## Abstract

In the eastern Pacific Ocean, three distinct forms of common bottlenose dolphin (*Tursiops truncatus*) have been identified, with suggestion they may be different species: a southern California/Mexico coastal, a northern temperate offshore, and an eastern tropical Pacific (ETP) offshore form. Currently, only one species (*T. truncatus*) is recognized in the region, with the first two forms described as distinct ecotypes. The goal of this study was to improve our understanding of the taxonomic status of these previously described forms through a re-examination of their morphological differentiation. We analyzed 135 skulls from the eastern and western Pacific, including the two nominal species, *T. gillii* and *T. nuuanu*, previously described for the eastern North Pacific and ETP, respectively. Additionally, we examined the holotypes of two currently recognized species in the genus, *T. truncatus* and *T. aduncus*. Our results showed significant morphological differentiation among bottlenose dolphins in the Pacific Ocean. The ETP offshore bottlenose dolphins were smaller in skull and body size and diagnostically distinct from dolphins in the western North Pacific and other regions in the eastern Pacific. Our results also indicated that while other bottlenose dolphins in the Pacific were more similar to the globally distributed *T. truncatus*, the ETP offshore dolphins shared similarities with a previously described species in that region. The distinct environmental conditions in the ETP may be driving the evolutionary differentiation of these bottlenose dolphins. Given these results, we here recommend the recognition of ETP offshore bottlenose dolphins as a distinct subspecies, *Tursiops truncatus nuuanu*.

Keywords: cetaceans, divergence, environment, speciation, tropical

52

## Introduction

53 Environmental conditions and biological interactions can promote ecological  
54 divergence in highly mobile predators even in the absence of physical barriers to dispersal  
55 (Pilot et al. 2012; Wolf et al. 2008; Teske et al. 2019; Costa et al. 2021). Water temperature  
56 and competition for prey, for example, can lead to morphological and genetic differentiation,  
57 splitting populations into different ecological groups with evolving traits that will allow an  
58 efficient exploitation of the space and/or specific resources (Smith and Skúlason 1996;  
59 Ackermann and Doebeli 2004; Ruffler et al. 2007; Keller and Seehausen 2012). This  
60 divergent adaptation may even lead to reproductive isolation and result in ecological  
61 speciation (Schluter 2001).

62 Although most marine mammal species have the potential for large geographic  
63 dispersal, many exhibit local adaptations and distinct ecological groups with differential  
64 habitat preferences and foraging behaviors between conspecific populations even within short  
65 geographic distances (e.g., Heyning and Perrin 1994; Ford et al. 1998; Perrin et al. 2011;  
66 Costa et al. 2016). For example, distinct ecological preferences may be contributing to the  
67 differentiation of delphinids in the eastern Pacific Ocean, which in turn may be leading to  
68 speciation. Based primarily on morphological differences, subspecies of spinner (*Stenella*  
69 *longirostris longirostris*, *S. l. orientalis*, and *S. l. centroamericana*), pantropical spotted (*S.*  
70 *attenuata attenuata* and *S. a. graffmani*), and common (*Delphinus delphis delphis* and *D. d.*  
71 *bairdii*) dolphins have been recognized in the eastern Pacific (Perrin et al. 1982; Perrin 1990;  
72 Dizon et al. 1994; Committee on Taxonomy 2022). Interestingly three of the *Stenella*  
73 subspecies (*S. l. orientalis*, *S. l. centroamericana*, and *S. a. graffmani*) are endemic to the  
74 eastern tropical Pacific (ETP), each one with a different habitat range (Perrin et al. 1982;  
75 Perrin 1990; Dizon et al. 1994).

76 Morphological differentiation within bottlenose dolphins (genus *Tursiops*) has also  
77 been suggested for the region (e.g., Walker 1981; Perrin et al. 2011; Esteves-Ponte et al.  
78 2022). Bottlenose dolphins are regularly sighted throughout the eastern Pacific (from Canada  
79 to Chile) and the Gulf of California (GoC) (e.g., May-Collado et al. 2005; Segura et al. 2006;  
80 Palacios et al. 2012; Hwang et al. 2014; Van Waerebeek et al. 2017; Halpin et al. 2018;  
81 Segura-García et al. 2018; Carretta et al. 2021; Esteves-Ponte et al. 2022) and currently only  
82 the species *T. truncatus* (the common bottlenose dolphin) is believed to occur throughout this  
83 geographic area (Committee on Taxonomy 2022). However, two nominal species of  
84 bottlenose dolphins have previously been described from the eastern Pacific. The first was  
85 collected in Monterey (California) in 1871 by Captain C. H. Scammon and then described in  
86 1873 as *T. gillii* Dall, 1873 based solely on the lower mandible. Its distribution was described  
87 as being off the coasts of California and Baja California (Scammon 1874; Townsend 1916;  
88 Anthony 1928; Hershkovitz 1963; Huey 1964), with records in the GoC as far north as La  
89 Choya (Punta la Cholla; ca. 31° N, 113° W), Sonora, Mexico (Mayer 1950). The second was  
90 collected in the offshore waters of the ETP (12° N, 120° W; estimated as less than 2,000 km  
91 from the Mexican coast) on 6 December 1906 during the voyage of the Nuuanu and later  
92 described as *T. nuuanu* Andrews, 1911 based on its skull. Its distribution was identified as  
93 along the Pacific coast of Central America, extending southwards from Panama, with its  
94 southernmost record in waters off the Galapagos (Andrews 1911; Mayer 1950). Skulls  
95 assigned to *T. nuuanu* were also found in the lower GoC, in Santa Catalina Island (ca. 33° N,  
96 118° W) (Andrews 1911; Townsend 1916; Anthony 1928), with a northerly record at  
97 Coronado Island (Isla Coronado; ca. 29° N, 113° W) (Van Gelder 1960). Such records suggest  
98 the GoC as an area of possible overlap between the two nominal species *T. gillii* and *T.*  
99 *nuuanu* (Andrews 1911; Mayer 1950; Van Gelder 1960). These nominal species were  
100 differentiated from each other and *T. truncatus* based on differences in tooth size, size of the

101 temporal fossae (and its proportion to the overall length of the skull), and width of the vomer  
102 posteriorly (Andrews 1911; Mayer 1950; Van Gelder 1960). However, the previous studies  
103 were based on small sample sizes ( $n < 10$ ) and showed some degree of overlap between the  
104 characters used to distinguish the three species.

105         Later, in an effort to better characterize *Tursiops* in the eastern Pacific (Northern  
106 Hemisphere), Walker (1981) suggested that at least three forms of *T. truncatus* with distinct  
107 habitat preferences, diets, parasite loads, and morphological traits exist in the region: (1) a  
108 southern California and Mexico coastal form, distributed in coastal waters of California and  
109 the Pacific side of the Baja California peninsula and throughout the GoC, with a southernmost  
110 record possibly around San Blas, Nayarit, along the Mexican mainland (21°30' N)  
111 (corresponding to the previously described *T. gillii*); (2) a northern temperate offshore form,  
112 mainly distributed in offshore waters off the California coast, with possible southern records  
113 offshore off northern Baja California; and (3) an ETP offshore form, distributed in offshore  
114 waters off southern Baja California, in the lower GoC, and in offshore waters of the ETP,  
115 with a southernmost record possibly in waters around the Galapagos Islands (corresponding  
116 to the previously described *T. nuuanu*). Although Walker (1981) recognized the southern  
117 California/Mexico coastal form and the ETP offshore form as “at least modally distinct”, he  
118 avoided any taxonomic proposal, considering it “premature and beyond the scope” of his  
119 work. He also proposed that the northern temperate offshore form was more morphologically  
120 similar to the ETP offshore form than the southern California/Mexico coastal form, although  
121 this suggestion was based on a very limited sample size.

