Running Head: Coral genet age estimates

Abstract

Foundation species such as redwoods, seagrasses and corals are often long-lived and clonal. Genets may consist of hundreds of members (ramets) and originated hundreds to thousands of years ago. As climate change and other stressors exert selection pressure on species, the demography of populations change. Yet, because size does not indicate age in clonal organisms, demographic models are missing data necessary to predict the resilience of many foundation species. Here, we correlate somatic mutations with genet age of corals and provide the first, preliminary estimates of genet age in a colonial animal. We observed somatic mutations at 5 microsatellite loci in range wide samples of the endangered coral, *Acropora palmata* (n=3352). Colonies harbored 342 unique mutations in 147 genets. Genet age ranged from 30-838 years old (y/o) assuming a mutation rate of 1.195^{-04} locus^{-1} year^{-1} based on colony growth rates and 236-6500 y/o assuming a mutation rate of 1.542^{-05} locus^{-1} year^{-1} based on sea level changes to habitat availability. Long-lived *A. palmata* genets imply a large capacity to tolerate past environmental change and yet recent mass mortality events in *A. palmata* suggest that capacity is now being frequently exceeded.

Author Manuscript

Introduction

The population dynamics of a species depend in part on the longevity of each individual. However, in colonial organisms such as corals neither "individual" nor "age" are easy to define, making longevity the least accessible demographic trait to study for these organisms. Coral colonies consist of genetically identical polyps that each fulfill the function of an individual (reproduction, growth, defense), yet it is the collection of polyps in a colony that represent the ecologically significant unit (Santelices 1999). Hence, studies of coral population dynamics often track the fate of colonies rather than that of individual polyps. The very nature of the clonality of corals allows colonies to survive partial mortality (Hughes & Jackson 1980), propagate asexually through fragmentation (Highsmith 1982), and partake in clonal fission and fusion (Hughes & Jackson 1980). The result is independent colonies (ramets) not connected by live tissue that share the same genotype (clonemates of the same genet). Coral species where clonemates constitute a significant proportion of local populations are found in at least nine coral genera (Supplementary Table 1). Ramets are produced throughout the lifetime of the genet and hence they can be of different chronological age and size although their genetic age (i.e. the time since meiosis and zygote formation) remains the same. Taken together these processes have the net effect of decoupling size of a ramet from its age (Hughes & Jackson 1980).

In non-colonial multicellular organisms, size is often a good proxy of genet age until adult size is attained. After adult size is reached, age determination becomes more challenging but the incorporation of environmental signals into tissues (Prouty *et al.* 2011), the shortening of telomeres with increasing numbers of cell divisions (Barrett *et al.* 2013), decreasing reproductive output, and phenotypic changes (Caspari & Lee 2004) can be quantified as indicators of age in a wide range of multicellular organisms. Many of these approaches are not useful in plants and colonial invertebrates: Radiocarbon or U-series dating (Radtke *et al.* 2003) is an alternative to using size or phenotypic changes as a proxy for genetic age, however this requires the identification and continued existence of the oldest portion of a genet because, as such, environmental signals reflect ramet age, not genet age (Eggins *et al.* 2005). This may be possible in some clonal plant species in which ramet attachment persists and the center, typically the oldest portion of a genet, can be identified (Vasek 1980), and perhaps for coral species not

This article is protected by copyright. All rights reserved

Author Manuscript

prone to fragmentation (Table 1, Supplementary Table 1). Furthermore, reproduction is tied to colony size so recently fragmented ramets belonging to previously fecund colonies might not produce gametes themselves (Okubo *et al.* 2007) and phenotypic changes are not obvious because a genetically old but small coral colony is not visually distinguishable from a genetically young and small colony.

A possible method for determining genet age is to use mutation accumulation in somatic tissues to estimate longevity. Despite their asexual origin, clonemates are not always exactly genetically identical. The concept is based on "the somatic mutation theory of clonality" (Klekowski 1997) which reasons that continuous division of mitotic cells in a clonal organism will lead to the accumulation of somatic mutations over time. Somatic mutations convert a genetically homogenous individual into a mosaic with divergent cell lineages (mosaicism). Due to the stochastic nature of somatic mutations, the incidence of genetic mosaicism would be expected to increase with increasing longevity of the organism and also with a higher prevalence of asexual reproduction; gain in ramet number or size increases the total number of dividing cells available for mutation (Orive 2001). Thus, it should be possible to relate the accumulation of somatic mutations to genet age.

Utilizing genetic divergence generated by somatic mutations is a novel approach for calculating lifespans in clonal organisms (Heinze & Fussi 2008). The use of neutral microsatellites is ideal for divergence estimates due to their high mutation rates that range from 10^{-2} to 10^{-6} per sexual generation (Shimoda *et al.* 1999; Ellegren 2000; Peery *et al.* 2012). Genetic divergence in microsatellite loci has been used to model clonal age in the aspen tree *Populus tremuloides* (Ally *et al.* 2008) and the water flea *Daphnia magna* (Robinson *et al.* 2012).

Limitations of life span estimates based on genetic divergence include the necessity of clonality, the low frequency or absence of mutations in some species (Lanner & Connor 2001; Cloutier *et al.* 2002) and difficulties in measuring mutational rates that are often variable among loci (Chakraborty *et al.* 1997; Schug *et al.* 1998). It can also be challenging to distinguish somatic mutations from allelic variation (Heinze & Fussi 2008) if the species under consideration is inbred.

This article is protected by copyright. All rights reserved

Author Manuscript

Furthermore, the rate of somatic mutational divergence not only differs between species (Klekowski & Godfrey 1989), but also among individuals (Haag-Liautard *et al.* 2007; Conrad *et al.* 2011) with intraspecies variation partly due to varying exposure to environmental stress (de Witte & Stöcklin 2010). Genetic homogeneity can be restored from a mosaic state through sexual reproduction, but also through parallel back mutations or lineage selection (Klekowski & Kazarinova-Fukshansky 1984) which would lead to underestimates of mutational load and thus clonal age. Despite the limitations, genetic divergence estimates are the most promising technique to estimate genet age in colonial marine invertebrates.

