

Empirical Insights Into the Fate of Ammonia in Western U.S. Wildfire Smoke Plumes

Special Section:

Fire in the Earth System

Key Points:

- We estimate e-folding loss timescales for ammonia in eight western U.S. smoke plumes from 24 to 4000 min old (median = 55 min)
- Ammonium nitrate formation is favorable in fresh, dense plumes injected higher into the troposphere, nitric acid is normally limiting
- Observed ammonium and nitrate fractions increase with lower temperatures in medium (1–3 days) and old (>3 days) chemical aged smoke

Abstract Wildfires are a major source of gas-phase ammonia (NH_3) to the atmosphere. Quantifying the evolution and fate of this NH_3 is important to understanding the formation of secondary aerosol in smoke and its accompanying effects on radiative balance and nitrogen deposition. Here, we use data from the Western Wildfire Experiment for Cloud Chemistry, Aerosol Absorption, and Nitrogen (WE-CAN) to add new empirical constraints on the e-folding loss timescale of NH_3 and its relationship with particulate ammonium ($p\text{NH}_4$) within wildfire smoke plumes in the western U.S. during summer 2018. We show that the e-folding loss timescale of NH_3 with respect to particle-phase partitioning ranges from ~ 24 to ~ 4000 min (median of 55 min). Within these same plumes, oxidation of nitrogen oxides is observed concurrent with increases in the fraction of $p\text{NH}_4$ in each plume sampled, suggesting that formation of ammonium nitrate (NH_4NO_3) is likely. We find wide variability in how close our *in situ* measurements of NH_4NO_3 are to those expected in a dry thermodynamic equilibrium, and find that NH_4NO_3 is most likely to form in fresh, dense smoke plumes injected at higher altitudes and colder temperatures. In chemically older smoke we observe correlations between both the fraction of $p\text{NH}_4$ and the fraction of particulate nitrate ($p\text{NO}_3$) in the aerosol with temperature, providing additional evidence of the presence of NH_4NO_3 and the influence of injection height on gas-particle partitioning of NH_3 .

1. Introduction

Wildfires are the largest natural terrestrial source of gas-phase ammonia (NH_3) to the atmosphere (Bouwman et al., 1997; Paulot et al., 2014) and these emissions may be growing in many regions of the world with increasing wildfire activity (e.g., Bray et al., 2018). NH_3 is the most abundant base in the atmosphere, and it can contribute to the formation of secondary inorganic (e.g., Behera & Sharma, 2010; Yokelson et al., 2009) and organic (e.g., Y. Liu et al., 2015) aerosol. This secondary aerosol has significant direct and indirect effects on the Earth's radiation budget, though the magnitude of these effects remains uncertain (Myhre et al., 2013; Paulot et al., 2017). NH_3 is a large fraction of the emitted reactive nitrogen (N_r) in wildfire smoke (Benedict et al., 2017; Lindaas et al., 2021; Roberts et al., 2020) and can also be an important source of reactive nitrogen to sensitive ecosystems via deposition as the smoke travels downwind (Chen et al., 2014; Karlsson et al., 2013; Prenni et al., 2014).

The magnitude of emissions of NH_3 from wildfires and the timescales of its fate in the atmosphere are both uncertain. Accurate and precise *in situ* measurements of gas-phase NH_3 are difficult due to its polarity and affinity for adsorption to surfaces (Pollack et al., 2019). Satellite retrievals of total column NH_3 hold promise for estimating emissions of NH_3 (Dammers et al., 2019), but efforts to infer the magnitude of NH_3 emission factors using satellite data from fires often rely on a prescribed value for the effective lifetime of NH_3 in smoke (Whitburn et al., 2015).

Few studies have empirically quantified the loss timescale of gas-phase NH_3 in biomass burning smoke plumes. Those that do most often call the estimated loss timescale a “lifetime” or “effective lifetime.” However, the loss of gas-phase NH_3 is likely more complicated than a first-order exponential decay toward zero. Oxidation is very slow, deposition to the ground is usually negligible, and it is generally assumed that gas-phase NH_3 in smoke is

lost by partitioning to the particle-phase via equilibrium-driven processes. These processes are dependent on T and RH and complicated by ongoing plume dilution and changing acid concentrations. Thus, while we report the estimated literature values in the same terms used by each analysis, we will employ the term “e-folding loss timescale toward quasi-equilibrium” or “e-folding loss timescale” in our own analysis (Section 2.3.4).

In situ observations from aerosol mass spectrometers and Particle-into-Liquid samplers have inferred that ammonium nitrate (NH_4NO_3) is quickly formed (within minutes to hours) in smoke plumes based on the presence of both ammonium (NH_4^+) and nitrate (NO_3^-) species or ions (Akagi et al., 2012; Alvarado et al., 2010; Hobbs et al., 2003; Kleinman et al., 2008; X. Liu et al., 2016; Yokelson et al., 2009). Abundant NH_3 in smoke accompanied by the oxidation of co-emitted nitrogen oxides (NO_x) is commonly assumed to lead to rapid association of NH_3 with nitric acid (HNO_3). However, several studies have acknowledged or offered evidence for the association of NH_3 with organic acids to form organic ammonium salts (Akagi et al., 2012; Song et al., 2005). Other studies have reported enhancements of particulate ammonium and/or nitrate ($p\text{NH}_4$; $p\text{NO}_3$) in smoke but did not attribute these enhancements to specific causes or compounds (Benedict et al., 2017; Collier et al., 2016; Hecobian et al., 2011).

Given the present uncertainties in NH_3 evolution and the processes driving NH_3 aging in smoke, there is a need for additional empirical constraints on the e-folding loss timescale of NH_3 and its relationship with $p\text{NH}_4$ within wildfire smoke plumes (Paulot et al., 2017). Here, we use data from the 2018 Western Wildfire Experiment for Cloud Chemistry, Aerosol Absorption, and Nitrogen (WE-CAN) field campaign to derive empirical insights into NH_3 evolution in wildfire smoke. These data dramatically expand the limited number of fires for which NH_3 aging has been characterized. First, we estimate the e-folding loss timescales and distances of gas-phase NH_3 decreases with respect to gas-particle partitioning, as well as the e-folding loss timescales and distances with respect to dilution and partitioning. These loss timescales can be compared with the e-folding production timescale estimated from observed increases in $p\text{NH}_4$. Next, we explore the connection between NO_x oxidation chemistry and NH_3 aging, and investigate the conditions under which thermodynamic equilibrium may favor NH_4NO_3 formation. Lastly, we calculate the fraction of $p\text{NH}_4$ and $p\text{NO}_3$ in older smoke and find anti-correlations with temperature, suggesting the smoke plume injection heights and transport pathways influence gas-particle partitioning of NH_3 through the abundance and equilibrium of NH_4NO_3 .

2. Methods

2.1. Pseudo-Lagrangian Sampling Strategy

The WE-CAN field project used the instrumented National Science Foundation/National Center for Atmospheric Research (NSF/NCAR) C-130 research aircraft to sample smoke from wildfires across the western U.S. between July 22, and September 13, 2018 (https://www.eol.ucar.edu/field_projects/we-can). The C-130 aircraft payload was organized to specifically probe the evolution of reactive nitrogen (N_i) in wildfire plumes, along with absorption properties of smoke aerosol, cloud-smoke interactions, and near-source smoke chemistry. Approximately two thirds of the 134 total flight hours were allocated to sampling emissions and aging of daytime plumes. Wildfire smoke plumes were typically sampled during their first day of atmospheric evolution and pseudo-Lagrangian sampling was attempted for 12 fires. Flight patterns typically involved sampling background conditions immediately upwind of the fire followed by sampling the downwind smoke plume in a “lawn-mower” pattern as shown in Figure 1. The plume was transected perpendicular to its direction of downwind travel, with the first transect being performed as close to the fire as possible, ranging between 18 and 54 min (mean = 38 min) estimated physical age for the fires included in this analysis (Section 2.3.3). Using real-time wind speed and direction measurements aboard the aircraft, downwind transects could be planned with the intention of repeatedly intercepting the same parcel of smoke as it was advected downwind. This sampling pattern was generally performed at a constant altitude, which was determined from the injection height of the thickest portion of the smoke plume. Changes in altitude were occasionally necessary to better follow the center portion of the smoke plume or were part of the flight plan to sample different parts of the plume's vertical structure. In some cases, unplanned altitude changes were necessitated by air traffic control. More details about the WE-CAN field project and other sampling strategies may be found in Lindaas et al. (2021).