122         Using a larger sample size, Perrin et al. (2011) also investigated differences in skull  
123 morphology between the coastal and offshore dolphins found along the California coast (i.e.,  
124 southern California/Mexico coastal and northern temperate offshore forms). Their results  
125 indicated that the two forms have cranial differences that reflect distinct habitat use and prey

126 preferences; however, this study did not include specimens from the ETP or other areas in the  
127 eastern Pacific outside of California. Adding evidence of genetic differentiation (Segura et al.  
128 2006; Lowther-Thieleking et al. 2015; Segura-García et al. 2018) to differences in feeding  
129 ecology (Hanson and Defran 1993; Segura-García et al. 2018) and distribution (Guevara-  
130 Aguirre and Gallo-Reynoso 2016; Carretta et al. 2021), the California/Mexico coastal form  
131 and northern temperate offshore form are now recognized as separate coastal and offshore  
132 ecotypes, respectively, without reference to the nominal species (Perrin et al. 2011; Lowther-  
133 Thieleking et al. 2015; Carretta et al. 2021).

134         The coastal ecotype (i.e., previous southern California/Mexico coastal form) occurs  
135 within 1 km of shore from northern California south to the Pacific side of northern Baja  
136 California (Defran et al. 2015; Lowther-Thieleking et al. 2015; Carretta et al. 2021). The  
137 offshore ecotype (i.e., previous northern temperate offshore form) is found in deeper waters  
138 (> 4 km from shore) between California and Washington (Barlow 2003), and may also be  
139 occasionally found in northern offshore waters off Canada (Halpin et al. 2018). The southern  
140 limit of the offshore ecotype is less well defined but might extend at least along the deeper  
141 waters off the Baja California Peninsula (Carretta et al. 2021), and may overlap with ETP  
142 offshore bottlenose dolphins (see below).

143         Coastal and offshore ecotypes are recognized within the GoC where they exhibit a  
144 more latitudinal than longitudinal distribution, with some overlap. Coastal dolphins are more  
145 commonly found towards the upper GoC, whereas offshore dolphins are found towards the  
146 lower GoC (Segura et al. 2006; Segura-García et al. 2018). Although Walker (1981)  
147 suggested the California/Mexico coastal form was also found throughout the GoC, recent  
148 findings (Segura-García et al. 2018) have identified genetic and ecological differences  
149 between coastal bottlenose dolphins on either side of the Baja Peninsula, suggesting that the  
150 GoC coastal dolphins are different from the coastal dolphins found in California waters and

151 the Pacific side of the Baja California. Lowther-Thieleking et al. (2015) also suggested (based  
152 on mitochondrial DNA) that California (CA) coastal and GoC coastal dolphins are genetically  
153 differentiated, while the CA offshore ecotype was more genetically similar to both GoC  
154 ecotypes than to the CA coastal dolphins.

155 Little is known about the ETP offshore bottlenose dolphin form and their degree of  
156 differentiation from the offshore ecotype found along the Baja California Peninsula. The ETP  
157 dolphins are described as occurring in deeper waters off southern Baja California, the Pacific  
158 coast of Central America and Colombia and Ecuador, out to approximately 120° W (Walker  
159 1981; Hamilton et al. 2009). Their northern range limit is suggested to be between Magdalena  
160 Bay (ca. 24° N) on the Pacific side of Baja California, and Santa Catalina Island, Mexico (ca.  
161 25° N) within the Gulf of California, whereas their southern limit might extend to at least the  
162 Galapagos Islands, ca. 2° S (Walker 1981).

163 Although previous studies have revealed differentiation between bottlenose dolphins  
164 throughout the eastern Pacific, there is still a need to understand the level of divergence  
165 between the bottlenose dolphins in the area. In this study, we re-examine morphological  
166 differentiation among the three previously recognized forms of bottlenose dolphins in the  
167 eastern Pacific (Northern Hemisphere) with an attempt to clarify their taxonomic status and  
168 distribution.

169

## 170 **Material and Methods**

### 171 **Samples**

172 We examined 135 physically mature skulls of common bottlenose dolphins (*Tursiops*  
173 *truncatus*) collected in the Pacific Ocean, which we divided into five geographic groups based  
174 on the region from which the skulls were originally obtained (Fig. 1; Online Resource 1). This

175 data set comprised 75 skulls collected along the west coast of California (CA)<sup>1</sup> (ca. 40° N to  
176 32° N), four from the Gulf of California (GoC), including two from the upper GoC (ca. 31° N)  
177 and two from the lower GoC (ca. 27° N; Santa Catalina Island), 30 from the eastern tropical  
178 Pacific (ETP), which included 28 from the tuna purse seine fishery collected between Mexico  
179 and Panama (ca. 7° N to 19° N) more than 200 km from shore, one from the waters around  
180 San Juanito Island (ca. 21° N; approximately 100 km from shore) and one sample from the  
181 Galapagos archipelago (approximately 1,000 km from the continental shore of Ecuador), four  
182 samples from the eastern South Pacific (ESP) south of 10° S, and 19 skulls collected from a  
183 drive fishery off Taiji, Japan in the western North Pacific (WNP). Three skulls were  
184 unassignable to a geographic group as two had original collection location information listed  
185 only as “Baja California, Mexico”, and the other as “Mexico”.

186 All the skulls from the CA group were previously used in a study by Perrin et al.  
187 (2011) for an examination of morphological differentiation between offshore and coastal  
188 ecotypes from California waters. A total of 61 of the CA samples had also been sequenced for  
189 the mitochondrial DNA (mtDNA) control region and the ecotype defined whenever possible  
190 according to the mtDNA haplotype for 47 of these samples (offshore: n = 14; coastal: n = 33)  
191 following data in Perrin et al. (2011) (see also Online Resource 1 in the current study). Our  
192 data set also includes 30 skulls previously used in Walker (1981): 17 classified as "Eastern  
193 Tropical Pacific offshore form" (15 ETP skulls and two lower GoC skulls); one as "northern  
194 temperate offshore form" (a CA offshore skull); and 12 as "southern California and Mexico  
195 coastal form" (ten CA coastal skulls and two upper GoC skulls) (Online Resource 1).

196 Included in the data set above are the two eastern Pacific type specimens: the holotype  
197 of *Tursiops nuuanu* Andrews, 1911 (deposited in the American Museum of Natural History

---

<sup>1</sup> A majority of the CA samples (n = 61) were strandings, 11 were captured in offshore waters (around Santa Catalina and St. Miguel Islands) and three captured in coastal waters (around San Diego).

198 under the accession number AMNH 35045), for which the skull was available, and the  
199 holotype of *T. gillii* Dall, 1873 (deposited in the Smithsonian National Museum of Natural  
200 History under the accession number USNM A13022), which comprises only the lower jaw.  
201 Finally, we also measured the skull of the holotype of *T. truncatus* (Montagu, 1821) collected  
202 in the River Dart in southwestern England (deposited in the Natural History Museum, London  
203 under the accession number NHMUK 353a), and also used the cranial measurements from  
204 Perrin et al. (2007) for the holotype of *T. aduncus* (Ehrenberg, 1832) collected in the Dahlak  
205 Archipelago of Ethiopia in the Red Sea (deposited in the Zoologisches Museum Berlin under  
206 the accession number ZMB66400). Thus, a total of 137 specimens were used in this study  
207 (Online Resource 1).