To demonstrate the potential of using somatic divergence estimates to estimate genet longevity, we used genetic divergence in 5 microsatellite loci to calculate the age of 90 genets of the elkhorn coral, *Acropora palmata*. *A. palmata* is an ideal species for determining genet age based on somatic mutations because this species relies heavily on fragmentation for local population maintenance (Highsmith 1982; Baums *et al.* 2006a; Williams & Miller 2012) and some genets have > 30 members (Baums *et al.* 2014). The process of fragmentation and re-growth of colonies from fragments has been documented photographically via quarterly surveys over the past decade or so (Supplemental Figure 1, Williams & Miller 2012) and fragments match donor colony genotypes. Furthermore, in a previous range-wide study of population genetic structure in *A. palmata* we noticed the occasional occurrence of three alleles per locus in this otherwise diploid species (Baums *et al.* 2005a). *A. palmata* is a self-incompatible hermaphrodite (Szmant 1986a; Baums *et al.* 2005a) and population genetic data show that the species is genetically diverse and outbred (Baums *et al.* 2005b). Here, we investigate whether third alleles in *A. palmata* arose from somatic mutations and then use somatic mutations to estimate genet age in this species.

Methods

Study System

Acropora palmata is a fast-growing, branching coral that once dominated coral reefs in the Caribbean and North-West Atlantic. Adult colonies release egg-sperm bundles once a year after the August full moon during a synchronized mass-spawning events (Szmant 1986b). Egg-

Author Manuscript

sperm bundles float to the surface where they break apart. Successful fertilization requires the union of egg and sperm from different genets, i.e. *A. palmata* is a self-incompatible hermaphrodite (Baums *et al.* 2005a). Gametes develop into non-feeding planula larvae during a 3 day – 2 week planktonic period. Mature larvae search for suitable habitat and metamorphose into primary polyps during a process generally referred to as settlement (Fig 1). Once the primary polyp is established, it will bud repeatedly, a type of asexual reproduction, and eventually form a colony of genetically identical polyps. In some cases, two genetically distinct primary polyps (recently settled larvae) can fuse, resulting in colonies with mixtures of polyps of different genotypes (chimerism, Barki *et al.* 2002; Puill-Stephan *et al.* 2009; Work *et al.* 2011). Signals and resources are shared across the colony. There is also division of labor to a degree with some polyps primarily engaged with defense, reproduction or growth (Soong & Lang 1992). Because of this integration, the colony is usually considered as the ecologically significant unit. We refer to an assemblage of genetically identical colonies that are descendants of a single zygote as a "genet" (Harper 1977; Hughes 1989; Carvalho 1994). Physiologically distinct colonies, formed from fragmentation, that can function and survive on their own but belong to the same genet are termed "ramets" (Kays & Harper 1974).

Samples of *A. palmata* were collected from Florida and the Caribbean (2001 to 2012, n=3352, Fig 2, Table 2). The time range of sample collection lends an error rate of +/- 12 years to the age calculations. Previous population genetic evidence (Baums *et al.* 2005b) divided *A. palmata* samples into two largely isolated populations, the eastern Caribbean (including Bonaire, Curacao, St Vincent and the Grenadines, the US Virgin Islands) and the western Caribbean (including the Bahamas, Belize, Cuba, Dominican Republic, Florida, Mexico, Mona, Navassa and Panama). Samples from Puerto Rico were assigned to the eastern Caribbean but show some degree of admixture between the east and the west. A subset of the total dataset (n = 430 from 14 reefs in the Bahamas, Bonaire, Curacao, Florida, Panama, the US Virgin Islands and Navassa) were sampled using a stratified, random sampling approach, as described in Baums *et al.* (2006a). Most colonies within our collection were only sampled once, however 11 colonies from Florida were resampled in 2011 and 2014 at 2-8 locations within the colony (Supplemental Table 1).

Microsatellite scoring.

All samples were genotyped at five (166, 181, 182, 192, and 207) previously published, polymorphic microsatellite loci with Mendelian inheritance as shown by experimental crosses (Baums *et al.* 2005b). All 5 microsatellite loci are AAT trinucleotide repeats. Two 10 µl multiplex PCR reactions (M-I and M-II) were performed per sample. M-I consisted of 0.2 µl each of primer pairs 166-PET (5 µM), 192-6FAM (5 µM) and 181-NED (5 µM), 1 µl 10× PCR Reaction Buffer (Promega), 0.8 µl of MgCl2 (25 mM), 0.2 µl of dNTPs (10 mM), 0.3 µl of Taq-Polymerase (5 U μl_{-1}, Storage Buffer B, Promega) and 6.1 µl H2O. M-II consisted of 0.2 µl each of primer pairs 207-PET (5 µM) and 182-6FAM (5 µM), 1 µl Promega 10× PCR Reaction Buffer, 1.2 µl of MgCl2 (25 mM), 0.2 µl of dNTPs (10 mM), 0.2 µl of Taq-Polymerase (5 U µl–1) and 6 µl H2O. DNA (100 to 200 ng, 1 µl) was added to each reaction. Thermal cycling was carried out with Eppendorf Mastercyclers with an initial denaturation step at 95°C for 5 min followed by 35 cycles of 95°C for 20 s, 50°C for 20 s, 72°C for 30 s. A final extension of 30 min at 72°C ensured that the majority of amplicons were +A (Brownstein *et al.* 1996). PCR products were visualized using an ABI 3730. An internal size standard (Gene Scan 500-Liz, Applied Biosystems) was used for accurate sizing. Electropherograms were analyzed with GeneMapper Software 5.0 (Applied Biosystems).

Unique clonal IDs for a genet were assigned to corals that have exact matching multilocus genotypes or have exact matching multilocus genotypes (share all the same diploid state ancestral alleles) and have an additional allele(s). The exceptions to this rule were 4% of mutations that were either a full mutation (e.g. ancestral state 166/175 to 166/178), or a loss of heterozygosity (e.g. to 166/166, Table 3), but at the other 4 loci all alleles were shared with other members of the genet (see Supplementary Table 2 for an example genet).