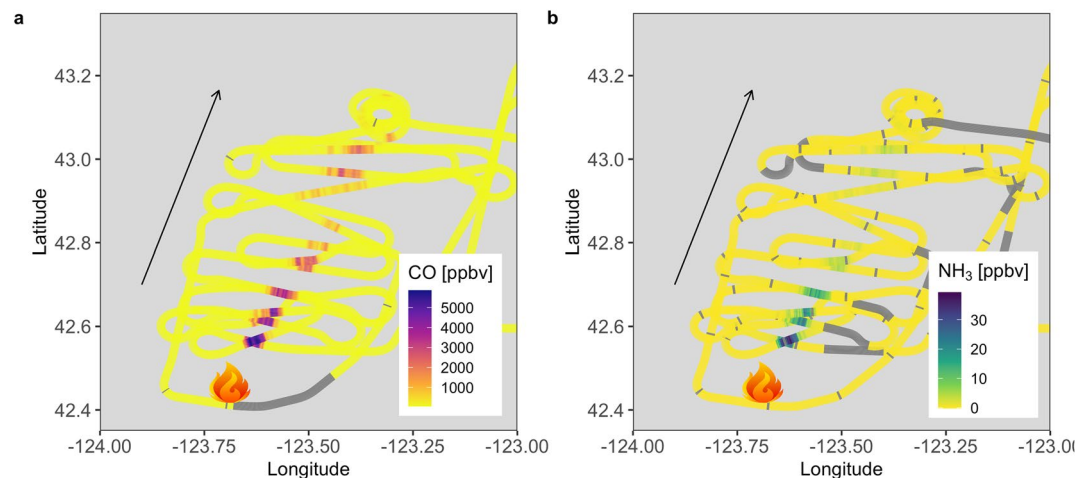

Figure 1. National Center for Atmospheric Research/National Science Foundation C-130 flight track around the Taylor Creek Fire, July 30, 2018 during Research Flight 3 (RF03), colored by (a) CO and (b) NH_3 mixing ratios. The black arrow shows the average wind direction and the fire icon shows the fire location. Gray periods in the flight track indicate calibration and/or instrument zero periods or other periodical instrument checks.

2.2. Measurements

The WE-CAN payload included a large suite of gas- and particle-phase measurements relevant to the fate of NH_3 species. Instruments used to measure the species used in this analysis include: the National Center for Atmospheric Research (NCAR) 2-channel and single-channel chemiluminescence instruments for the measurement of nitrogen oxide, nitrogen dioxide, and ozone (NO , NO_2 , and O_3); the Colorado State University quantum cascade tunable infrared laser direct absorption spectrometer (CSU QC-TILDAS) for the measurement of gas-phase NH_3 ; the University of Washington iodide-chemical ionization mass spectrometer (UW I-CIMS) for the measurement of hydrogen cyanide, nitric acid, nitrous acid, and multifunctional organic nitrates (HCN, HNO_3 , HONO, ONs); the NCAR PAN-CIMS for the measurement of peroxyacetyl nitrate (PAN) and peroxypropionyl nitrate (PPN); the University of Montana proton transfer reaction time-of-flight mass spectrometer (UM PTR-ToF-MS) for the measurement of acetonitrile (CH_3CN); the CSU aerosol mass spectrometer (AMS) for the measurement of particulate-phase ammonium and nitrate ($p\text{NH}_4$ and $p\text{NO}_3$); the NCAR QC-TILDAS for the measurement of carbon monoxide (CO) and nitrous oxide (N_2O); the NCAR Picarro for the measurement of carbon dioxide, carbon monoxide and methane (CO_2 , CO, and CH_4); and the NCAR Trace Organic Gas Analyzer (TOGA) for the measurement of 2-methylfuran, acrolein, and acrylonitrile. Full instrument descriptions and related references are reproduced in the SI with permission from Lindaas et al. (2021) and O'Dell et al. (2020) (for TOGA).

2.3. Calculation Methods and Data Treatments

2.3.1. Plume Transect Criteria

A plume transect is defined as an individual flight segment that perpendicularly transects a smoke plume with background air present on both sides. Start and end times for plume transects were visually identified when the time series of CO, HCN, and NH_3 all concurrently and sharply deviated from their average background mixing ratios. For reproducibility, we have included a file with the start and stop times for each plume transect in the SI. If one or more of these measurements was missing (e.g., during a calibration) additional tracers were employed such as PAN and NO_2 . CO and HCN are considered to be conservative tracers on the timescales of interest here (0–5 h of physical transport) given their lifetimes of ~ 10 days and ~ 3 months, respectively, during summer (Holloway et al., 2000; Li et al., 2000). Plume transects attributed to a single fire are grouped for further analysis.

2.3.2. Normalized Excess Mixing Ratio (NEMR)

The NEMR enables comparison of abundances between and within plumes (Yokelson et al., 2013). By accounting for dilution through normalizing a given measurement by a conserved tracer such as CO, we can investigate changes in abundances due to chemical production or consumption, as well as differences in emissions and aging

between plumes. Here, we calculate the NEMR of species X for a given plume transect by calculating the integrated $\Delta X (= \Sigma[X_{\text{measured}} - X_{\text{background}}])$ and the integrated $\Delta \text{CO} (= \Sigma[\text{CO}_{\text{measured}} - \text{CO}_{\text{background}}])$ and dividing ΔX by ΔCO . Backgrounds for CO and the species X are calculated as the mean of 15 s of measurements before and after a given plume transect's start and end times, respectively. Data points with missing measurements of either X or CO are not included in this calculation, and most observations included in this analysis were reported at 1-Hz or faster. AMS data were reported on a 5-s timebase in standard mass concentration units, and these data are converted to an ambient mixing ratio equivalent before merging them with the other 1-Hz data for analysis. Reported precision and accuracy as well as the standard deviation in the background estimates for X and CO are summed in quadrature to calculate an uncertainty for the NEMR of a given species over each plume transect.

2.3.3. Physical and Chemical Age Estimates

We estimate the physical age of a plume by dividing the distance between the fire emission source and each downwind plume transect by the plume wind speed. The distance is measured from the centroid of the active burn area on that day to the center of the plume transect, and wind speed is estimated as the average wind speed across all downwind plume transects sampled for that fire. If a smoke plume from a given fire was followed downwind and the sampling pattern was repeated, a separate average wind speed was calculated from the second set of passes and used to estimate the physical age of the transects in that pseudo-Lagrangian pattern. Estimated physical ages could deviate from the true plume age at each transect due to several factors including variable wind speeds along the aircraft and plume trajectories, uncertainties in the active burn location, and differences in atmospheric friction and entrainment. We estimate the uncertainty in our calculations of physical age using the 1-sigma standard deviation in the mean wind speed across each set of plume transects. Uncertainty in the fire location at the specific time of sampling is not available. To assess the efficacy of attempted pseudo-Lagrangian sampling efforts, an estimated emission time (t_0) was calculated for each plume transect by subtracting the estimated physical age from the time the plume transect occurred. Most sets of plume transects contained transects all with estimated t_0 within 2 h. Fires with Pseudo-Lagrangian sampling patterns with sets of transects containing t_0 differences >2 h were excluded from this analysis in order to limit the possible influence of time-varying emissions and evolution on our analysis. We also excluded plume intercepts that were not connected to the intended pseudo-Lagrangian sampling efforts (i.e., sampled smoke from other fires nearby or from portions of the plume not entrained in the mean atmospheric flow). See the SI for a full list of plume transect start and stop times. Since the lifetime of both HCN and CO are much greater than the elapsed sampling time, we would expect HCN NEMRs to remain constant with plume physical age in a true Lagrangian sampling system. In the eight pseudo-Lagrangian sampling cases identified, HCN NEMRs were confirmed to remain within initial propagated error during the time spent sampling the plume (Figure S1).