208

## 209 **Skull Measurements**

210 For each skull, where available, a total of 20 measurements (Online Resource 2) were  
211 taken with dial and digital calipers and anthropometers by APBC, FIA, and WFP as in Perrin  
212 (1975a). Measurements made by FIA and WFP were calibrated to those made by APBC with  
213 linear regressions fit to sets of skulls measured by both pairs of authors ( $n = 6$  for FIA and  
214 APBC;  $n = 23$  for WFP and APBC). We only measured skulls defined as physically mature  
215 following the definition in Perrin and Heyning (1993). For the holotype *T. gillii*, only LORO,  
216 RAML, and RAMH were collected since the specimen is only represented by the lower  
217 mandible. Each measurement was also paired with each of the other 19 measurements,  
218 resulting in 190 unique pairs of measurements. The ratio was then computed for all 190  
219 unique combinations and used in the analyses of sexual dimorphism and geographical  
220 variation described below. All analyses and summaries described in the methods were  
221 conducted using R version 4.1.0 (R Core Team 2021).

222

## 223 **Sexual Dimorphism**

224           We investigated the presence of sexual dimorphism in order to determine whether  
225 analyses of geographical variation would be influenced by differences between the sexes. We  
226 conducted Kolmogorov-Smirnov (KS) tests of differentiation between sexes for each of the  
227 original measurements. Tests were conducted using the R *ks.test* function for all samples and  
228 within each group that contained more than 10 samples (CA, ETP, and WNP). We also  
229 created Random Forest models using the *randomForest* package (Liaw and Wiener 2002) to  
230 quantify the degree to which sex could be classified as a function of the original  
231 measurements and the measurement ratios. We first created one model using data from all  
232 skulls with sex information available, followed by a separate model for each group as in the  
233 KS tests. Within the CA group, we also evaluated sexual dimorphism within the coastal and  
234 offshore ecotypes separately. CA samples were classified to an ecotype based on the findings  
235 of Perrin et al. (2011) using the mtDNA data (coastal: 33; offshore: 14; unassigned: 28). In  
236 order to create balanced models, the same number of samples was randomly selected for each  
237 sex without replacement for each tree in the Random Forest as described in Archer et al.  
238 (2017). For each model, 10,000 trees were run and the number of measurements sampled at  
239 each node (the *mtry* parameter) was left at the *randomForest* default of the square root of the  
240 total number of measurements.

241

## 242 **Geographical Variation**

243           The morphological distinctiveness of each geographic group was evaluated with  
244 another set of Random Forest models. As with the models for sexual dimorphism described  
245 above, these models classified groups as a function of the original measurements and the  
246 measurement ratios. Only the three groups with a sufficient number of samples for statistical  
247 power were examined (CA, ETP, WNP). Random Forest models were constructed with the

248 CA coastal and offshore ecotypes considered together as a single CA group as well as  
249 separate groups. Additionally, a Random Forest model was also conducted to classify just the  
250 CA coastal and offshore ecotypes alone. All of these models were also balanced as described  
251 above. A total of 10,000 trees were run for each model. The relative importance of  
252 measurements and measurement ratios to the classification accuracy of a model was assessed  
253 using the Mean Decrease in Accuracy metric (Liaw and Wiener 2002). We identified  
254 measurements that were significantly more important than a randomly distributed  
255 measurement with the permutation test implemented in the *rfPermute* R package (Archer  
256 2020). A total of 1,000 permutation replicates were run for each Random Forest model to  
257 create a null distribution of importance scores from which p-values were estimated. These  
258 models were also used to assign skulls that could not be stratified due to low sample sizes  
259 (GoC and ESP) as well as the three skulls that had ambiguous collection localities.

260

## 261 **Unsupervised Clustering**

262 We also identified distinct clusters of skulls in the Pacific Ocean using the  
263 unsupervised Density Clustering algorithm of Rodrigues and Laio (2014) as implemented in  
264 the *densityClust* R package (Pedersen et al. 2017). This method first identifies peaks of  
265 clusters by computing the local density ( $\rho$ ) of each individual and its distance ( $\delta$ ) to the  
266 nearest individual of higher density. Other individuals are then assigned to the cluster  
267 belonging to the nearest peak of higher density (Rodrigues and Laio 2014). The input for  
268 Density Clustering is a matrix of pairwise distances between samples based on the original  
269 measurements. In order to avoid having this distance overly influenced by differences in the  
270 absolute values measurements, all of the original measurements were first scaled and centered  
271 such that they each had a mean of zero and standard deviation of one. A matrix of pairwise  
272 Euclidean distances among skulls was then computed from these scaled measurements.

273 Ordination of the same scaled original skull measurements was also performed with a  
274 Principal Component Analysis (PCA) as implemented in the R *prcomp* function, and the  
275 distributions of clusters identified by Density Clustering and *a priori* defined groups were  
276 visualized along the first two components.

277

### 278 **Holotype Assignment**

279 Random Forest classification models were also created for each of the four holotype  
280 specimens to evaluate the taxonomic affiliations of the CA, ETP, and WNP groups. In each  
281 model, only original measurements present in the holotype specimen under consideration  
282 were used (Online Resource 3) and all samples that did not have missing data for these  
283 measurements were used to train the model. The type specimens themselves were excluded  
284 from the training data for the model. Parameters for these Random Forest models followed  
285 descriptions above. The models were then used to compute the assignment probabilities of  
286 each holotype specimen to each of the three groups.

287

### 288 **Total Body Length**

289 We evaluated differences in the total external body length (TL) between male and  
290 female samples from the CA, ETP, and WNP groups. Of the four holotypes, only *T. nuuanu*  
291 had a TL available (7 ¼ feet – estimated as 221 cm) and it was included in this analysis. A  
292 non-parametric Kolmogorov-Smirnov test (KS-test) using the *ks.test* function was performed  
293 to evaluate whether body length varied among the three groups (CA, ETP, WNP).  
294 Distributions of body length (mean and standard deviation) were summarized for each group  
295 by sex.

296

297

## **Results**

## 298 **Measurement Summaries**

299           A total of 121 skulls, including the holotypes of *Tursiops nuuanu* and *T. aduncus*, had  
300 data available for all of the 20 original measurements. The three mandibular measurements  
301 (LORO, RAML, RAMH) and the distance from the tip of the rostrum to the internal nares  
302 (TIPP) were most frequently missing across skulls (varying from 7 to 12 individuals).  
303 Therefore, these four measurements were excluded from the majority of the multivariate  
304 analyses requiring complete data sets (with exception of the holotype assignment analyses –  
305 see below). Furthermore, six individuals were missing data for at least one of the other 16  
306 cranial measurements (Online Resource 4): two samples in the CA group (one missing  
307 measurement each), two samples in the GoC group – collected at Santa Catalina Island, Baja  
308 California (1-2 missing measurements), and the holotypes *T. gillii* and *T. truncatus*. For the  
309 holotype *T. gillii*, only the three mandibular measurements were obtained (i.e., the holotype is  
310 only the lower jaw). The holotype *T. truncatus* presented four missing measurements: the  
311 three mandibular measurements (LORO, RAML, RAMH) and EXTN (a measurement  
312 available for the majority of the samples). Therefore, these six specimens were excluded from  
313 all multivariate analyses based on the 16 cranial measurements available for the majority of  
314 the data set (i.e., with the exclusion of LORO, RAML, RAMH, and TIPP), resulting in a total  
315 of 131 skulls with complete data for the 16 measurements. Summaries of measurements for  
316 each group are provided in Online Resource 4.