Loci had an average of 19.6 alleles (StDev ± 2.3). This level of polymorphism translated into a high power of distinguishing closely related (i.e. inbred) multilocus genotypes (MLGs) from those that were the product of asexual reproduction (i.e. clonemates) where the probability of identity = 10^{-5} (Baums *et al.* 2005b) (See Supplementary Figure 2). When considering only genotypes with 2 alleles per locus (n=2643, i.e. those without somatic mutations) the average probability of encountering a genotype more than once by chance (psex) was 2.23^{-07} (MLGsim 2.0, http://www.rug.nl/research/gelifes/tres/software), indicating that identical genotypes were the result of asexual reproduction. Once asexually produced, identical MLGs are removed from

Author Manuscript

the dataset, no heterozygote deficits are detected (i.e. all loci adhere to Hardy-Weinberg expectations (Baums *et al.* 2005a)) and thus *A. palmata* shows no sign of inbreeding (Halkett *et al.* 2005).

Mutation Step Analysis

For all genets with at least two ramets each novel mutation was reported (referred to as a unique mutation, UM). A total of 342 unique mutations were found in 147 genets with 1387 ramets (Table 2, Fig 3). In order to discriminate between a mutated allele and a PCR error, a singleplex PCR was performed for all unique mutations. Following a step-wise mutation model (Kimura & Ohta 1978) the smallest possible mutational step that could have resulted in the new allele was used to determine which of the two ancestral alleles mutated and the size of the mutation step (in repeat units). Mutations were excluded if there were no other samples within the genet that were bi-allelic at that locus making it impossible to determine the mutation step. However, sometimes a genet had only two ramets and both ramets had different mutations at the same locus. In that case the ancestral allele state was determined to consist of the two alleles found in both ramets (Table 2). The mutational-step analysis contained a reduced sample size of n=1387 (Table 3).

Clustering analysis

To determine whether the samples with three alleles could be attributed to somatic mutations or chimerism, we applied a Bayesian clustering analysis using the program STRUCTURE 2.3.4 (Pritchard *et al.* 2000) to all genets with at least 5 ramets (n_{genets} = 90, Table 2). We forced a diploid state by replacing the ancestral allele with the 3rd allele mutation. There was no missing genotype data. We assumed that ramets should only diverge from the ancestral genotype in one or two loci or alleles if somatic mutations were the cause, following previous studies (Puill-Stephan *et al.* 2009; Maier *et al.* 2011). Alternatively, colonies were defined as chimeras if genotypes differed by more than 60% in their major cluster assignment probability from other members of their genet as defined by Schweinsberg *et al.* (2015). STRUCTURE 2.3.4 (Pritchard *et al.* 2000) was run with a burn-in period of 100,000 and 1,000,000 MCMC repeats with 3 iterations per K, without a prior (Fig 4). Because of their large number, Florida genets were run in two separate groups each containing 22 genets, with K=22. The eastern Caribbean

This article is protected by copyright. All rights reserved

Author Manuscript

samples (23 genets, K=23) and all other western Caribbean samples (23 genets, K=23) were run in two additional groups. Results of the three runs per group were merged with CLUMPAK (Kopelman *et al.* 2015).

Clonal Richness vs. Mosaicism

We evaluated whether somatic mutations were found more often on reefs where little sexual recruitment was evident (and thus were presumably inhabited by older individuals) by tallying all mutations in all samples and comparing the number of mutations detected with the number of genets present. This was expressed as clonal richness. We did this analysis on two datasets. We compared the proportion of non-mosaic samples to clonal richness on reefs with ≥10 samples, with no limitations placed on the genet size (Table 2). Therefore, clonal and non-clonal samples were included in this analysis (i.e. all genotype samples n=3352, Table 2). Then, we only compared reefs that were sampled with similar sampling effort. (see Table 1 in Baums *et al.* (2006a). The clonal richness R is calculated as the number of genets G relative to the number of analyzed ramets N with the modification by Dorken and Eckert (2001):

$$R = \frac{G - 1}{N - 1}$$

A monoclonal stand has a clonal richness of R=0 whereas the maximum clonal richness of R=1 is reached when all samples from a reef are of a different MLG. We chose clonal richness as an indicator for clonal diversity because other measures assume a constant ploidy level (most often diploidy e.g. G_o/G_e) and were not designed for samples with somatic mutations.

Estimates of Genet Age using Genetic Divergence

The methods for calculation clonal age utilizing genetic divergence are described in (Ally *et al.* 2008). In brief, there are two statistics, π_k and S_k, that describes genetic divergence within a clone (Slatkin 1996). We calculated the average number of pairwise differences per locus for the kth clone: $\pi_k = \frac{1}{\binom{n}{2}} \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} s_{ij}$

where n is the number of sampled ramets, s_{ij} is the number of genetic differences between ramet i and j averaged across loci, and $\binom{n}{2}$ is the total number of pairwise differences (Ally *et al.* 2008). We chose π_k to measure the level of genetic divergence because it has been shown to be

This article is protected by copyright. All rights reserved

Author Manuscript

more robust to deviations from a star-like phylogeny than S_k (the observed proportion of polymorphic loci) (Ally *et al.* 2008). Two demographic models were contrasted: one of constant ramet population size (as in the classic Wright–Fisher model), while the second demographic model is one of population growth. The ramet population growth model was determined by plotting both π_k vs. $Sk/\sum_{i=1}^{n-1}(\frac{1}{i})$, which should exhibit a 1:1 slope if a population has been constant in size, and π_k vs. 2Sk/n in which a 1:1 slope would be predicted for a clonal growth model. The fit of the models was determined by regression analysis obtained in Sigmaplot 10.0.