We also assigned a broader set of smoke plume intercepts an approximate chemical age following O'Dell et al. (2020). This assignment of chemical age is useful because it allows us to examine the partitioning of NH_x in all the smoke samples intercepted during WE-CAN, not just those that were sampled in a pseudo-lagrangian fashion from known fires. Briefly, smoke-influenced data were identified using co-elevated $\text{CO} > 85$ ppbv, $\text{HCN} > 275$ pptv, and $\text{CH}_3\text{CN} > 200$ pptv. Smoke-influenced data were assigned an approximate chemical age using three VOCs with different second-order reaction rate constants for loss via reaction with OH: 2-methylfuran ($k_{\text{OH}} = 7.31 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, Aschmann et al., 2011), acrolein ($k_{\text{OH}} = 1.96 \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, Atkinson, 1986; NIST Chemical Kinetics Database), and acrylonitrile ($k_{\text{OH}} = 4.04 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$, Harris et al., 1981; NIST Chemical Kinetics Database). Based on which of these three VOCs is above background abundances in a plume, O'Dell et al. (2020) grouped smoke samples into three bins. Young smoke has an estimated age of <1 day, the medium smoke group includes smoke plumes with estimated ages of 1–3 days, and all smoke with estimated chemical ages >3 days is categorized as old smoke. While this method likely captures the general progression of chemical aging in smoke, there are limitations: the binning of smoke samples is impacted by the age tracer dilution as well as chemistry, and the age assignments do depend on an assumed constant smoke OH concentration.

2.3.4. Exponential Fitting of Empirical Relationships

We calculate first-order exponential decay toward a quasi-equilibrium value (Equation 1) and asymptotic growth (inverse exponential decay; Equation 2) equations to fit the change in calculated NH_3 and $p\text{NH}_4$ NEMRs respectively with estimated plume age (nls and SSasympt functions: R software, package "stats," v3.5.1). These equations are fit separately to the NEMRs for each species and set of plume transects. The estimated timescale

with respect to loss or production is the inverse of the exponential coefficient, $\tau = \frac{1}{k}$. Here, we call τ the e-folding loss (production) timescale. A first-order exponential decay to zero equation (Equation 3) is also fit to the enhancement mixing ratios above background of NH_3 and CO for each set of plume transects. The inverse of the exponential coefficient, $\tau = \frac{1}{k}$, of these fits is an estimate of the e-folding timescales (or distances if fit using the distance from the fire) with respect to dilution plus chemistry (NH_3), and just dilution (CO).

$$y = y_{\text{asymptote}} + (y_0 + y_{\text{asymptote}}) * e^{-kx} \quad (1)$$

$$y = y_{\text{asymptote}} * (1 - e^{-kx}) \quad (2)$$

$$y = y_0 * e^{-kx} \quad (3)$$

Because we did not sample the plumes exactly at the emission source (t_0), we make one important assumption about the NH_3 and $p\text{NH}_4$ NEMR fits. All NH_3 and $p\text{NH}_4$ is assumed to be in the form of gas-phase NH_3 at emission. Accordingly, a calculated NH_3 NEMR data point of magnitude NH_3 NEMR + $p\text{NH}_4$ NEMR from the closest transect to the fire is added at t_0 and used in calculating the e-folding loss timescale of NH_3 NEMR for each plume. Likewise a $p\text{NH}_4$ NEMR point of magnitude zero is added at t_0 and used in the calculation of the $p\text{NH}_4$ NEMR e-folding growth timescale. With this assumption, we are able to estimate the rate of rapid partitioning often occurring in the minutes before the aircraft was able to sample the plume. We did test the sensitivity of the estimated loss and growth timescales to this initial assumption and found no change outside error for relaxed assumptions of down to 50% of $p\text{NH}_4$ assumed to be NH_3 at emission.

3. Results and Discussion

Figure 1 shows the sampling pattern downwind of the Taylor Creek Fire sampled on July 30, 2018 during RF03. The flight track is colored by CO (1a) and NH_3 (1b) mixing ratios with darker colors indicating the plume core as the aircraft transited the smoke plume. Transects further downwind contained progressively less CO (evidence of dilution) and NH_3 (evidence of dilution plus chemistry). The Taylor Creek Fire plume was a discrete plume that was injected above the boundary layer and entrained into the free-tropospheric flow. The aircraft was nearby when the plume pushed up and out of a smoke-filled boundary layer, and this time was noted. As the plume dispersed, the front edge of the plume continued to be visible because the surrounding free tropospheric air was quite pristine. However, the plume was also sufficiently large enough to also be easily intercepted by the aircraft. This fire afforded the best opportunity to repeatedly sample a very fresh plume using a pseudo-Lagrangian flight pattern. The estimated emission times (t_0 , described in section 2.3.3) for most of the individual plume transects shown in Figure 1 are within 1 h (during a several-hour flight time), indicating the pseudo-Lagrangian sampling was effective. We have identified seven other cases of pseudo-Lagrangian sampling where the estimated emission times from individual passes were within ~ 2 h of each other. The Bear Trap Fire (August 9, 2018; RF09) plume was sampled with two separate pseudo-lagrangian patterns and the South Sugarloaf Fire (August 26, 2018; RF15) plume was sampled at multiple altitudes at each distance downwind. These cases were separated and kept distinct during this analysis. Thus, the eight pseudo-Lagrangian sampling cases correspond to six individual fires.

Measurements of gas-phase NH_3 and aerosol species such as $p\text{NH}_4$ from the AMS are tightly correlated with CO in fresh and old smoke in the WE-CAN data set ($R^2 = 0.68$ for NH_3 and CO over all plume transects); and NH_3 enhancements above background reached >400 ppbv in fresh smoke. Distinct enhancements of NH_3 of >1 ppbv are generally present even in old smoke (Figure S2a), while detectable background mixing ratios of ~ 0.2 – 1 ppbv are present in the clean free troposphere. Figure 2 shows the evolution of dilution-corrected gas-phase NH_3 , $p\text{NH}_4$, and the sum of NH_3 and $p\text{NH}_4$, ΣNH_x . While six out of the eight plumes are observed to lose NH_3 with physical aging, both altitudes of the South Sugarloaf plume maintain roughly constant NH_3 NEMRs and $p\text{NH}_4$ NEMRs appear to increase. If all the NH_3 lost from the gas-phase partitions to the aerosol, in a perfectly Lagrangian-sampled plume we would expect ΣNH_x to remain constant after correcting for dilution. We observe steady or slightly decreasing ΣNH_x NEMRs with estimated physical age for all fires with the exception of South Sugarloaf. Several of the apparent decreases are within the propagated uncertainty of the measurements and NEMR calculations. Background errors become larger as the plume dilutes and enhancements above background are less pronounced. However, the decrease in the Bear Trap smoke plume is outside the propagated uncertainty, and represents $\sim 40\%$