317

## 318 **Sexual Dimorphism**

319           A total of 115 samples with complete data for the 16 measurements had sex  
320 information available (females: 47; males: 68). Of these, two males belonged to GoC and ESP  
321 groups, respectively, and the other 113 belonged to one of the three main groups (i.e., WNP,  
322 CA, and ETP): 65 from CA (females: 27; males: 38), 29 from the ETP (females: 13; males:

323 16), and 19 from WNP (females: 7; males: 12). Within the CA group, 28 coastal (females: 13;  
324 males: 15) and 14 offshore (females: 5; males: 9) samples had sex information available and  
325 complete data for the 16 original measurements. No strong evidence of sexual dimorphism  
326 was observed when evaluating the differences in skull morphology based on sex using the full  
327 data set, within each group, or within each CA ecotype. A KS-test indicated that most width  
328 measurements (ROSH, PREO, POST, ZYGO, PMXM, FOSH, ANTO) were significantly ( $p$   
329  $\leq 0.05$ ) greater for males than females, by an average of 6 mm in the CA group. Only ANTO  
330 was significantly larger for males in the ETP samples, and there were no differences in the  
331 WNP. In Random Forest models, the sex of fewer than 70% of the specimens could be  
332 correctly classified (Table 1). Thus, given the low absolute difference in measurements and  
333 lack of significant diagnosability, in further analyses of geographical variation, skulls were  
334 not separated by sex in order to maximize sample sizes of groups.

335

### 336 **Geographical Variation**

337 The Random Forest model based on skulls from CA (coastal and offshore ecotypes  
338 combined), ETP, and WNP correctly classified 103 of the 121 (85%) skulls from these three  
339 groups (Table 2). All of the ETP skulls (100%) were correctly classified, while only 57 of the  
340 72 (79%) CA and 16 of the 19 (84%) WNP skulls were correctly classified. When the CA  
341 skulls were separated into coastal ( $n = 32$ ; one coastal sample was excluded due to missing  
342 data) and offshore ( $n = 14$ ) ecotypes in a separate model, 29 (96.7%) of the ETP skulls were  
343 correctly classified and one ETP skull was misclassified as CA offshore (Table 2). CA coastal  
344 and offshore had 81% and 43% of their skulls correctly classified, respectively. Only 15 of  
345 the 19 (79%) skulls from WNP were correctly classified in this model. In the model based  
346 only on the CA ecotypes, 84.4% of the coastal and 78.6% of the offshore skulls were  
347 correctly classified.

348 In the two Random Forest models classifying CA, ETP, and WNP skulls (with CA  
349 ecotypes both combined and separated), there were eight measurements that best explained  
350 the differentiation among groups based on Mean Decrease in Accuracy importance scores  
351 (significant scores higher than 25.0;  $p \leq 0.01$ ). The measurements reflected differences in the  
352 overall length (CBLN) and width (ZYGO, POST, and PREO) of the skull, as well as in the  
353 width of the rostrum (ROSW and ROSH), premaxillaries (PMXM) and internal nares (INTN)  
354 (Online Resource 5).

355 Skulls of specimens collected in the ETP were significantly and diagnosably smaller  
356 than those in other regions. For example, when considering overall length and width of the  
357 skull, ETP skulls were relatively shorter (CBLN: 423-512 mm) and narrower (ZYGO: 225-  
358 257 mm) than those from CA (CBLN: 470-572 mm; ZYGO: 239-304 mm) and WNP (CBLN:  
359 496-578 mm; ZYGO: 263-301 mm) groups (Fig. 2). We also detected a narrower rostrum,  
360 premaxillaries, and internal nares in the ETP skulls. Lastly, the Random Forest models  
361 indicated that the skulls from the upper GoC ( $n = 2$ ) and the ESP ( $n = 4$ ) were more likely to  
362 be classified to CA or WNP skulls than to the ETP (Table 3). Of the three unassigned skulls,  
363 only one was more likely to be classified to the ETP (Table 3).

364

### 365 **Clustering and PCA**

366 We used all specimens collected in the Pacific Ocean ( $n = 130$ ) with complete data for  
367 the 16 cranial measurements in the Density Clustering analysis. The *densityClust* parameters  
368 were set to  $\delta = 3.032$  and  $\rho = 8.151$  after evaluation of the decision graph, and two clusters  
369 were identified (Fig. 3). As seen in Table 4, Cluster 1 ( $n = 98$ ) was composed of a majority of  
370 the CA skulls ( $n = 69$ ), all of the skulls from the WNP ( $n = 19$ ) and the ESP ( $n = 4$ ), two  
371 skulls from upper GoC, two samples collected in the ETP, and two unassigned samples.  
372 Cluster 2 ( $n = 32$ ) was composed of most of the ETP skulls ( $n = 28$ ; and included the holotype

373 *T. nuuanu*), three skulls collected in CA waters (one CA coastal and two CA offshore), and  
374 one unassigned skull. Thus, 96.9% of the specimens knowingly collected outside the ETP  
375 composed Cluster 1, whereas 93.3% of the specimens collected in the ETP were in Cluster 2.  
376 It is noteworthy that the three CA skulls assigned to Cluster 2 were among the smallest  
377 samples in the CA data set based on overall length (CBLN: 479-491 mm) and width (ZYGO:  
378 240-247 mm) of the skull, whereas the two ETP samples assigned to Cluster 1 were among  
379 the biggest samples in the ETP data set (CBLN: 495-511.5 mm; ZYGO: 242-257 mm)  
380 (Online Resource 4).

381 The first two components in the PCA accounted for 75.4% of the variance in the  
382 measurements. The first component, which accounted for 65.2% of the variance, had negative  
383 loadings on all measurements, indicating that it was related to variability in overall skull size.  
384 The second component (10.2% of the variance) was mainly defined by measurements along  
385 the length of the skull (CBLN, ROST, UPRO, and TIPN) and those describing the width of  
386 the external nares (EXTN) and the shape of the temporal fossa (FOSH and FO SL) (Online  
387 Resource 6). All of the Cluster 2 skulls had more positive values on the first component,  
388 while the Cluster 1 skulls tended to be more negative on this component (Fig. 4). No visible  
389 differences were detected between Cluster 1 and Cluster 2 on the second component,  
390 suggesting that differences in size are the primary driver of the differentiation between the  
391 clusters, with Cluster 1 skulls being larger than Cluster 2.

392

### 393 **Holotype Assignment**

394 Random Forest models were conducted using all ETP, CA, and WNP samples that had  
395 complete sets of the measurements present in each of the four holotype skulls. The *T. nuuanu*  
396 and *T. aduncus* holotypes had all 20 measurements so we were able to classify them in a  
397 single model, while the other two specimens (*T. truncatus* and *T. gillii*) were only classifiable

398 based on models built with the measurements each had present. The holotypes of *T. truncatus*  
399 (16 measurements) and *T. gillii* (three mandibular measurements) were both assigned to the  
400 CA group with 73% and 88% probability, respectively. The *T. nuuanu* holotype was assigned  
401 to the ETP group with 80% probability. Of the three groups available (i.e., ETP, CA, WNP),  
402 *T. aduncus* was assigned to ETP with 69% probability. None of the holotypes strongly  
403 assigned to WNP, although *T. truncatus* was more similar to skulls in this group than the  
404 other three holotypes (Table 5).