Further restrictions, to the sample set, were applied for clonal age estimates, with ramet size of n≥5 resulting in n=90 genets used in this analysis (Table 2). While most colonies were sampled once, we captured the allelic variation within a genet by restricting age calculations to those genets with at least 5 ramets. We still may have missed some somatic mutations at these loci leading to an underestimation of the minimum genet age. Note that ramets lacking mutations but belonging to a genet that had other ramets with mutations (ramet number 5 or greater) were included (Table 2). If the genet had at least 5 ramets but no ramets had mutations then microsatellite divergence and therefore age could not be calculated.

There are currently no direct estimates for microsatellite mutation rates in *A. palmata*. We assumed the same mutation rate for all samples, but we were uncertain about that rate. Hence, we used a range by setting a maximum and a minimum. The upper bound for the mutation rate (relatively fast mutation rate) implies that a shorter amount of time has passed to accumulate the observed variation relative to the lower bound of the estimate (relatively slow mutation rate). Genet P1028 from Elbow reef in Florida had the smallest microsatellite divergence rate. This genet had 55 ramets, among which the largest single colony was 270 x 170 x 70 cm (L x W x H). The branch extension rate was measured directly on three ramets of this genet (P1028) during Jan-July 2006. A small beaded cable tie was deployed on each of three branches of each ramet as a benchmark. The length of the branch tip from this benchmark was measured in situ over this six-month period, averaged over branches and ramets, and converted to an annualized rate of linear branch extension equal to 4.441 (± 2.64 cm Stdev) cm/year. The annual increment in colony diameter was assumed to be twice the branch extension rate, 8.882 cm/year. The maximum measured diameter of a ramet of this genet was 270 cm then the colony

This article is protected by copyright. All rights reserved

Author Manuscript

must have been growing for at least 30.4 years. This results in a maximum mutation rate of 1.195^{-04} per locus per year.

We turned to the geological record to establish a minimum mutation rate. C14 dates from cores taken at Looe Key in Florida put the start-up of *A. palmata* reef growth at the base of present-day shallow spur & reef zone at around 6,500 ybp (Lidz *et al.* 1985). Our clone with the highest π_k value is from Looe Key in Florida (Supplemental Table 2), thus assumed to be the oldest, and the minimum mutation rate can be calculated by setting this clone at a maximum age of 6,500 years. This results in a minimum mutation rate of 1.542^{-05} per locus per year. This is likely a maximal estimate because reef growth may not have been continuous at Looe Key.

Results

Identification of mutation type (somatic vs. chimera)

There were three samples in two genets (2 samples in genet P2445 from Looe Key, Florida and 1 sample in genet P2151 from Molasses Reef, Florida) out of 90 genets with at least 5 ramets (comprising 1294 samples), that differed by more than 60% in their major cluster assignment from other ramets of the genet (Fig 4). Therefore, the majority of samples (98%) showing three alleles were determined to be the result of somatic mutations rather than chimerism (Fig 4).

Somatic Mutations

Genets with at least two ramets were included in the mutational step analysis. Of the 3352 samples genotyped, 1387 ramets of 147 genets satisfied this requirement across the Caribbean and Florida. We found 342 unique mutational changes across the 5 microsatellite loci (Table 3). Of the 342 somatic mutations, 305 involved a one-step increase (150) or decrease (155), with an additional 14 one-step mutations in which direction could not be determined due to the mutated allele size being equidistant from each parental allele (for example 163/169 parental genotype with mutated allele 166). This results in 93% of the mutations being either a one-step increase or decrease further supporting the explanation of somatic mutation for the 3rd alleles. The remaining 22 mutations were the result of either multi-step changes or, in one case, involved the loss of heterozygosity.

This article is protected by copyright. All rights reserved

Author Manuscript

An important factor contributing to a microsatellite mutation rate is the repeat length; the more repeat units, the greater the opportunity for replication slippage. The five loci used here had repeat lengths from 10 to 28 trinucleotide repeats (Fig 3A). As expected, with increasing repeat length the number of unique mutations observed at a locus increased linearly (slope =6.465 +/- 0.473 SE, $F_{1,3}$=186.633, p<0.001, adjusted (adj.) R^2=0.979, Fig 3A). [This result has also been confirmed in experiments with trinucleotides in humans where the mutation rate for 28-31 repeat lengths was more than 4 times that seen for 20-22 repeat lengths (Zhang *et al.* 1994).] When considering all loci together, and designating allele 1 as the smaller allele in an individual and allele 2 as the larger, there are more mutations found in allele 2 (213) than allele 1 (97) (Fig 3B, excluding the 14 mutations in which the mutated allele could not be determined, 17 mutations in homozygotes, and the 1 mutation determined to be a loss of heterozygosity).

Most colonies within our collection were only sampled once, however 11 colonies from Florida were resampled in 2011 and 2014 at 2-8 locations within the colony (these samples were not included in any other analysis, Supplementary Table 3). There were five colonies from Sand Island and Molasses reefs in Florida that had no mutations when initially sampled from 2005-2009 and re-analysis in 2011 and 2014 also showed no mutations (average n=4.6 samples per colony). One colony from Sand Island had multiple alleles at locus 166 of 149/173/176 bp in 2007. The same three alleles were found in the additional sampling throughout the colony (n=4) in 2011. In two colonies, multiple alleles were not recovered when resampled (n=8). In three colonies intracolonial variation was observed: in one case a mutation was found in only half the samples from one colony. In the other two colonies, a new mutation was recovered in some samples, with the original mutation(s) varying throughout replicate samples (Supplementary Table 2, Supplementary Fig 4). Thus, sampling a colony once may cause an underestimation of mutational load due to intracolonial variation in some colonies (Supplementary Table 2).

Clonal Richness vs. Mosaicism

Clonal richness ranged from 0 to 1 and is directly proportional to the number of sexual recruits. The proportion of non-mosaic genotypes (i.e. those with only bi-allelic loci) increased with increasing genotypic diversity of the *A. palmata* stand (Fig. 5A) considering a total sample size of 3352 from 13 regions. However, we were concerned that this result may be due to a

This article is protected by copyright. All rights reserved

Author Manuscript

greater power of detection in genets with more ramets. Therefore, we limited our analysis to colonies that were sampled on three spatial scales (5, 10, and 15 m radii) using a random sampling procedure (Baums *et al.* 2006a) to detect both common and rare genets, resulting in 486 total samples from 7 regions. Again the proportion of non-mosaic genotypes increased with increasing genotypic diversity when only considering reefs sampled with similar sampling effort (Fig. 5B). Therefore, mosaicism appears to be more common on reefs dominated by asexual reproduction than those dominated by sexual recruitment.