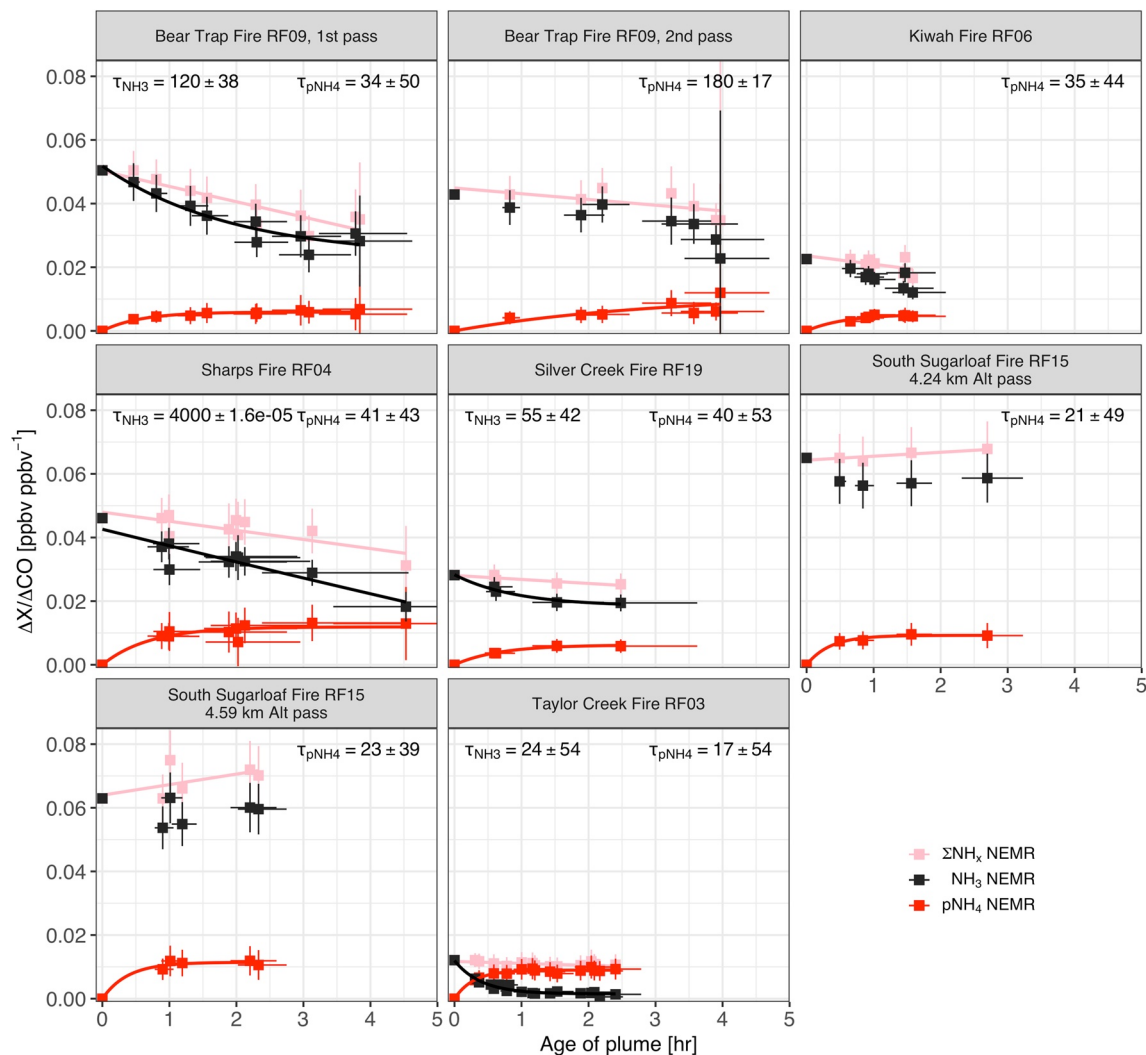

Figure 2. Evolution of ammonia (NH_3) and particulate ammonia ($p\text{NH}_4$) normalized excess missing ratios (NEMRs) with estimated physical plume age. The sum of NH_3 and $p\text{NH}_4$ is shown in pink points, NH_3 is in black, and $p\text{NH}_4$ is shown in red, with empirical fits plotted as lines. Points at time 0 are assumed NEMRs. Empirical fits are an exponential decay to a quasi-equilibrium value for NH_3 , and an asymptotic increase (inverse exponential decay) for $p\text{NH}_4$. τ_{NH_3} and $\tau_{p\text{NH}_4}$ represent the estimated e-folding time with respect to chemical losses and chemical production respectively, ± 1 -sigma standard deviation in minutes. No estimate for the e-folding time is shown if the fit did not converge.

loss of ΣNH_x over ~ 4 h of physical aging. A possible explanation for “missing” ΣNH_x include partitioning of NH_3 to smaller (e.g., recently nucleated) particles than the size range captured by the AMS (70–1000 nm). NH_3 is not likely removed from plumes sampled in the upper boundary layer/free troposphere by deposition during our timescales of interest (e.g., Akagi et al., 2012), nor via oxidation by OH, given the lifetime of NH_3 against oxidation by OH is ~ 14 days ($k_{\text{OH}} = 1.6 \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$) (Sander et al., 2006).

NH_3 partitioning fractions in these plumes sampled during WE-CAN span a wide range. After 1.5 h, the plumes included here ranged from $p\text{NH}_4$ fractions of 0.2–0.9 ($p\text{NH}_4$ fraction = $p\text{NH}_4/\Sigma\text{NH}_x$). This is a wider range than described in the limited existing literature covering plumes that have been sampled as they age. For example, Akagi et al. (2012) observed a $p\text{NH}_4$ fraction of 0.13 after 1.5 h of aging in a southern California chaparral fire, and Yokelson et al. (2009) observed a $p\text{NH}_4$ fraction of ~ 0.32 after 1 h of aging in tropical Yucatán Peninsula smoke plumes.

We assume the loss of NH_3 from the gas-phase to follow a first order exponential decay toward a quasi-equilibrium value greater than zero. Our observations in older smoke show continued NH_3 enhancements (Figure S2a) and so an exponential decay toward 0 would not make sense, nor does it make sense from a thermodynamic

point of view if NH_4NO_3 is present in the aerosol phase. Because we are fitting both an e-folding loss timescale as well as a quasi-equilibrium asymptote, our fits converge in only four out of the eight plumes. The estimated e-folding loss timescale of NH_3 , τ_{NH_3} , in these four plumes is between ~ 24 and 4000 min (median of 55 min), with the Sharps Fire plume a possible outlier even though the fitting routine did converge. For comparison, Goode et al. (2000) observed an e-folding timescale of 2.5 h in aircraft observations of an Alaskan boreal fire plume, Akagi et al. (2012) estimated a lifetime of ~ 6 h after observing NH_3 normalized excess mixing ratios decreasing by 50% over 4.5 h of physical aging in aircraft measurements of a chaparral fire plume in California, and Adams et al. (2019) used IASI and CrIS satellite retrievals within 200 km of the Horse River wildfire in Canada to empirically estimate an NH_3 lifetime of 3 h. In wildfire smoke further from the fire source however, four studies have inferred longer first-order or effective lifetimes of NH_3 : 36–48 h from correlation analysis of ground-based FTIR measurements (Lutsch et al., 2016); 6–24 h from regional analysis of IASI satellite retrievals over Russia (R'Honi et al., 2013); 36 h from a regional mass balance approach of IASI satellite retrievals over four tropical regions (Whitburn et al., 2015); and 21 h for an average effective lifetime in Indonesian peat fire plumes from IASI satellite retrievals (Whitburn et al., 2016). The differences between the shorter observed lifetimes in fresh smoke and the longer lifetimes inferred by the ground—and satellite-based regional analyses could be due to more abundant reactants for gas-particle partitioning reactions in fresh smoke (Paulot et al., 2017) as well as changing equilibrium conditions as the smoke dilutes and is advected downwind.

As Figure 3 shows, the Sharps Fire plume as sampled did not behave similarly to a gaussian-dispersing plume (with exponentially decaying CO enhancements). The flight scientist during that flight noted that at certain points it appeared as if smoke from a previous day of burning was being lifted out of the valley into the free troposphere. While we excluded transects with clear evidence of this influence from the current analysis, and the transects kept in meet the t_0 emission time criteria, the Sharps Fire plume likely represents an unideal case from which to estimate the timescale of gas-phase NH_3 loss. Timescales in the most well-defined plumes, Bear Trap first Pass and Taylor Creek, were estimated to be 120 ± 38 and 24 ± 54 min, respectively. The e-folding timescale of the average mixing ratio enhancements (i.e., not dilution corrected) of NH_3 and CO are shown in Figure 3. We observe e-folding timescales of NH_3 with respect to dilution plus chemical losses that range from 22 to 350 min (median of 77 min), generally shorter for a given plume than the timescales with respect to chemical losses only. E-folding distances range between 12 and 130 km (Figure S3) and could be useful in future satellite analyses and comparisons.

