sound speed in air c , $v =$
69 $dp/\rho c$ or 2.5 m/sec. Such particle velocities can produce
70 significant effects on a falling water sheet. This pressure level
71 is equivalent to a head of water of about 10 centimeters.

72 The vertical fall speed of the water at Niagara Falls (estimated
73 at 9 m/s) will mean that a fluid parcel will take about 5 seconds
74 to fall from the top to the base of the falls. The time scale is
75 much larger than the ~ 0.1 second involved with the observed
76 sound frequency time scale.

77

78

79 A conceptual view of a process causing waterfall infrasound
80 is shown in the Fig.14.

81
82

83 **Fig.14** A conceptual view of a process causing waterfall
84 infrasound. The water striking the surface creates a bubble
85 plume generating an intense sound wave The sound wave
86 propagates to the top of the waterfall modulating the water
87 flow release A pressure change of 1000 Pa is equivalent to
88 several inches of water column height (color online)

89 In summary, this model involves the impact of a surge of water
90 on the pool at the base of a water fall creating a bubble plume
91 and the resulting sound wave propagates to the crest of the fall,
92 behind the falling curtain of water. The column of air trapped
93 is resonant for select frequencies, acting as a vertical organ
94 pipe closed at both ends. The powerful sound waves can
95 disturb the curtain of water causing surges of flow, which in
96 turn can create impulses of sound when the disturbances reach
97 the pool at the base of the fall. Figure 1 shows periodic bursts
98 of infrasound observed at Niagara Falls. It will be valuable to
99 model this process in the laboratory. For example, Schwartz

1 (1965) shows a photograph of a laboratory nappe oscillation
 2 which may result from a process similar to that described
 3 above. Figure 1 after Schwartz (1965) is reproduced here as
 4 Fig.15.

5
 6
 7 **Fig.15** Oscillating nappe in a 6-foot wide laboratory flume with
 8 a transparent side panel. There are 1-inch squares on the side
 9 wall (after Schwartz 1965 his Fig.1)

10

11 Because of the effects of turbulent flows and complex
 12 geometries, there will probably be a range of sound frequencies
 13 generated.

14 There is also the possibility of using waterfall infrasound
 15 sources as a resource for documenting sound propagation under
 16 differing environmental conditions, and comparing
 17 observations with ray trace and other model predictions.

18 Waterfalls also provide opportunities for direct study of
 19 hydroacoustic processes or to test the process of waterfall
 20 sound generation outlined in this paper. It will be valuable to
 21 make simultaneous measurements at the base and top of a
 22 waterfall and compare signal phase and spectra. For a smaller
 23 waterfall it may be possible to modify the flow impact details
 24 to change the dynamics of underwater bubble plumes.

25 This analytical appendix should help with the interpretation of
 26 results presented in earlier sections.