405

### 406 **Total Body Length**

407 Total external body length (TL) was available for all 63 samples from CA (27  
408 females, 34 males, 2 unknown sex), 28 from the ETP (13 females, 14 males, 1 unknown sex),  
409 and 19 from WNP (7 females, 12 males). The KS-tests between groups indicated that each  
410 had significantly different ( $p \leq 0.001$ ) TL distributions. Samples from the ETP had the  
411 smallest total body length (mean ♀: 243.85 cm; mean ♂: 255.86 cm), followed by CA (mean  
412 ♀: 274.63 cm; mean ♂: 297.94 cm) and WNP (mean ♀: 297.86 cm; mean ♂: 305.42 cm)  
413 (Fig. 5). It is noteworthy that for the CA group, both coastal and offshore samples were  
414 grouped together, which might be contributing to the large range in size for this group in Fig.  
415 5. There is also indication of sexual dimorphism within each group for TL, with males  
416 tending to be larger than females in all groups, by approximately 8-23 cm. Total length for the  
417 holotype *T. nuuanu* was 221 cm, being slightly smaller than the minimum size observed in the  
418 ETP group and suggesting that it is also more similar to the ETP samples for the total external  
419 body length.

420

421

## 421 **Discussion**

422           The results of our analyses demonstrate significant morphological differentiation  
423 between bottlenose dolphins collected from various regions of the Pacific Ocean, with skulls  
424 separating into two distinct clusters. The unsupervised clustering analysis placed 93.3% of the  
425 ETP samples into a single cluster (Cluster 2), whereas 96.9% of the samples outside the ETP  
426 (i.e., CA, ESP, GoC, and WNP) formed the other cluster (Cluster 1). The two samples from  
427 the upper GoC that were assigned to the same cluster as the CA samples showed congruence  
428 with previous findings: Walker (1981) classified these two samples as belonging to the  
429 southern California/Mexico coastal form. Due to missing data, we were unable to evaluate if  
430 the other two GoC samples, collected from Santa Catalina Island (lower GoC), were more  
431 similar to the ETP group, as previously suggested by Andrews (1911) and Walker (1981).

432           Although the two CA ecotypes (offshore and coastal) were not diagnosably distinct  
433 from each other, we observed slight cranial differences between them that together with the  
434 analyses reported in Perrin et al. (2011) support the finding that the CA ecotypes are distinct  
435 populations, possibly in an early stage of divergence, and should continue to be managed  
436 separately to preserve local ecological adaptations. However, in our analysis, the degree of  
437 differentiation between CA ecotypes was low in the context of an analysis of geographical  
438 variation including skulls from WNP and the ETP. Thus, for the purposes of this analysis, we  
439 consider these ecotypes to be a single group. Additionally, while Perrin et al. (2011) also  
440 reported the presence of sexual dimorphism for some cranial variables in the CA coastal  
441 ecotype, we did not detect sexual dimorphism in any of the three main groups examined to a  
442 degree that is likely to bias our analysis of geographical variation.

443           ETP offshore bottlenose dolphins were found to be diagnosably distinct when  
444 compared to dolphins from CA and the WNP, with the ETP samples being significantly  
445 smaller than the other groups based on both skull and body size. In fact, with a CBLN ranging  
446 from 423-512 mm and an observed maximum total body length of 287 cm, the ETP offshore

447 bottlenose dolphin is the smallest common bottlenose dolphin reported from the Atlantic and  
448 Pacific coasts of the Americas, and of similar size range to Tamanend's bottlenose dolphin (*T.*  
449 *erebennus*), a small coastal species described for the western North Atlantic (see Table 6 in  
450 Costa et al. 2022).

451 In a variety of locations, morphological differentiation between parapatric coastal and  
452 offshore dolphin ecotypes has been identified, for example long-beaked and short-beaked  
453 common dolphins off California (Heyning and Perrin 1994), common bottlenose and  
454 Lahille's bottlenose dolphins in the western South Atlantic (Costa et al. 2016), and common  
455 and Tamanend's bottlenose dolphins in the western North Atlantic (Costa et al. 2022). In  
456 these cases, the morphological differences in the skull have been primarily attributed to  
457 differences in prey preference (Heyning and Perrin 1994; Costa et al. 2016, 2022). However,  
458 the ETP offshore bottlenose dolphins, the CA offshore and WNP dolphins are all categorized  
459 as offshore dolphins: the majority of the ETP dolphin samples were obtained through  
460 incidental catch in oceanic waters, and, as previously reported by Walker (1981), the  
461 bottlenose dolphins of this area seem to feed primarily on squids and small epipelagic and  
462 mesopelagic fishes, differing from the feeding habits of the CA coastal ecotype, which mainly  
463 feeds on nearshore fishes such as croakers (Sciaenidae) and surfperches (Embiotocidae)  
464 (Walker 1981; Hanson and Defran 1993). Although no stomach contents have been examined  
465 for the CA offshore ecotype to date, Perrin et al. (2011) suggested its diet might parallel the  
466 ETP dolphins due to the similarity in habitat preference (i.e., oceanic waters). So why do the  
467 ETP bottlenose dolphins differ morphologically from the other offshore bottlenose dolphins  
468 in the eastern North Pacific? The answer may lie in the unique physical oceanographic

469 characteristics of the eastern tropical Pacific, which appear to have influenced the divergence  
470 of several delphinids in the region (e.g., Au and Perryman 1985; Reilly 1990).

471         Comparable to the results obtained in our study of *Tursiops* skulls, significant  
472 differences in the overall length and width of skulls were observed in two *Stenella* species in  
473 the ETP – the spinner dolphin *S. longirostris* and the pantropical spotted dolphin, *S.*  
474 *attenuata*. The differences in these characteristics, along with external morphology, and  
475 differences in habitat, were considered important enough to distinguish spinner and  
476 pantropical spotted dolphin subspecies (Perrin 1972a, 1972b, 1975a, 1975b, 1990). More  
477 specifically, the offshore pantropical spotted subspecies (*S. a. attenuata*) exhibits both a  
478 shorter and narrower skull than the coastal subspecies (*S. a. graffmani*) (Perrin 1975a), and  
479 the eastern spinner dolphin subspecies (*S. l. orientalis*) found in ETP offshore waters has a  
480 shorter and also narrower skull when compared to the large coastal spinner dolphin (*S. l.*  
481 *centroamericana*), as well as a smaller skull than the globally distributed nominate subspecies  
482 (Perrin 1990). Like the bottlenose dolphins of the ETP group, the two offshore subspecies (*S.*  
483 *a. attenuata* and *S. l. orientalis*) found in the ETP were also considered the smaller form.