We also fit an asymptotic growth curve (the inverse of an exponential decay) to the $p\text{NH}_4$ NEMR estimates for each fire (Figure 2). The presence of $p\text{NH}_4$ in the downwind transect nearest to each fire suggests that a large fraction of the partitioning of gas-phase NH_3 into the aerosol happens on a timescale of tens of minutes between emission and the first *in situ* sampling transect. As we note above, the succeeding increase in $p\text{NH}_4$ is enough to balance the loss of gas-phase NH_3 within measurement errors for many fires. Over the short time span represented by these data (0–4 h of physical transport), in some cases (e.g., South Sugarloaf Fire Plume), $p\text{NH}_4$ NEMRs continue to increase as the plume ages, while in other cases the $p\text{NH}_4$ NEMR appears to stabilize. The e-folding timescales of the asymptotic growth in $p\text{NH}_4$ range from 17 to 180 min, with Bear Trap first Pass and Taylor Creek plumes estimates of 34 ± 50 and 17 ± 53 min, respectively.

NH_3 partitioning to aerosol can end up in three forms. NH_3 can form inorganic salts with nitrate, sulphate, or other inorganic species (Seinfeld & Pandis, 2016). It can form salts with organic acids (Akagi et al., 2012; Malm et al., 2005; Schlag et al., 2017) or react with some organic compounds (e.g., some carbonyls) to form nitrogen-containing organic compounds (Laskin et al., 2015; Y. Liu et al., 2015; Updyke et al., 2012). It can also dissolve into solution and exist as an ammonium ion if a liquid phase exists in the aerosol (Seinfeld & Pandis, 2016). AMS $p\text{NH}_4$ should capture each of these forms, as well as reduced organic nitrogen such as amines, amides, and other N-containing molecules that fragment to ions attributed to $p\text{NH}_4$. Therefore, total $p\text{NH}_4$ may contain contributions from primary emissions of amines and other reduced N compounds, but these contributions to the observed increase in $p\text{NH}_4$ during pseudo-Lagrangian plume sampling are likely small since gas-phase amines and amides were measured at less than 5% of gas-phase NH_3 across all WE-CAN smoke plumes when they were intercepted (PTR-ToF-MS measurements; Lindaas et al., 2021).

If oxidized nitrogen chemistry is linked to (or indicative of) the partitioning of NH_3 to the aerosol through the formation of NH_4NO_3 , we would expect a positive relationship between the fraction of ΣNH_x that is $p\text{NH}_4$ and the fraction of the sum of measured oxidized nitrogen ($\Sigma\text{NO}_y = \text{NO}_x + \text{HONO} + \text{PAN} + \text{PPN} + \text{HNO}_3 + p\text{NO}_3 +$

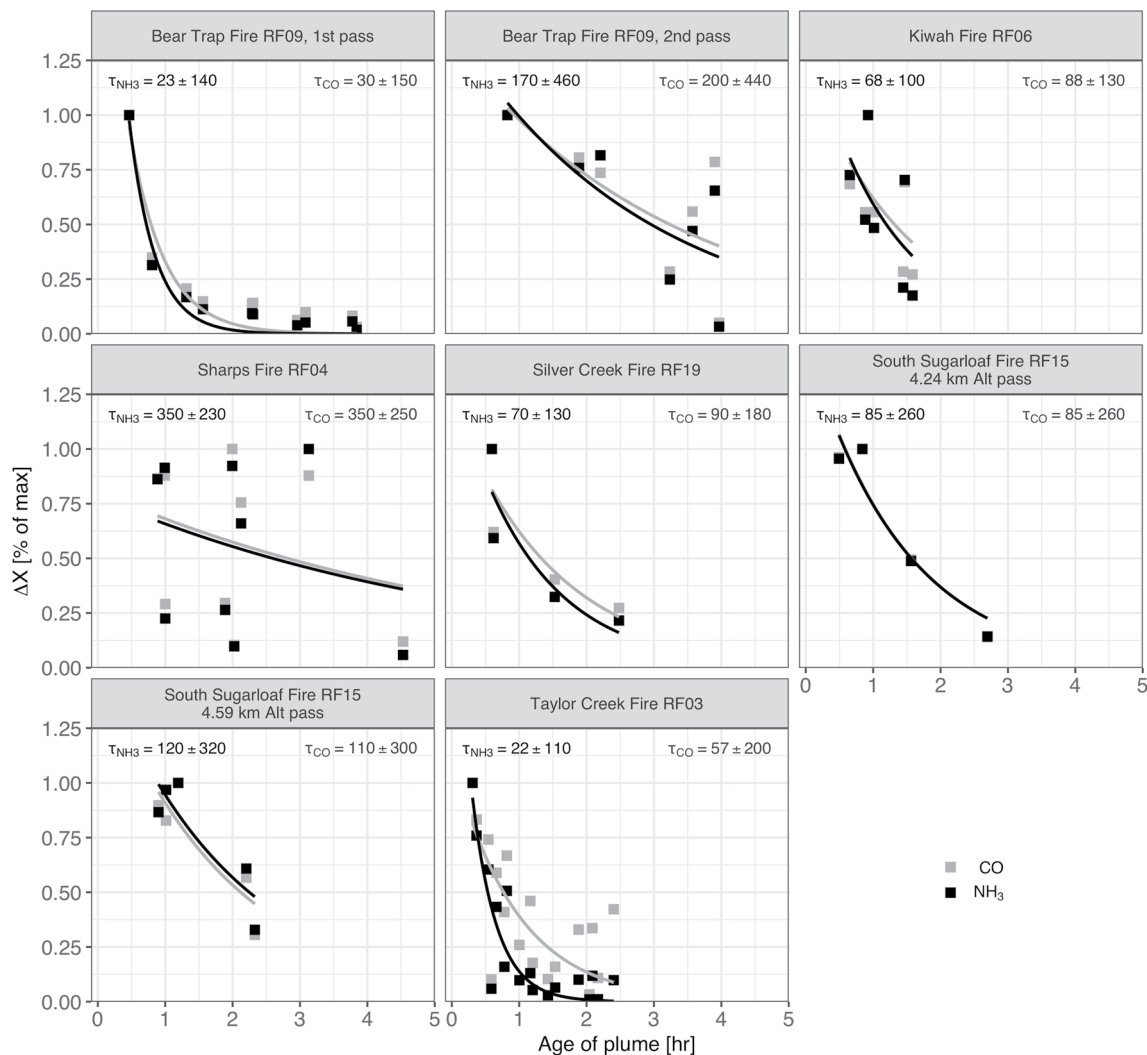

Figure 3. Evolution of ammonia (NH_3) and CO mixing ratios with estimated physical plume age. Points plotted are the mean mixing ratio of NH_3 in black and CO in gray of each plume transect, minus the estimated background and normalized by the greatest value across all passes in that plume (usually the youngest plume transect). τ_{NH_3} represents the estimated e-folding time with respect to dilution + chemical losses with 1-sigma standard deviation in minutes, calculated for a first-order exponential decay to zero. τ_{CO} represents the estimated e-folding time with respect to dilution with 1-sigma standard deviation in minutes, again calculated for a first-order exponential decay to zero.

ΣONs) that is NO_z ($\Sigma\text{NO}_z = \text{PAN} + \text{PPN} + \text{HNO}_3 + p\text{NO}_3 + \Sigma\text{ONs}$). This relationship is shown in Figure 4 for each plume where all data are available. Fresh plumes start with lower quantities of $p\text{NH}_4/\Sigma\text{NH}_x$ and $\Sigma\text{NO}_z/\Sigma\text{NO}_y$ and both quantities increase as the plume ages. The $\Sigma\text{NO}_z/\Sigma\text{NO}_y$ fraction is qualitatively similar to the negative log of NO_x fraction proxy for chemical age used in previous studies of wildfire smoke (e.g., Kleinman et al., 2008; Sedlacek III et al., 2018), and an increase in this fraction with aging reflects the transformation of NO_x into more highly oxidized products such as PAN, HNO_3 , and organic nitrates. As this chemistry proceeds, partitioning of NH_3 into $p\text{NH}_4$ is also occurring, whether via the formation of inorganic salts or through NH_3 -organic reactions. Figure 4 demonstrates three important patterns. First, for most plumes, ΣNO_z is more than 50% of ΣNO_y . This is the case for even the first transect of the smoke plumes shown in Figure 4 and is a result of rapid oxidation of NO_x in the first tens of minutes after emission (Juncosa Calahorrano et al., 2021; Peng et al., 2020). Second, the $p\text{NH}_4$ fraction ranges widely between 0.1 and 0.9. The Taylor Creek Fire plume is an obvious outlier, with a $p\text{NH}_4$ fraction ~ 0.5 even in the freshest plume transects. There is evidence that Taylor Creek was a particularly chemically active plume, with high NO_x and HONO emission factors (Lindaas et al., 2021; Peng et al., 2020), the highest estimated NO_x relative to NH_3 (NO_x/NH_3 ratio) of any fire (Lindaas et al., 2021), and more rapid O_3 production than any other plume sampled. This plume is also unique with respect to the amount