A previous study showed that genotypic richness was greater and more homogeneous (mean Ng/N=0.64± 0.17) in the eastern (US Virgin Islands, St. Vincent and the Grenadines, Bonaire, and Curaçao) than the western province (Florida, Bahamas, Panama, and Mexico) with the exclusion of Navassa (Baums *et al.* 2006b). When comparing the proportion of non-mosaic genotypes per reef between western (also including Belize, the Dominican Republic, Mona, and Navassa) and eastern populations, the east had significantly more non-mosaic genets than the west (Mann-Whitney U-Test, east n=38, west n=48, $p<0.001$).

Growth Models

The regression of π_k vs. $Sk/\sum_{i=1}^{n-1}\left(\frac{1}{i}\right)$ (Fig 6A) for the western population had a slope of 1.027 +/- 0.1037 SE ($F_{1,66}$=98.088, $p<0.0001$, adj. R^2=0.594) and was not significantly different from the value expected (1:1 relationship of π_k vs. $Sk/\sum_{i=1}^{n-1}\left(\frac{1}{i}\right)$) if genet size were approximately constant over time with continuous ramet turnover (ANCOVA, p=0.468). Whereas, the regression of π_k vs $2S_k/n$ (Fig 6B) for the western population had a slope of 1.194 +/- 0.222 SE ($F_{1,66}$ =29.059, $p<0.0001$, adj. R^2=0.295) and was significantly different from the value expected (1:1 relationship of π_k vs $2S_k/n$) if the genet had been spatially expanding continuously since larval settlement (ANCOVA, $p<0.0001$)

The regression of π_k vs $2S_k/n$ (Fig 6C) for the eastern population had a slope of 1.069 +/- 0.109 SE ($F_{1,14}$=95.471, $p<0.0001$, adj. R^2=0.863) and was significantly different from the value expected (1:1 relationship of π_k vs. $Sk/\sum_{i=1}^{n-1}\left(\frac{1}{i}\right)$) (Fig 6D) if genet size were approximately constant over time with continuous ramet turnover (ANCOVA, $p<0.01$). The regression of π_k vs. $Sk/\sum_{i=1}^{n-1}(\frac{1}{i})$ for the eastern population had a slope of 0.818 +/- 0.111 SE ($F_{1,14}$=54.372,

$p<0.0001$, adj. $R^2=0.781$) and was not significantly different from the value expected (1:1 relationship of π_k vs $2S_k/n$) if the genet had been spatially expanding continuously since larval settlement (ANCOVA, $p=0.17$).

Microsatellite Divergence Estimate of Age

Estimated age calculations in the western Caribbean reefs ranged from 30-838 years old (y/o) from the maximum mutation rate and 236-6500 y/o from the minimum mutation rate. Both the youngest genet and the oldest genet were from reefs in Florida (Elbow and Looe Key, Table 4). Genets in the eastern Caribbean were from 76-627 y/o to 590-4865 y/o. An age comparison between the eastern and western populations, including only genets with somatic mutations (west n=61, east n=15) yielded no significant differences (Kruskal-Wallis Test, $p>0.05$).

Discussion

Determination of genet age distribution in coral populations is important for understanding demographic changes in response to environmental perturbation and ultimately for understanding the evolutionary potential of these foundation species. *A. palmata,* the now endangered but previously dominant shallow reef-builder in the Caribbean, lends itself to somatic mutation analyses because of the importance of asexual reproduction via fragmentation resulting in genets with many members. Here, we show that some *A. palmata* genets are apparently of substantial age (Table 4). This was surprising, as previously only cold-water corals were found to be >1000 y/o (Table 1).

The Quaternary fossil record of *A. palmata* assemblages suggests that their habitat tolerances and preferences have remained relatively constant through time and space (Goreau 1959; Shinn 1963; Gischler 2015). Consequently, the distribution of *A. palmata* on shallow-water reefs has persisted through repeated glacial–interglacial cycles. Thus, at scales from decades to millennia, the persistence of *A. palmata* and the assemblages they comprise has been met through the capacity of those corals incrementally to track favorable environments that have shifted spatially over time (Precht and Aronson personal correspondence). These geological data point to the possibility of potentially millenial-age (or older) genets within modern-day populations of *A. palmata.*

We stress that absolute genet ages derived from somatic mutations as presented here have to be interpreted cautiously. Because direct measurements of microsatellite mutation rates in corals are not available and probably will not be for some time, we used other evidence to bracket minimum and maximum mutation rates. We assigned the highest mutation rate to the genet with the smallest microsatellite divergence rate among clone members and measured the growth rate of the largest colony. Growth rates of *A. palmata* can vary with season, latitude and reef location, and the measured linear extension rate of 4.44 cm/year of this colony was somewhat slower than published growth rate measurements of 6 – 9 cm/year from Florida and across the Caribbean (Gladfelter *et al.* 1978; Lirman 2000; Bak *et al.* 2009). We set the minimum mutation rate to the genet with the largest microsatellite divergence rate among clone members and asked how long this genet could have existed in this location (Looe Key, Florida). By turning to the published fossil record, we ascertained that *A. palmata* colonies at this location could not have been more than 6,500 years old (Lidz *et al.* 1985). While it is perhaps unlikely that this genet is 6,500 years old because *A. palmata* presence at this location may not have been continuous over this time frame, it is a maximal estimate. The resulting mutation rates (1.195^{-04} - 1.542^{-05} per locus per year) fall within reported microsatellite mutation rates from 10^{-2} to 10^{-6} per sexual generation (Kruglyak *et al.* 1998; Shimoda *et al.* 1999; Ellegren 2000; Hoekert *et al.* 2002; O'Connell & Ritland 2004; Peery *et al.* 2012) when adjusted to generational times of acroporids (4-8 years, Wallace 1985). An analysis of environmental markers in extant *A. palmata* skeletons could substantiate genet age estimates (however the oldest portion of the genet may no longer exist).