484         These *Stenella* subspecies are distributed in the ETP in a region of high productivity,  
485 including the Costa Rica Dome, a biodiversity hotspot, influenced by warm and highly  
486 stratified surface waters, with a shallow thermocline and oxygen minimum layer (Fiedler et  
487 al. 2017). The distribution of the ETP offshore bottlenose dolphin overlaps at least in part  
488 with this highly productive region of the ETP, suggesting the factors influencing divergence  
489 in the *Stenella* species may also be driving evolutionary divergence in *Tursiops* in the ETP. It  
490 has been suggested that adaptation to different thermal habitats can promote ecological  
491 speciation, where the differentially adapted populations usually exhibit a parapatric

492 distribution along the thermal gradient with reproductive isolation sometimes evolving as a  
493 result of this divergent adaptation (Keller and Seehausen 2012). While bottlenose dolphins in  
494 the eastern North and South Pacific are under the influence of the cold California and Peru  
495 Currents, respectively, ETP offshore bottlenose dolphins inhabit much warmer temperature  
496 regimes (Perrin et al. 1976; Findler et al. 2017). Furthermore, these warmer waters may also  
497 explain why ETP offshore bottlenose dolphins are smaller than their colder water  
498 counterparts, following predictions of Bergmann's rule (Meiri and Dayan 2003).

499         Geographic varieties within species with sufficient diagnostic distinctness can be  
500 considered different subspecies (see Winker 2010; Archer et al. 2017; Taylor et al. 2017). We  
501 observed a small classification error rate (less than 5%) in the group assignment for the ETP  
502 samples in all Random Forest models. The morphological differentiation observed suggests a  
503 low level of gene flow between the ETP offshore bottlenose dolphins and the other groups,  
504 indicating that they are likely to be on independent evolutionary trajectories. The ETP group  
505 was morphologically similar to the holotype of *T. nuuanu*, a species previously described  
506 from ETP waters. Although we also observed that *T. aduncus* was assigned to the ETP with  
507 almost 69% probability, this is likely due to similarities in size based on cranial measurements  
508 between both taxonomic groups. Jedensjö et al. (2020), who also examined the holotype *T.*  
509 *aduncus*, has shown that the skulls of *T. aduncus* are overall smaller, with a longer and  
510 narrower rostrum than *T. truncatus*. Furthermore, our ETP samples do not exhibit the  
511 morphological characteristics that distinguish *T. aduncus* from *T. truncatus* (e.g., premaxillary  
512 convexity from lateral view, premaxillary ‘pinch’ at approximately 1/3 rostral length from  
513 dorsal view; see Wang et al. 2000), being therefore more similar to *T. truncatus* in this sense,  
514 thereby ruling out the possibility that the ETP dolphins belong to *T. aduncus*.

515           In contrast, the holotype assignment indicated that the WNP and CA groups were  
516 more similar to the *Tursiops truncatus* holotype. A few of the WNP samples of this study (n =  
517 4) were also used in the worldwide morphological analyses performed in Costa et al. (2022)  
518 showing that they cluster with other worldwide distributed *T. truncatus* samples, and  
519 separately from the ETP samples. Further studies with larger sample sizes are needed to better  
520 investigate the relationship of these WNP samples with other *T. truncatus* samples collected  
521 worldwide. The CA samples were highly assigned to the nominal species *T. gillii* based on the  
522 three mandibular measurements but our results did not detect significant differences between  
523 the CA bottlenose dolphins and the common bottlenose dolphins collected outside the ETP  
524 when considering the overall skull. True (1889) had suggested that *gillii*-type skulls were  
525 similar to *truncatus*-type skulls based on shape and size, with the main difference between the  
526 two based on the size of the mandibular condyles and the position of the optic canal (True  
527 1889; p. 160). Taken together, our morphological findings, therefore, agree with the  
528 description of *T. gillii* as a junior synonym of the common bottlenose dolphin, *T. truncatus*. In  
529 addition, as suggested by Walker (1981), previous skulls classified as *gillii*-type specimens  
530 might in fact represent the coastal common bottlenose dolphins of California and Baja  
531 California.

532           Based on these findings and considering that we are limited to a single line of  
533 evidence (i.e., cranial morphology), we recognize the offshore bottlenose dolphins in the ETP  
534 as a distinct subspecies of common bottlenose dolphins: *Tursiops truncatus nuuanu*, the  
535 Eastern Tropical Pacific bottlenose dolphin. Further studies examining its distribution and  
536 genetic differentiation are necessary to better establish the subspecies range and level of  
537 evolutionary divergence from the bottlenose dolphins found elsewhere, as well as its

538 conservation status. In particular, the full distribution of the ETP bottlenose dolphins remains  
539 unresolved. It is possible that the northern limit of the ETP offshore dolphins overlaps with  
540 the southern limit of the CA offshore ecotype. Although the southern limit of the CA offshore  
541 ecotype is not well defined outside the U.S. waters, it appears to be continuously distributed  
542 through the Pacific coast of Baja California (Carretta et al. 2021). For the suggested southern  
543 limit of the ETP offshore bottlenose dolphins (i.e., Galapagos), our single sample from the  
544 area was also classified as an ETP dolphin in our analyses. Sightings of bottlenose dolphins  
545 also continue south of the ETP, into the eastern South Pacific (ESP), where further coastal  
546 and offshore ecotypes have been recognized (Van Waerebeek et al. 1990, 2017). There are  
547 also suggestions that bottlenose dolphins in offshore waters off Colombia and Ecuador belong  
548 to the same population as the ETP offshore bottlenose dolphins rather than to bottlenose  
549 dolphins found closer to the coast or farther south (Van Waerebeek et al. 2017). However,  
550 although skulls (examined in the current study) from the eastern South Pacific (mainly from  
551 Peru and Chile) and those from upper Gulf of California were considered more similar to the  
552 CA and WNP samples, our ability to infer the identity of animals from these areas  
553 immediately to the north and south of the ETP range are based on a small sample size.  
554 Further, because our data set did not include samples from Hawaii, from east of  
555 approximately 90° W in the Costa Rica Dome, or from coastal waters in Central America, we  
556 cannot comprehensively define the distribution of this morphological form. Further work,  
557 which should include the use of genetic markers, is necessary to understand the distribution  
558 and hence to understand the ecological factors that may be driving the morphological  
559 divergence of this ETP offshore form.

560

561 **Conclusion**

562           In this study, we examined morphological differentiation among three previously  
563 recognized forms of bottlenose dolphins in the eastern North and tropical Pacific Oceans with  
564 the aim of clarifying their taxonomy and better defining their geographic distributions. We  
565 also compared the bottlenose dolphins of the eastern Pacific to bottlenose dolphins collected  
566 in western North Pacific waters offshore of Japan. Our results indicated significant  
567 morphological differentiation among bottlenose dolphins in the Pacific Ocean, with skulls  
568 separating into two distinct clusters. The ETP offshore bottlenose dolphin cluster comprised  
569 skulls that were smaller and more diagnosable than those from other groups. We did not  
570 detect diagnostic differences between the CA ecotypes; however, the observed differences  
571 suggest they are different populations, possibly in an early stage of divergence. We suggest  
572 that the distinct environmental conditions in the ETP (i.e., distinct oxygen, salinity and  
573 temperature conditions), associated with possible differences in feeding ecology, may be  
574 influencing the evolutionary differentiation of the bottlenose dolphins in the eastern Pacific.  
575 Given our morphological findings, we recognize the offshore bottlenose dolphins in the  
576 eastern tropical Pacific as a distinct subspecies: *Tursiops truncatus nuuanu*.