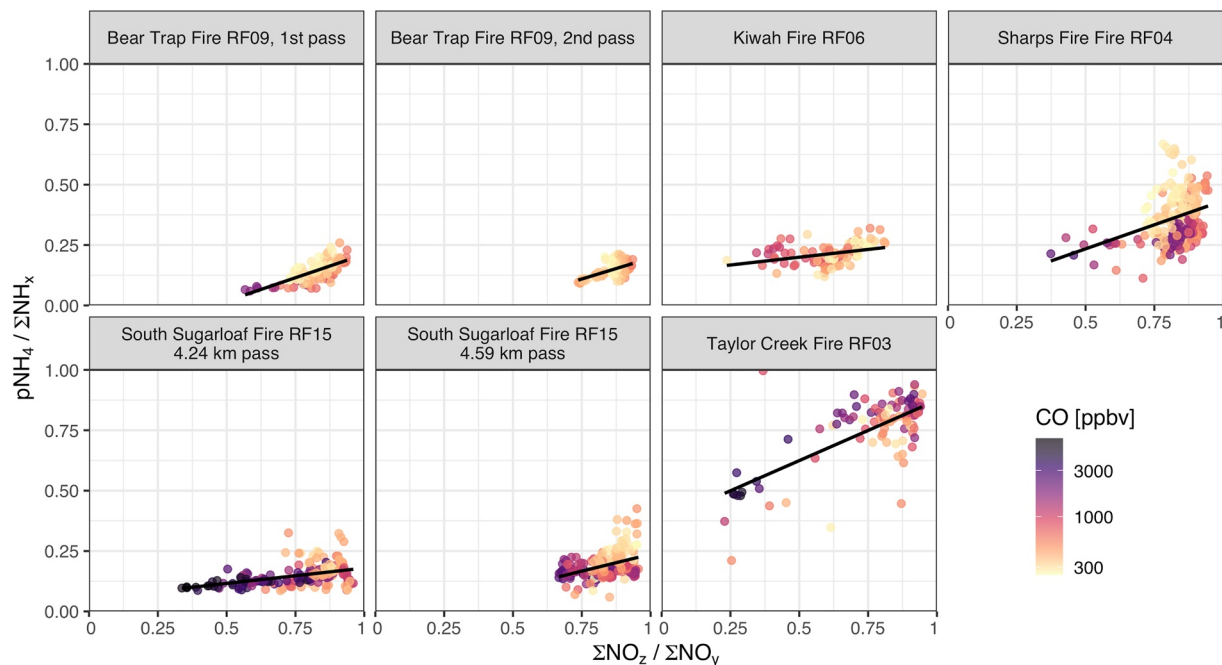

Figure 4. Relationship between the fraction of particulate ammonia ($p\text{NH}_4$) out of total ammonia ($\Sigma\text{NH}_x = \text{NH}_3 + p\text{NH}_4$) and the fraction of more oxidized nitrogen species ($\Sigma\text{NO}_z = \text{PAN} + \text{PPN} + \text{HNO}_3 + p\text{NO}_3 + \Sigma\text{ONS}$) out of total reactive nitrogen oxides ($\Sigma\text{NO}_y = \text{NO}_x + \text{HONO} + \text{PAN} + \text{PPN} + \text{HNO}_3 + p\text{NO}_3 + \Sigma\text{ONS}$). All observations are averaged according to the 5 s timebase for measurements collected by the aerosal mass spectrometer. Black lines represent linear least squares regression of the data points. Data points are colored by CO mixing ratio for all measurements above 250 ppbv.

of aerosol sulphate ($p\text{SO}_4$) relative to ΣNH_x . In nearly all the fresh smoke plumes encountered during WE-CAN, Garofalo et al. (2019) show that there is more fine aerosol $p\text{NH}_4$ and $p\text{NO}_3$ mass than $p\text{SO}_4$ mass. The exception is the plume associated with the Taylor Creek Fire. This is the only plume where the ratio of the total moles of $p\text{SO}_4$ is greater than 10% of ΣNH_x . We note that the timescale for gas-phase reaction of SO_2 with OH oxidation to eventually form $p\text{SO}_4$ is relatively slow (~ 2 days) compared to the timescales here (Long et al., 2017). Third, smaller CO mixing ratios at higher $p\text{NH}_4$ fractions in the South Sugarloaf and Sharps Fire plumes suggest that under some circumstances more dilute smoke (either plume edges or physically older smoke) partitions a higher fraction of NH_3 into the aerosol phase for a given fraction of NO_z .

A companion manuscript by Juncosa Calahorrano et al. (2021) estimates HNO_3 formation from the OH oxidation of NO_2 in the Bear Trap and Taylor Creek fire plumes. Assuming all produced HNO_3 partitions to the aerosol phase in association with NH_3 , they find that NO_2 oxidation by OH can account for $\sim 100\%$ of the $p\text{NO}_3$ formation in the Taylor Creek plume, and $\sim 300\%$ of the $p\text{NO}_3$ formation in Bear Trap. Possible reasons for the overestimation of $p\text{NO}_3$ increases could include an incomplete understanding of OH concentration evolution and uptake of HNO_3 by super-micron particles. These rough estimates support the conclusion that the partitioning of NH_3 into the aerosol phase is at least in part due to the formation of NH_4NO_3 through the association with gas-phase HNO_3 .

To investigate the thermodynamics of possible NH_4NO_3 formation within WE-CAN smoke plumes, we calculate the dissociation constant of NH_4NO_3 , K_p (Table 10.7 in Seinfeld & Pandis, 2016), and compare it to the product of partial pressures of gas-phase NH_3 and HNO_3 (Figure 5). K_p is dependent on temperature (Figure 5a) (see also Stelson & Seinfeld, 1982), and it indicates whether a parcel is supersaturated with respect to NH_4NO_3 when particles are dry (which assumes a low environmental relative humidity and particles have not deliquesced). This K_p formulation does not consider physical and chemical properties of the smoke aerosol that may shift particles away from NH_4NO_3 equilibrium such as mixing state, phase separation, and aerosol pH (e.g., Guo et al., 2018; Kanakidou et al., 2005). Higher relative humidities (typically $> 60\%$) will likely cause NH_4NO_3 -containing aerosol to deliquesce at the temperatures sampled here, increasing the likelihood of additional NH_4NO_3 formation. 63% of samples had $\text{RH} < 60\%$ in the data shown in Figure 5d, but for simplicity we always assume the aerosol is dry. When the product of NH_3 and HNO_3 partial pressures is greater than K_p , or a ratio > 1 (vertical dashed lines in Figure 5), the parcel is assumed to be NH_4NO_3 supersaturated, and NH_4NO_3 will form as the system moves

