## ABSTRACT

Cohort analysis (Pope 1972) was used to examine the abundance of Pacific herring in the eastern Bering Sea between 1959 and 1981. The results of the analysis show that herring abundance declined through the 1960's, going from a high of 1.7 million $t$ in 1962 to 153 thousand $t$ in 1973. Since 1973 herring abundance has been increasing.

## INTRODUCTION

Pacific herring (Clupea harengus pallasi) of the eastern Bering Sea have been exploited since 1959, first in a winter food fishery by Japanese and Soviet fisheries and in more recent years by a U.S. spring-summer roe fishery. Very little quantitative fishery or research data is available prior to the establishment of the United States fishery conservation zone. An unpublished manuscript, Naumenko (1979), was presented by Soviet scientists at the 1979 U.S.-U.S.S.R. bilateral scientific discussions which contained data and analyses based on Soviet fisheries from 1960-78. He determined that the average spawning biomass during 1961-78 was 289 thousand metric tons (t) and ranged between 133 and 445 thousand $t$.

Naumenko's analysis cannot be totally validated, as some of his procedures and assumptions were not clearly defined and some of the basic data used in the analysis were omitted. However, data in his paper can be used to examine the history of eastern Bering Sea herring. This report summarizes the results of a cohort analysis (Pope 1972) utilizing Soviet and Alaska Department of Fish and Game (ADFG) age composition data.

## METHODS

Cohort analysis estimates the population abundance of a year class in preceding years using catch data and natural mortality (M) estimates. The catch data used are those contained in the Bering Chuckchi-Sea herring fishery management plan (North Pacific Fishery Management Council 1982). Catches from 1959-77 were converted from weight (t) to numbers (Table 1) by dividing the catch by the estimated annual mean weight. The estimated total number of herring in the catch were then apportioned to age using the catch age composition (Table 2). Annual mean weights were estimated by multiplying the catch

Table 1.--Catch (number of fish) of Pacific herring in the Bering-Chukchi Sea, 1959-81.

age distribution by age specific weights derived from a regression of weights collected during the 1978-81 roe fisheries on age (Clark 1978; McBride et al. 1981) (Figure 1). Catches from 1978 to 1981 were distributed using age composition and weight data reported by Clark (1978), McBride et al. (1981), and unpublished ADFG data reports.

The second set of input data, natural mortality rates (M), are not well defined for eastern Bering Sea herring. An approximation of average natural mortality can be obtained using the Alverson and Carney (1975) procedure which estimates M by:

## $\operatorname{tmb}=(1 / k) \ln [(M+3 k) / M]$ <br> tmb $=0.25$ maximum observed age

where $k$ is the Von Bertalanffy growth coefficient.

Using $k=0.35$ computed from back calculated length-at-age data (Shaboneev 1965) obtained when stocks were near virgin levels, and maximum observed age = 15 years, the estimate of average instantaneous natural mortality $=0.39$.

Regression analysis of catch composition data ( $\mathrm{x}=\mathrm{age}, \mathrm{y}=1 \mathrm{n}$ [catch age xl) resulted in a total instantaneous mortality (z) estimate of 0.57 ( $\mathrm{r}^{2}=.90$ ) for ages $4-12$ during 1959-81. Subtracting the estimated instantaneous natural mortality rate (.39) from these estimates indicates that fishing mortality was 0.18 or $32 \%$ of total mortality in fully recruited ages.

Age specific estimates of $Z$ were estimated from the mean catch composition of ages $4-12$ as the $1 \mathrm{n}\left(N_{i} / N_{i-1}\right)$. The estimated $Z$ for age 5 was extremely low because of its inordinately high catch proportion in 1980 due to failure of younger fish to enter the fishery in that year. An exponential regression was fitted to the age specific $Z$ estimates following the adjustment for age 5 (Figure 2). Age specific natural mortalities were

Figure 1. --weight-at-age relationship derived from variable mesh gillnet samples of Pacific herring collected by Alaska Department of Fish and Gane in the Togiak area of Bristol Bay during the spawning period in 1978-81.

Figure 2.--Age specific estimates of total mortality (Z) derived from the 1959-81 catch of Pacific herring in the eastern Bering Sea. Rates for ages $1-3$ are assumed rates.
estimated from fitted total mortality by assuming that fishing mortality accounted for $32 \%$ of total mortality during the period of analysis. For ages l-2, fishing mortality (F) was assumed to be zero and $M$ for ages $1-3$ was assumed equal to 0.25. Decaying a cohort by these rates shows maximum cohort biomass at age 5 (Table 3). A maximum at age 5 indicates that the estimated rates are too low at least for ages $1-4$, since cohort biomass peaks at age 3 and catches are observed to peak at age 4 (Naumenko 1979; North Pacific Fishery Management Council 1982).