577

578 **Systematics**

579                           Order Artiodactyla Owen, 1848

580                                   Cetacea Brisson, 1762

581   Odontoceti Flower, 1867

582   Family Delphinidae Gray, 1821

583   Subfamily Delphininae LeDuc 1997

584   Genus *Tursiops* Gervais, 1855

585   *Tursiops truncatus* (Montagu, 1821)

586 *Tursiops truncatus nuuanu* Andrews, 1911

587

588 **Type Specimen and Locality**

589 The name *Tursiops nuuanu* was originally used to describe the holotype of a  
590 bottlenose dolphin collected by John T. Nichols from the eastern tropical Pacific on 6  
591 December 1906 at approximately 12° N, 120° W (Nichols 1908). The total body length was 7  
592 ¼ feet (approximately 221 cm) and sex unknown. The skull from this specimen is deposited  
593 in the American Museum of Natural History as AMNH 35045, and was named and described  
594 by Andrews (1911).

595

596 **Etymology**

597 The species name was derived from the name of the ship from which J. T. Nichols  
598 collected the first specimen from the eastern tropical Pacific (Andrews 1911), which in turn is  
599 from the Hawaiian word, “nu’uanu”, meaning “cliff”. The species was recognized and later  
600 was considered as a junior synonym of the common bottlenose dolphin, *T. truncatus*. Walker  
601 (1981) used the term Eastern Tropical Pacific offshore form to refer to the individuals of this  
602 group. We recommend the common name, Eastern Tropical Pacific bottlenose dolphin for the  
603 subspecies *Tursiops truncatus nuuanu* based on its restricted distribution to this region (see  
604 *Distribution* below). The subspecies name was registered in ZooBank under the LSID:  
605 urn:lsid:zoobank.org:pub:B9715F20-CEBF-419D-A456-3D9A9D8E22DE.

606

607 **Diagnosis**

608 The subspecies *Tursiops truncatus nuuanu* differs from the nominate subspecies *T. t.*  
609 *truncatus* in California waters by skull morphometrics, where the former presents a smaller  
610 skull, with relatively short and narrower rostrum. Further differentiation has been described

611 based on skull morphology (Andrews 1911; Walker 1981; this study), body length (this  
612 study), and distribution (Walker 1981; this study). There is also some indication of  
613 differentiation based on sexual maturity (Walker 1981). However, more studies are needed to  
614 investigate further differentiation based on other lines of evidence, such as genetic analyses.

615 This is a small subspecies of *Tursiops truncatus*, with total body length reaching at  
616 least 287 cm (mean ♀: 243.85 cm; mean ♂: 255.86 cm). The condylobasal length in  
617 physically mature skulls ranges from 423 mm to 512 mm (based on our data set). The  
618 physically mature skulls have a relatively short (based on our data set: 228 mm to 283 mm)  
619 and narrow (based on our data set: 68 mm to 83 mm) rostrum, and slightly narrow internal  
620 nares (based on our data set: 67 mm to 79 mm). No sexual dimorphism was detected based on  
621 the cranial morphology, but it is possible that males are larger than females based on total  
622 external body length.

623 The coloration of the holotype of *T. nuuanu* was described as “slaty black, grayer  
624 from throat to vent” (Nichols 1908) and its total body length was approximately 221 cm  
625 (originally described as 7 ¼ feet). A very brief description of its stomach contents was also  
626 provided: “mostly large shrimp-like animals; also a few fish, and perhaps other food matter,  
627 and many parasitic worms” (Nichols 1908).

628

## 629 **Distribution**

630 *Tursiops truncatus nuuanu* is restricted to the eastern tropical Pacific (ETP), with the  
631 northern limit around 25° N, southern limit around 2° S, and western limit at least at 120° W  
632 (based on the holotype location), and likely a more offshore habitat preference, i.e.,  
633 preference for the deeper waters of the ETP (Walker 1981). Andrews (1911) suggested that  
634 two specimens stranded in Santa Catalina Island (25°40' N) in the lower Gulf of California  
635 (AMNH 31830 and AMNH 31831) were similar to the *nuuanu*-type based on the shape of the

636 vomer and size of the temporal fossa. However, in this study we were unable to confirm this  
637 due to the extent of missing data from these skulls (i.e., several cranial structures were broken  
638 and the mandibles were missing). Specimens from the upper Gulf of California and north of  
639 25° N in the coastal and offshore waters of Baja California (Pacific side) and southern  
640 California were considered more morphologically similar to the *truncatus*-type; however, our  
641 inferences for the GoC were based on a small sample size. The suggested southern limit for  
642 this subspecies encompasses the Galapagos area (Walker 1981) and might also include  
643 offshore waters off Colombia and Ecuador (Van Waerebeek et al. 2017). This area is  
644 influenced by both warmer (Panama Current) and colder (Humboldt/Peru Current) water  
645 currents. The single skull from this region used in our study was considered more similar to  
646 the *nuuanu*-type (USNM 258642), differing from other samples from the eastern South  
647 Pacific (from farther south than the subspecies' southern limit) (Fig. 6). However, these  
648 inferences were also based on a small sample size. Therefore, more samples from these  
649 northern and southern locations, as well as samples from Hawaii and those east of  
650 approximately 90° W in the Costa Rica Dome, and inhabiting coastal waters in the Pacific  
651 Central America need to be included in future studies to better define the distribution of this  
652 subspecies.

653

#### 654 **Remarks**

655 Hershkovitz (1963) was the first to treat *Tursiops nuuanu* as a synonym of *T.*  
656 *truncatus*, but the confusion of species recognition within *Tursiops* can be seen when  
657 Hershkovitz (1966) reversed himself and made *T. nuuanu* a synonym of *Tursiops truncatus*  
658 *aduncus*.

659

660

#### **Data Availability**

661 The dataset generated and analyzed during the current study is available in the Figshare  
662 repository, <https://doi.org/10.6084/m9.figshare.20769460>

846

#### 847 **Acknowledgements**

848 We dedicate this work to Dr. William F. Perrin, who passed on July 11, 2022. Starting  
849 in the late 1960s, his research in the eastern tropical Pacific was instrumental in highlighting  
850 the killing of dolphins in the tuna purse-seine fishery and played a crucial role in creation of  
851 the Marine Mammal Protection Act of 1972. Additionally, he is considered the father of  
852 modern marine mammal taxonomy due to his pioneering work on both small cetaceans and  
853 large whales. Dr. Perrin approved the submission of this manuscript prior to his passing, but  
854 sadly passed before its acceptance and publication. We thank James Mead, John Ososky, and  
855 Michael McGowen (Smithsonian National Museum of Natural History) for the sample access  
856 provided to APBC and FIA. Our acknowledgements are also extended to Neil Duncan and

857 Eleanor Hoeger (American Museum of Natural History, New York) for access to specimens,  
858 including the holotype of *T. nuuanu* (AMNH 35045), and to Richard Sabin (Natural History  
859 Museum, London) for his help with access to the holotype of *T. truncatus* (NHMUK 353a).  
860 We are grateful to Anke Klueter, who assisted FIA during the collection of measurements of  
861 some of the specimens used. We also thank all curators and collection managers that provided  
862 access to specimens to WFP in previous years (California Academy of Sciences, Los Angeles  
863 County Museum, Santa Barbara Museum of Natural History, San Diego Natural History  
864 Museum, Museum of Comparative Anatomy, American Museum of Natural History, and  
865 Smithsonian National Museum of Natural History), and to Toshio Kasuya, who collected the  
866 19 Taiji skulls (offshore Japan – WNP) used in this study and deposited in the Smithsonian  
867 National Museum of Natural History. Special acknowledgments to Robert Brownell Jr.,  
868 Thomas Jefferson, and Phillip Morin for insightful comments and suggestions on the first  
869 versions of this manuscript, and to two anonymous reviewers for their comments on the final  
870 version. The scientific results and conclusions, in addition to any views or opinions expressed  
871 herein, are those of the authors and do not necessarily reflect those of NOAA or the  
872 Department of Commerce.