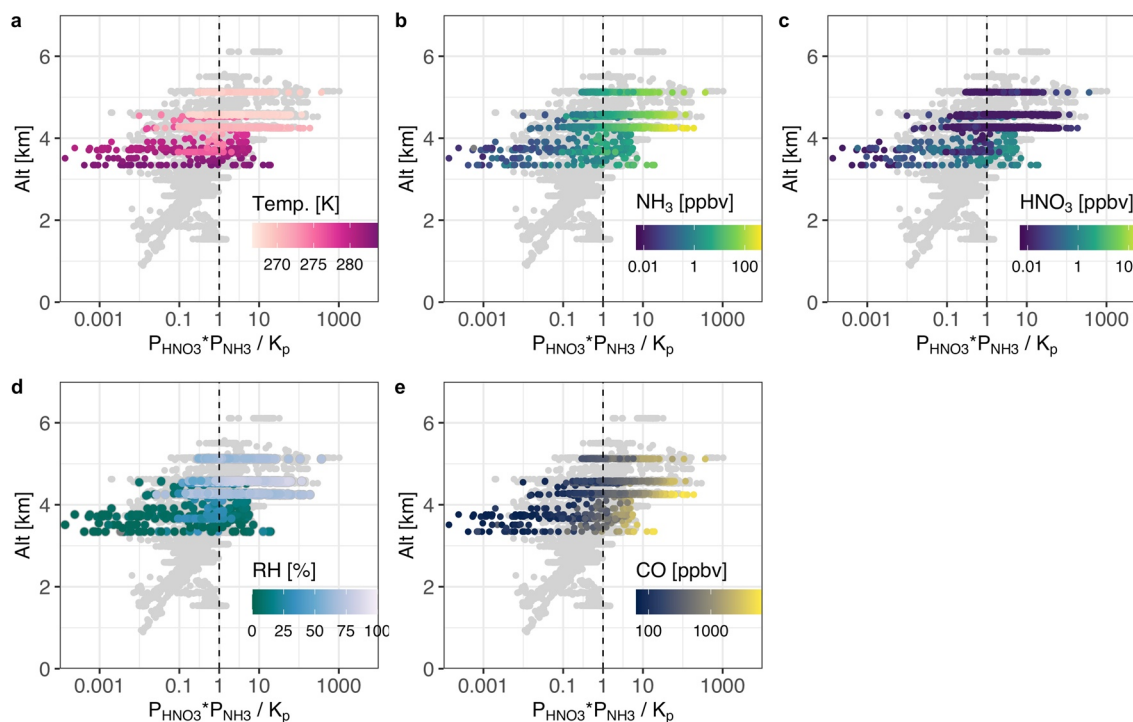

Figure 5. The altitude dependence of the ratio of the product of NH_3 and HNO_3 partial pressures with the dry dissociation constant for NH_4NO_3 , K_p . All points are averaged measurements on the AMS timebase (5 s). Gray points show all measurements within identified smoke plumes throughout the campaign. Colored points are those from the eight fire plumes included in prior figures. Each panel is colored by a different measurement: (a) ambient temperature, (b) NH_3 mixing ratio, (c) HNO_3 mixing ratio, (d) ambient relative humidity, and (e) CO mixing ratio. The vertical dashed line in each panel indicates a K_p ratio of 1.

toward thermodynamic equilibrium. Conversely a K_p ratio < 1 indicates the parcel is NH_4NO_3 subsaturated and NH_4NO_3 in aerosol, if it exists, will start to dissociate and transition back into the gas-phase as the system moves toward equilibrium.

Figure 5 shows that NH_4NO_3 supersaturation (points to the right of the vertical dashed lines) is more likely in higher altitude plumes because the temperature dependence of K_p pushes partitioning of NH_4NO_3 toward the particle phase, as inferred by Paulot et al. (2017). Individual data points in the plumes sampled during WE-CAN span a wide range of K_p ratios, from 0.001 to 1,000; low values are driven by low NH_3 and HNO_3 mixing ratios and warmer temperatures (Figures 5a–5c), and high values are driven by high NH_3 mixing ratios and colder temperatures. The total amount of available NH_3 and HNO_3 drives the relative amount of possible NH_4NO_3 formed, assuming there are no other physical or chemical constraints to the systems' equilibrium, and under this assumption the large range of observed K_p ratios indicates that the smoke is not often near NH_4NO_3 equilibrium. It is possible these observations of K_p ratios far out of equilibrium could constitute evidence for the influence of different physical and chemical properties mentioned above. Garofalo et al. (2019) showed that sub-micron aerosol measured during WE-CAN were generally $> 85\%$ organic, and thus it is likely many bulk properties are dominated by organic compounds.

NH_3 is nearly always in excess in these plumes, particularly when the K_p ratio is > 1 , and thus HNO_3 may be a limiting factor in the formation of NH_4NO_3 (Figures 5b and 5c). Gas-phase HNO_3 enhancements were not observed or they were small (typically < 5 ppbv; Figure S2b) compared to tens or hundreds of ppbv in observed NH_3 mixing ratios (Figure S2a), implying that NH_4NO_3 formation is HNO_3 limited. NH_4NO_3 supersaturation is also more common in fresher denser plumes (Figure 5e), where appreciable quantities of HNO_3 have sometimes been produced (Figure 5c) and before dilution reduces the total abundances of both NH_3 and HNO_3 .

As stated earlier, the $p\text{NH}_4$ measurement in smoke may contain contributions from inorganic NH_4^+ as salts with either inorganic acid anions (i.e., NH_4^+ associated with NO_3^- or SO_4^{2-}) or with organic acids (e.g., Akagi et al., 2012). Additionally, the $p\text{NH}_4$ measurement includes reduced organic N such as amines or other covalently bonded reduced organic nitrogen compounds (e.g., Farmer et al., 2010; Lin et al., 2016). Thus, not all of the

$p\text{NH}_4$ measured in smoke is necessarily inorganic, and not all of the inorganic $p\text{NH}_4$ is necessarily in salts with inorganic acids. We note that organic acid ions from the PILS measurements (formate, acetate, oxalate, malonate, succinate, and glutarate) are present in the WE-CAN data set. The formation of organic NH_4 salts would be consistent with previously observed enrichment of organic acids and NH_4^+ observed in boreal forest fire smoke (Talbot et al., 1992) and tropical Amazon biomass burning haze (Andreae et al., 1988), though we note that smoke in these studies was estimated to be older than the fresh smoke measurements analyzed here. Though outside the scope of this analysis, further work is needed to estimate the fraction of inorganic versus organic NH_4 salts, as well as to investigate the possibility of covalently bonded reduced N to the $p\text{NH}_4$ measurement. Empirical AMS species apportioning analyses for $p\text{NH}_4$ during WE-CAN are ongoing.

While Figure 5 shows the physical and chemical context for NH_4NO_3 thermodynamic equilibrium in smoke connected to a specific fire and with a physical age of <1 day, we also encountered smoke of indeterminate origin, some of which had likely been emitted more than 1 day prior to sampling. Though establishing an estimated physical age is difficult for this smoke, we can use estimated chemical age categories described by O'Dell et al. (2020) to assess how the physical smoke context may change the $p\text{NH}_4$ fraction ($p\text{NH}_4/\Sigma\text{NH}_x$) in older smoke. The first three panels in Figure 6 shows that there is a negative correlation between the ambient environmental temperature and the $p\text{NH}_4$ fraction in medium (1–3 days chemical aging) and old (>3 days chemical aging) smoke, while this relationship is not present in the young smoke (<1 day chemical aging). We note that most of the data previously presented in Figures 2–5 is classified as young smoke. Temperature here can be considered an inverse proxy for altitude, with higher sampling altitudes typically having lower temperatures. As might be expected, relative humidity is also correlated with $p\text{NH}_4$ fraction in medium and old smoke, meaning higher $p\text{NH}_4$ fractions are observed at both colder temperatures and higher relative humidities (Figure S4). Since colder and wetter conditions push