To run a cohort analysis, estimates of $F$ must be supplied for the oldest age of a year-class (Table 4). This involves all ages in the last year and the oldest age in prior years. For the last year, 1981, initial terminal F values of 0.10 were used for all ages. In subsequent runs, $F$ values were adjusted until the age distribution of the population estimate equalled the age distribution of weighted 1981 ADFG test fish samples. The weighted age distribution was derived by weighting the distribution of each sample (spawning area) by sample size. The weighted test fish samples were further modified by maturity rates (1959-77 averages) to adjust for fish not recruited to the roe fishery. The estimate of $F$ for the last age of a year class in the catch was set equal to the value computed for the immediate younger age in the sane year based on the assumption of equal catchability.

The actual cohort analysis is number based and results are in numbers of fish. However, to increase the comprehension of the output, estimates in numbers were converted to biomass using regression derived weights (Figure 1). Spawning biomasses were also calculated by multiplying the biomass at age in each year by the corresponding maturity rate reported by Naumenko (1979) (Table 5).

Table 3.--Age specific estimates of total mortality (Z), natural mortality (M), and the distribution of numbers (N) and biomass of a cohort of Pacific herring decayed by these rates of natural mortality.

[^1]
## RESULTS AND DISCUSSION

The results show a decreasing trend in abundance to a low in 1973 and then an increasing to stable trend through 1981 (Tables 6 and 7). Estimates of total biomass ranged from a high of 1.73 million $t$ to a low of 153 thousand t. Estimates of spawning biomass ranged from 80 thousand $t$ to 1.45 million $t$. The results confirm that herring abundance was much greater in the late 1960's than in the late 1970's and that a rapid decline occurred in the early 1970's, apparently due to overfishing, a series of weak year-classes (1968-71), and the demise of the very strong 1957 and strong 1956 and 1958 year-classes. Examination of abundance at age in recent years indicates the fishery has been supported by the 1972-74 year-classes. It appears that the 1975 yearclass was extremely weak, and the 1976 only slightly better, while the 1977 year-class appears to be of the same order of magnitude as those in 1972-75. Abundance of the 1978 year-class appears to be weak based on 1981 catches of age 3 fish and the assumption that 43\% of the year-class recruited to the spawning population. Adjusting the 1981 observed frequency of age 3 herring in ADFG test net samples by the lowest observed maturation at age 3 (3\% in 1972, Table 5) results in an estimate of abundance about equal to the 1977 year-class which means that the 1978 year-class could be significant in coming years. However, length-frequency data collected by U.S. observers indicated an increase in the mean length of herring in the second half of 1981 which supports the possibility of reduced age 3 abundance (Table 8).

The abundance estimates resulting from this analysis should not be considered to be absolute because of the uncertainty of natural mortality rates. The natural mortality rates utilized are very low with respect to rates recorded in southeastern Alaska (Skud 1963) and British Columbia (Tester 1955). The use of lower than actual natural mortality rates in cohort analysis produces low

estimates of abundance; therefore, the results presented should be considered minimum estimates of abundance, since it is likely that natural mortality rates are somewhat higher. The fit of estimated numbers-at-age from cohort analysis to 1979-80 maturity adjusted ADFG test fishing samples was good (Table 9). The number of fish at age computed by the cohort analysis is more dependent on $M$ than the terminal $F$ values in these years, therefore, differences between calculated and observed values would be due to errors in natural mortality estimates. The only severe discrepancies were for the 1976 yearclass at ages 3 and 4 which appears to be due to underestimation of the rate of maturation. The observed and calculated frequency of age 6 in 1979 also differed, but the reason is unclear. These comparisons indicate that natural mortality rates for fully recruited fish are near those used in the analysis.

```
Table 9.--Comparison of cohort analysis estimated number of Pacific herring by age in percentage to test fishing samples collected on the spawning grounds.
```

| Age | 1979 |  | 1980 |  | 1981 |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Observed 1 | Calculated | Observed | Calculated | Observed | Calculated |
| 2 | 36.0 | 44.8 | -- | -- | -- | -- |
| 3 | 22.0 | 5.4 | 46.6 | 47.4 | 4.5 | 4.6 |

| 7 | 6.9 | 5.1 | 13.7 | 16.1 | 21.9 | 21.8 |
| 8 | . 2 | 1.2 | 5.7 | 4.8 | 13.1 | 13.1 |
| 9 | 1.0 | 1.6 | . 9 | 1.1 | 3.7 | 3.7 |

l/ Number at age from each fishing district was weighted by district proportion of total sample size and summed over all areas. Total number of age 2 were divided by 0.06 (average proportion mature at age 2), age 3 by 0.43 , age 4 by 0.86 , and age 5 by 0.97 . Percentages were computed from this adjusted distribution.