873

874

### **Supplementary Information**

875 **Online Resource 1:** Collection information for specimens measured.

876 **Online Resource 2:** Skull measurements taken (reprinted from Perrin 1975a).

877 **Online Resource 3:** Skull measurements for each *Tursiops* holotype used in this study.

878 **Online Resource 4:** Summaries of measurements for each group.

879 **Online Resource 5:** Ten most important variables explaining the differentiation between the  
880 groups based on mean decrease in accuracy scores.

881 **Online Resource 6:** Loadings on first two principal components (PC1 and PC2) for 16 skull  
882 measurements.

883

## Figure Legends

884 **Fig. 1** Map of collection locations for bottlenose dolphin (*Tursiops* spp.) specimens measured.

885 Upper map: worldwide samples. Bottom map: eastern Pacific samples. aduncus: holotype *T.*

886 *aduncus*; CA: California; ESP: eastern South Pacific; ETP: eastern tropical Pacific; GoC:

887 Gulf of California; truncatus: holotype *T. truncatus*; WNP: western North Pacific. Scale bar

888 equals 3,000 km. Maps were created with R packages *ggplot2* (Wickham 2016) and

889 *rnaturalearth* (South 2017)

890 **Fig. 2** Frequency distribution of condylobasal length (CBLN) and zygomatic width (ZYGO)

891 in each of the three main groups. Points are randomly distributed about the centerline for each

892 group. CA: California; ETP: eastern tropical Pacific; WNP: western North Pacific. Figure was

893 created with R package *ggplot2*

894 **Fig. 3** Density clustering plots. Upper left plot shows the decision graph, a plot of  $\delta$

895 (minimum distances to observations of higher density) as a function of  $\rho$  (local density values

896 of each individual) where we can identify peaks of clusters. Upper right plot shows the

897 gamma ( $\gamma$ ) graph depicting the decrease of  $\gamma$  ( $\delta^*\rho$ ) across samples. Bottom plot shows the

898 multi-dimensional scaling (MDS) scatterplot based on the distance matrix of the

899 densityCluster object, with individual samples (represented by circles) colored according to

900 their clustering affiliation defined by the analysis. Figure was created with R package

901 *densityClust*

902 **Fig. 4** Distribution of skulls on first and second principal components. Point color indicates

903 cluster assignment from Density Clustering, while shape indicates group. CA: California;

904 ESP: eastern South Pacific; ETP: eastern tropical Pacific; GoC: Gulf of California; WNP:

905 western North Pacific. The holotype of *Tursiops nuuanu* is highlighted by the number 1.

906 Figure was created with R package *ggbiplot* (Vu 2011)

907 **Fig. 5** Frequency distribution of total body length (TL) in each of the main three groups.  
908 Points are randomly distributed about the centerline for each group. White line shows the  
909 standard deviation. White point shows the mean. CA: California; ETP: eastern tropical  
910 Pacific; WNP: western North Pacific. Figure was created with R package *ggplot2*

911 **Fig. 6** Suggested distribution of *Tursiops truncatus nuuanu* in the eastern tropical Pacific. The  
912 open triangle area represents the distribution area suggested by Walker (1981). The wavy area  
913 indicates a potential expanded area of distribution based on the sampling records of the ETP  
914 skulls examined in this study and suggestions of ETP offshore dolphins in offshore waters off  
915 Colombia and Ecuador following Van Waerebeek et al. (2017). Nevertheless, further data are  
916 needed to better clarify the limit ranges of the subspecies' distribution (see main text). Scale  
917 bar equals 3,000 km. CA: California; ESP: eastern South Pacific; ETP: eastern tropical  
918 Pacific; GoC: Gulf of California

**Tables**

**Table 1** Confusion matrices from Random Forest models to classify skulls to sex for California (CA), eastern tropical Pacific (ETP), and western North Pacific (WNP) groups. Classifications based on sex for each CA ecotype (coastal and offshore) are also provided. NA: Not Applicable.

<b>Group</b>	<b>Sex</b>	<b>Female</b>	<b>Male</b>	<b>% Correct</b>	<b>Lower 95% CI</b>	<b>Upper 95% CI</b>
All ( <i>n</i> = 115)	Female	31	16	66.0%	50.7%	79.1%
	Male	28	40	58.8%	46.2%	70.6%
	Overall	NA	NA	61.7%	52.2%	70.6%
CA ( <i>n</i> = 65)	Female	17	10	63.0%	42.4%	80.6%
	Male	14	24	63.2%	46.0%	78.2%
	Overall	NA	NA	63.1%	50.2%	74.7%
ETP ( <i>n</i> = 29)	Female	9	4	69.2%	38.6%	90.9%
	Male	6	10	62.5%	35.4%	84.8%
	Overall	NA	NA	65.5%	45.7%	82.1%
WNP ( <i>n</i> = 19)	Female	2	5	28.6%	3.7%	71.0%
	Male	8	4	33.3%	9.9%	65.1%
	Overall	NA	NA	31.6%	12.6%	56.6%
CA coastal ( <i>n</i> = 28)	Female	10	3	76.9%	46.2%	95.0%
	Male	6	9	60.0%	32.3%	83.7%
	Overall	NA	NA	67.9%	47.6%	84.1%
CA offshore ( <i>n</i> = 14)	Female	3	2	60.0%	14.7%	94.7%
	Male	5	4	44.4%	13.7%	78.8%
	Overall	NA	NA	50.0%	23.0%	77.0%

13 **Table 2** Confusion matrix from Random Forest models classifying skulls to geographic  
 14 groups. CA: California; ETP: eastern tropical Pacific; WNP: western North Pacific; NA: Not  
 15 Applicable.

<b>Lumping CA ecotypes</b>						
<b>Group</b>	<b>CA</b>	<b>ETP</b>	<b>WNP</b>	<b>% Correct</b>	<b>Lower 95% CI</b>	<b>Upper 95% CI</b>
CA	57	5	10	79.2%	68.0%	87.8%
ETP	0	30	0	100.0%	88.4%	100.0%
WNP	3	0	16	84.2%	60.4%	96.6%
Overall	NA	NA	NA	85.1%	77.5%	90.9%

<b>Separating CA ecotypes</b>							
<b>Group</b>	<b>CA coastal</b>	<b>CA offshore</b>	<b>ETP</b>	<b>WNP</b>	<b>% Correct</b>	<b>Lower 95% CI</b>	<b>Upper 95% CI</b>
coastal	26	3	1	2	81.2%	63.6%	92.8%
offshore	2	6	2	4	42.9%	17.7%	71.1%
ETP	0	1	29	0	96.7%	82.8%	99.9%
WNP	1	3	0	15	78.9%	54.4%	93.9%
Overall	NA	NA	NA	NA	80.0%	70.5%	87.5%

16 **Table 3** Assignment probabilities of specimens collected outside the three main groups (CA, ETP, WNP). CA: California; ESP: eastern South  
 17 Pacific; ETP: eastern tropical Pacific; GoC: Gulf of California; U: Unassigned; WNP: western North Pacific.

Museum ID	Group	Location	CA	ETP	WNP
USNM 395381	ESP	30 mi of Caleta Padilo, South of Iquique, Tarapaca, Chile	0.09	0.05	0.86