Despite the uncertainties surrounding absolute genet age determination, relative genet age comparisons across the range of *A. palmata* should still be valid and are presented here for the first time.

Range edge populations and dominance of asexual reproduction

Sessile organisms capable of asexual reproduction are often largely clonal at the edge of the species' range, both in terrestrial and marine ecosystems (Eckert 2002; Baums 2008). Populations at the range margins of the marine angiosperm *Zostera marina* had clonal richness values of less than 0.2 and sexual reproduction was rare or absent (Reusch & Boström 2011).

This article is protected by copyright. All rights reserved

Author Manuscript

The marginal *A. palmata* population of Florida averaged 3.7 unique mutations per multilocus genotype whereas eastern, lower latitude populations such as Bonaire, Curacao and USVI ranged from 1.2-1.3 UMs per MLG, n=1387 (Table 3). This would mean that the Florida genets are older. Nevertheless, when considering only the large clonal stands the ages were not significantly different between the eastern and western populations (Table 4) suggesting a more or less similar historical presence of *A. palmata* in both populations but a higher frequency of sexual renewal in the East.

Mosaicism due to somatic Copy Number Variations

At first glance, the appearance of three alleles per locus in *A. palmata* multilocus genotypes is puzzling. One explanation is gene or genome duplication (Wang *et al.* 2009; Richards & Oppen 2012). However, several lines of evidence argue against this interpretation. Preliminary assembly of 2 lanes of genomic sequencing data (Illumina) showed no evidence of genome duplication (I.Baums pers. observ). Additionally, a chromosomal spread analysis of *A. palmata* larvae revealed a count of n=24 (supplemental Fig. 5), a diploid state. The basic scleractinian chromosome number is x=14 and x=12 (Kenyon 1997). Inherited, duplicated genomic regions are also unlikely. In the latter case, all 5 microsatellite loci would have to be located in duplicated regions as all five loci show tri-allelic genotypes, albeit usually only one locus was mutated in any given sample: for genets with n≥5 ramets, 15.56% had 0 mutated loci, 58.89% had 1 mutated locus, 20% had 2 mutated loci, and 5.56% had 3 mutated loci. Four of the five loci amplify a similar range of allele sizes in the Caribbean sister species, *A. cervicornis*. Fossil records date back 6.6 (Budd & Johnson 1999) and 2.6-3.6 (McNeill *et al.* 1997) million years, respectively for *A. cervicornis* and *A. palmata*. Thus, the duplication events would have to have occurred before the speciation event because tri-allelic genotypes were found in both species across the entire Caribbean range. Such duplicated genomic regions would have been mutating separately for several million years making it unlikely that the majority of mutations are just one mutation step away as observed here.

Genomic instability is a mechanism of aging with somatic copy number variations (CNV) prevalent in many human cancers (Shlien & Malkin 2009) and somatic CNVs increase with age in human blood cell genomes (Forsberg *et al.* 2012). We posit that *A. palmata* genomes

This article is protected by copyright. All rights reserved

Author Manuscript

accumulate somatic duplications with age, resulting in multiple copies of the microsatellite loci available for replication slippage (Fig 7). This led to some ramets having up to 4 alleles at a single locus.

Recovery of tri-allelic genotypes was robust to repeated DNA extractions, and repeated PCR reactions, and has been observed in other coral species (Wang *et al.* 2009) and the marine angiosperm *Zostera marina* (Reusch & Boström 2011). Baums et al. (2005a) found triploid larvae in some experimental crosses, ranging from 7 to 36% of the larvae genotyped. Larvae did survive to 90 hours post fertilization but it is unknown if they would settle and grow into reproductive adults. The most likely explanation for the triploid status was having a second maternal allele, either due to retention of a polar body, self-fertilization or mitotic parthenogenesis. Multiple alleles (3-5) were detected in 15% of Pacific Acroporids at a single locus due to inherited gene duplication; in this study, all alleles in the example chromatogram were greater than a one mutation step difference (130, 140, 150, 162 bp, Richards & Oppen 2012). Interestingly, predominately sexually reproducing coral species on the Great Barrier Reef show somatic mutation in the form of two-alleles per locus (presumably generated by a single slippage event without duplication) rather than three alleles (Schweinsberg *et al.* 2015). This leads us to hypothesize that highly fragmenting coral species such as *A. palmata* accumulate somatic CNVs over the long lifetime of the genet. Independent evidence for or against somatic CNV would have to come from Flourescent In Situ Hybridization (FISH, Langersafer *et al.* 1982) or through controlled crosses of gametes from a tri-allelic genet and a genet without mutations within the 5 microsatellite loci, if there is not a sequestered germline. A triploid (or tretraploid) state at a microsatellite locus could also stem from the mutation of cells that are able to proliferate, such as stem-like cells (Reyes-Bermudez & Miller 2009), resulting in two (or more) diploid cell lineages found throughout the colony.

Mosaicism versus Chimerism

Genetic diversity within a colony could stem from the fusion of two or more larvae or juvenile corals, producing a chimera (Fig 7). Such fusion in early life stages has been observed in scleractinian corals and is generally attributed to an immature immune system that is not yet able to distinguish between self and non-self (Frank *et al.* 1997; Permata & Hidaka 2005; Puill-

This article is protected by copyright. All rights reserved

Author Manuscript

Stephan *et al.* 2009). However, the prevalence of chimerism in adult colonies in the genus *Acropora* is generally low (2-5%, Schweinsberg *et al.* 2015). Retrieval of genotypes that vary at several loci among branches from one colony may indicate chimerism (Fig 7). A colony was classified as a chimera if it differed by more than 60% in its major cluster assignment probability from other members of its genet as defined by Schweinsberg *et al.* (2015). Only 0.2% of samples from the 90 genets (n=1296) were classified as possible chimeras, thus making mosaicism the more likely explanation for most of the observed intracolony genetic variation.