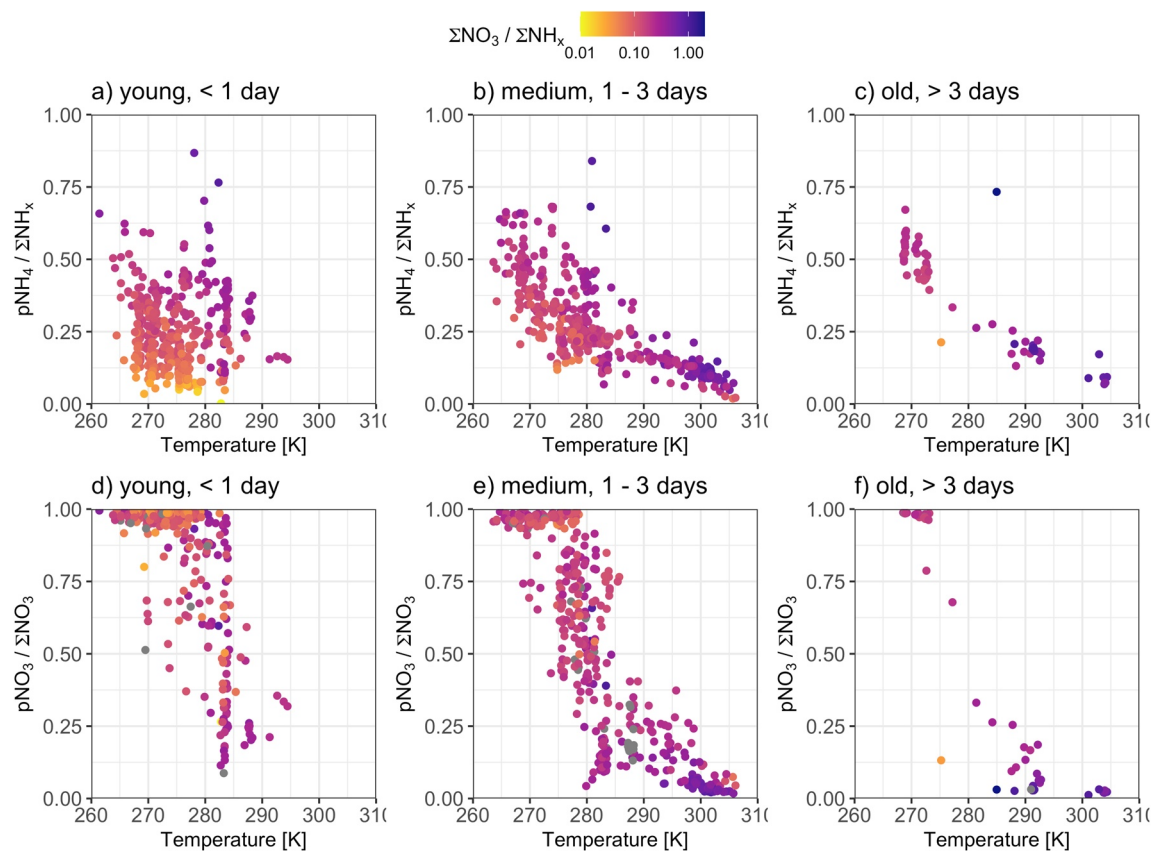

Figure 6. (a–c) Measured $p\text{NH}_4$ fraction ($p\text{NH}_4/\Sigma\text{NH}_x$) as a function of temperature, binned by young, medium, and old smoke, as defined by chemical age estimates from O'Dell et al., (2020). (d–f) Measured $p\text{NO}_3$ fraction ($p\text{NO}_3/\Sigma\text{NO}_3$; $\Sigma\text{NO}_3 = p\text{NO}_3 + \text{HNO}_3$) as a function of temperature, binned by the same chemical age estimates. Observations are averaged to the timebase of the TOGA instrument (~30-s samples every 100 s) and colored by the ratio of measured sum nitrate to measured sum ammonia ($\Sigma\text{NO}_3/\Sigma\text{NH}_x$) on a \log_{10} scale. Data points include only the observations collected >2 km above sea level in order to limit ground-based emission influence, and are not background-corrected.

the NH_4NO_3 equilibrium toward the aerosol-phase, these empirical relationships suggest a larger contribution from inorganic NH_3 partitioning in colder and wetter smoke plumes. Figures 6e and 6f support this conclusion, showing the same negative relationship with temperature for the fraction of $p\text{NO}_3$ in the sum measured nitrate ($\Sigma\text{NO}_3 = p\text{NO}_3 + \text{HNO}_3$) in medium and old smoke. This conclusion is also consistent with the inference made by Paulot et al. (2017), that smoke plumes injected higher into the free troposphere more favorably produce NH_4NO_3 . The fractions of $p\text{NH}_4$ and $p\text{NO}_3$ in each of the Figure 6 panels are colored by the ratio of measured sum nitrate to measured sum ammonia ($\Sigma\text{NO}_3/\Sigma\text{NH}_x$). This ratio suggests that a greater abundance of sum nitrate relative to sum ammonia is correlated with a higher $p\text{NH}_4$ fraction in young and medium chemically aged smoke. Higher $\Sigma\text{NO}_3/\Sigma\text{NH}_x$ correlating with greater NH_3 partitioning is consistent with one of the insights from Figure 5, that NH_4NO_3 production is often limited by HNO_3 availability, as well as the observations from individual fires, where Taylor Creek has the fastest e-folding loss timescale and the highest oxidized N to reduced N ratios (Lindaas et al., 2021). We note that the data shown in Figure 6 are not background-corrected, thus describing the behavior of total ammonia (panels a–c) and total nitrate (panels d–f) in smoke-impacted air. While entrainment of NH_3 , $p\text{NH}_4$, and $p\text{NO}_3$ from surrounding air masses is not likely to be contribute to already enhanced abundances in older smoke, HNO_3 may be present in the free troposphere (Figure S2b) and affect the $p\text{NO}_3$ fraction in well-diluted (medium and old) smoke along with smoke-produced HNO_3 . By showing the full observed behavior of the $p\text{NH}_4$ and $p\text{NO}_3$ fractions in smoke across different chemical ages, we conclude that aged smoke plumes in the western U.S. likely contribute to the production of NH_4NO_3 in the free troposphere. This production may be enhanced in smoke with lower temperatures (injection at higher altitudes) and higher $\Sigma\text{NO}_3/\Sigma\text{NH}_x$ ratios.

4. Conclusions

We have characterized evolution of gas-phase NH_3 in a set of western wildfire smoke plumes during summer 2018 and investigated some of the complexity in the partitioning of NH_3 to $p\text{NH}_4$, including the relationship of NH_3 partitioning to HNO_3 and other acids as well as to temperature and RH. NH_3 mixing ratios decrease in fresh smoke plumes in most of the sampled plumes, faster than can be explained by dilution alone, and concurrent increases in observed sub-micron $p\text{NH}_4$ from the AMS are able to account for this loss in many plumes. While the limited existing literature on NH_3 evolution in smoke tends to estimate a lifetime or effective lifetime for NH_3 loss, we recognize the complexity in this term: NH_3 is likely lost from the gas phase through an equilibrium process dependant on T and RH that happens concurrent with ongoing dilution and changing inorganic and organic acids abundances. Thus, we describe an e-folding loss timescale to quasi-equilibrium for NH_3 gas-particle partitioning that is on the order of tens of minutes to several hours in the fresh smoke plumes sampled. We find empirical evidence for the association of NH_3 and HNO_3 to form NH_4NO_3 through the positive relationship between the $p\text{NH}_4$ fraction of ΣNH_x and the ΣNO_z fraction of ΣNO_y . We examine the thermodynamic context for the formation of NH_4NO_3 by calculating the K_p ratio. Under the assumption that this equilibrium is independent from aerosol mixing state, phase separation, or pH, we find that many of our *in situ* measurements are far from equilibrium, both super- and sub-saturated with respect to NH_4NO_3 . Fresh, dense plumes injected at higher altitudes (and lower temperatures) are more likely to favor NH_4NO_3 formation. Lastly, in smoke with chemical ages older than ~ 1 day, we find evidence for the presence of NH_4NO_3 via the negative relationship between the environmental temperature and both $p\text{NH}_4$ and $p\text{NO}_3$ fractions. This again suggests that smoke injected higher in the free troposphere favors the formation of NH_4NO_3 , consistent with the findings of Paulot et al. (2017).

There is a need for more *in situ* observations of NH_3 evolution, not only in this region but also for boreal and tropical regions. Fires in these regions can have very different emission ratios of reactive nitrogen species (e.g., Akagi et al., 2011). This study concurs with expectations that larger emission ratios of NO_x/NH_3 produce faster NH_3 partitioning via formation of NH_4NO_3 . Additional *in situ* observations could help confirm partitioning rates under real-world conditions. Additionally, there is a need for *in situ* and satellite analyses that bridge the first few hours of physical aging with the evolution that occurs over the first few days of atmospheric transport, including nighttime chemical processes. Subsequent smoke-centered field projects or opportunistic smoke sampling efforts might include this focus in their data collection and analyses.