Evolutionary and ecological consequences of genet longevity

The presence of large, potentially centennial-aged genets within a population begs questions with regard to their history as well as their adaptive potential over the coming decades of rapid environmental change. It is likely that the environmental conditions in most shallow coastal habitats over the lifespan of these very old genets were quite different from today, which implies that these old genets 1) possess a great degree of plasticity enabling them to persist throughout these environmental variations (Barshis *et al.* 2013) and/or 2) that they have in fact 'migrated' among nearby coastal habitats over the centuries. For example, it is possible that our current observation of a very old clone is in a distinct location from where it originally recruited with fragments 'migrating' upslope in tracking slow holocene sea level change (Gischler 2015).

Alternatively, the General-Purpose Genotype model (Baker 1965) explains the ubiquity of clonal organisms by their ability to retain the most competent genotypes over time; favoring the absence of sexual reproduction once an optimal genotype is found. For example, (Van Doninck *et al.* 2002) showed much higher ecological tolerances of a ubiquitous asexual ostracod in comparison with additional species that were asexual and narrowly distributed or that had mixed reproductive modes. If *A. palmata* genets have persisted over hundreds to thousands of years, it implies persistence through substantial environmental changes, and possibly gives hope that they can survive additional anticipated climate change. The overall recent declines of *A. palmata* including declines of certain moderate-sized clones in particular (Banks *et al.* 2010) suggest there is a limit to this tolerance, which may be exceeded soon.

However, *A. palmata* is not entirely asexual and there is also the possibility that a preponderance of large, old genets is not necessarily adaptive. Potts (1984) suggested that

This article is protected by copyright. All rights reserved

Author Manuscript

because of corals' extreme longevity, many species (or populations) have not had the opportunity, since current coastal habitats became habitable, to complete adequate sexual generations to reach evolutionary equilibrium. Because fecundity of corals increases with genet size (senescence notwithstanding), there may be a tendency for large old clones to dominate the gene pool and diminish the chances for newer genets, possibly even those better-adapted to current environmental conditions, to expand. If this is true, it implies that the presence of large old clones (possibly of General Purpose Genotypes) may impair the rapid adaptation needed for persistence under climate change.

The occurrence of somatic mutations raises the question of whether they can be the target of selection and rapid adaptation. Mosaicism is thought to be favored in plants because it offers an advantage in the Red Queen race against pests and parasites by increasing the standing genetic diversity that prevents the evolution of specific metabolic pathways that could be used to overcome the defenses of the plant (Valen 1974; Gill *et al.* 1995). Mutations in the soma are available for immediate selection pressure from the environment as they compete with other wild-type and mutated lineages within the organism. The selection of somatic cell lineages, termed intra-organismal selection (also called somatic, diplontic, or cell-lineage selection; see (Buss 1983; Hughes 1989; Otto & Hastings 1998; Clarke 2011)) may have the potential for rapid evolutionary change in a modular organism by allowing within-organism gene frequency changes within a single generation (Klekowski & Kazarinova-Fukshansky 1984). Through the displacement of the wild-type lineage, the mutation of regenerating cells can be considered evolution since they are potentially heritable in clonal Cnidaria through both sexual and asexual routes. Alternatively, the coexistence of multiples lineages within an organism may result in intra-organismal competition or cell parasitism leading to the decrease of overall fitness (Michod & Roze 1999; Pineda-Krch & Lehtilä 2004). A theoretical population model suggested that strong negative selection against intra-individual mutations keeps changes of allele frequencies due to somatic mutations very low (Orive 2001).

Currently, empirical confirmation of somatic selection has been limited. However, there are many organisms that have been evolving in the absence of sex including rotifers (Welch & Meselson 2000), *Artemia* (Perez *et al.* 1994) and salamanders in the genus *Ambystoma* (Hedges *et al.* 1992). [See Van Oppen *et al.* (2011) for a review on somatic mutations as fuel for

546 adaptation in invertebrates]. Somatic selection has also been demonstrated experimentally in
547 plants (Breese *et al.* 1965; Whitham & Slobodchikoff 1981; Monro & Poore 2009). Somatic
548 mutations may be widespread in corals (Levitan *et al.* 2011; Schweinsberg *et al.* 2015) and
549 within mosaic *Acropora hyacinthus* colonies it was shown that transfer of intercolonial genetic
550 variation to the next generation via gametes is possible (Schweinsberg *et al.* 2013) albeit this was
551 not the case in *Orbicella* (Barfield *et al.* 2016).

552 The ability of the coral host to respond to a changing environment occurs not only
553 through genetic adaptation but also through acclimatization by varying phenotypic responses. It
554 has recently become apparent that some environmentally induced nongenetic or epigenetic
555 changes are also heritable through a process known as transgenerational acclimatization (van
556 Oppen *et al.* 2015). Epigenetic changes include histone modifications, DNA methylation,
557 chromatin remodeling, and gene regulatory mechanisms involving small noncoding RNAs
558 (Danchin *et al.* 2011). A recent study in the clonal tree poplar showed the persistent influence of
559 geographic origin on the ability to respond to stress within a common garden experiment,
560 showing that the older the clone (longer clones of the same genet lived in different
561 environmental conditions) the more divergent the transcriptomic response was to drought and the
562 greater the variation in genome methylation patterns (Raj *et al.* 2011). Although not directly
563 linked to epigenetic changes, the pacific coral *Acropora hyacinthus* (cryptic species E) was able
564 to acclimatize to new microenvironments by increasing bleaching resistance, as measured
565 through transcriptomic responses and chlorophyll A changes, without altering their abundances
566 of symbiont type (Palumbi *et al.* 2014). This imprinted "memory" of past stress responses could
567 have profound implications for asexually reproducing corals in that ramets distributed across a
568 reef could have divergent epigenetic "memories" due to varying environmental conditions such
569 as water flow, light and pathogen exposure. In addition, epigenetic changes along with somatic
570 mutations have the ability to be passed on to the next generation in organisms without segregated
571 germ lines.

572 The current paucity of clonal age estimates impairs our understanding of the ecology and
573 evolution of marine foundation fauna. These estimates are difficult to come by because size and
574 age are not related in colonial, asexually reproducing organisms. Significant asexual colony
575 reproduction occurs in at least nine coral genera and thus the decoupling of size and genet age is

This article is protected by copyright. All rights reserved

Author Manuscript

a widespread phenomenon in corals (Supplementary Table 1). Alternative methods to estimating genet age include the use of somatic mutations but without direct mutation rate measurements, the uncertainty of the age estimates is considerable. Regardless, when applied to a fragmenting Caribbean coral, the results point towards genet ages that rival those of the most ancient organisms on earth alive today. This raises questions about their adaptive potential to a rapidly changing climate. Does their past ability to survive environmental change predict future success? The answer will come from experimental studies combined with demographic and theoretical models.

Data Accessibility

Multilocus genotypes are available at DRYAD: http://dx.doi.org/10.5061/dryad.f6600

Author contributions

MD and IB designed the study and wrote the manuscript with key input from MM and WP. MD analyzed and interpreted the data. Funding was provided and samples were collected by IB and the Caribbean *Acropora* Research Group.

Tables

Table 1 Published age estimates of coral colonies.

Species	Age Estimate (years)	Method	Region	Depth	Year Collected	Reference
Leiopathes	70 - 2040	C14 and growth ring measurements	Gulf of Mexico	304-317m	Not stated	(Prouty *et al.* 2011)
Gerardia sp. *Leiopathes*	300 - 2700 350 - 4200	δ13C	Hawaii	400-500m	2004	(Roark *et al.* 2009)
Keratoisis, *Isidella*, or *Acanella spp.*	75–126	C14	Gulf of Alaska	634-720m	2002	(Roark *et al.* 2005)
Lophelia pertusa	451 ± 36	C14	West Ireland	840–1300m	1995-1997	(Hall-Spencer *et al.* 2002)

Figures

Figure 1 Diagram depicting (A) the formation of a chimera from the settlement and fusion of gametes of different genets. (B) An illustration of asexual reproduction by fragmentation and the accumulation of mutations with age. See Supplemental Figure 1 for a photo time series of fragmentation. Example alleles at one locus are given in basepairs (three digit numbers separated by forward slashes). Diagram not to scale.

Figure 2 Samples of *Acropora palmata* were collected throughout Florida and the Caribbean. DR = Dominican Republic, USVI = U.S. Virgin Islands, SVG = St.Vincent and the Grenadines. See (Baums *et al.* 2005b, 2006a) for sampling location details.

Figure 3 Mutation Step Analysis**.** In panel (A), as the repeat length of a microsatellite locus increases, the total number of unique mutations found within each locus increases linearly (slope $=6.47 \pm 0.47$ SD, $F_{2,3}=186.6328$, $p=0.0008$, adj. $R^2=0.98$). (B) Most mutations were one step away from the ancestral allele size (i.e. +/– 3 bp) with allele 1 (the smaller of the two alleles) showing more repeat unit losses than gains and the larger allele (allele 2) showing more gains than losses of repeat units. 29 mutations were excluded from (B). 28 mutations were excluded because the mutation step was equidistant for allele 1 and 2 so that the mutated allele could not be determined; 1 mutation was a dropped allele.

Figure 4 Assignment of ramets to genets using Bayesian clustering analysis in *A. palmata*. Included were all genets with $n \geq 5$ ramets (Table 2). Black lines above graphs indicate samples that have mutations. An asterisk indicates colonies that have a <40% assignment probability to the most closely related genet. These colonies are possible chimeras. Probability of membership to a given cluster (Y-axis) is plotted for each sample (X-axis). Colors indicate cluster membership for each panel (A – D). Genets from the eastern Caribbean are shown panel A, genets from the western Caribbean in panels B – D. Florida was split into two groups (C, D) because of the large number of genets from this region.

Figure 5 The proportion of non-mosaic genets per reef as a function of clonal richness at each reef. A) Total sample size of 3352 colonies from 86 reefs within 13 different regions across the Caribbean with n≥10 colonies reef $^{-1}$. Exponential Rise to Maximum, Single, 2 Parameter equation: f = 0.8763*(1-exp(-3.9422*x)) (adjusted R^2= 0.6495). B) Including only colonies that were sampled on three spatial scales (5, 10, and 15 m radii plots) using a random sampling procedure (described in Baums *et al*. 2005a) for a total of 486 total samples from 7 regions. Exponential Rise to Maximum, Single, 2 Parameter equation: f = 1.0192*(1-exp(-2.4822*x)) (adjusted R^2= 0.7575).

Figure 6 A comparison of two growth models for the western (Panel A,B) and eastern (Panel C,D) Caribbean. The western Caribbean population included Florida, Bahamas, Panama and Belize. The eastern Caribbean population included Curacao, US Virgin Islands, and St. Vincent and the Grenadines. Panel (A,C): In a constant population model with continuous ramet turn-over, the slope of π_k vs. $Sk/\sum_{i=1}^{n-1}(\frac{1}{i})$ would exhibit a 1: 1 relationship (dotted line). Panel (B,D): In a population that is growing in size, the slope of π_k vs $2S_k/n$ should exhibit a 1:1 relationship (dotted line). See text for statistical analysis.

Figure 7 Diagram depicting how duplication of a microsatellite (msat) locus (yellow) leads to copy number variation (CNV) on chromosomes (blue) in a diploid species. Once a locus is duplicated, the microsatellite repeats (orange/white) may mutate through slippage of the DNA polymerase during mitotic replication leading to the detection of three alleles in electropherograms. With time, alleles on both chromosomes may duplicate and mutate leading to detection of four alleles per samples (not shown). Allele sizes are given in basepairs. Diagram not to scale.
