ABSTRACT: Management of the commercially important Washington coastal Chinook Salmon troll fishery depends on the Chinook Fishery Regulation Assessment Model (FRAM). The Chinook FRAM uses historical and contemporary coded-wire tag (CWT) recoveries to estimate abundance and exploitation rates for particular indicator stocks. Those estimates are used to set limits on overall harvest and protect sensitive stocks. Current efforts are underway to implement a newer "base period" (time period on which exploitation rates are based). Our collaboration of science, management, and industry used genetic mixture modeling to provide independent stock composition estimates supporting FRAM recalibration. Genetic modeling suggests total catch includes a much smaller proportion of a limiting Columbia River stock and a larger fraction of Canadian stocks, as well as an abundant Oregon coastal stock not previously included in the FRAM. Our results focus attention on particular stocks that will benefit from refinements in the Chinook FRAM.

INTRODUCTION

Commercial troll fishing for Chinook Salmon *Oncorhynchus tshawytscha* off the coast of Washington State began around 1912 and grew rapidly during World War I. By 1919, there were more than 1000 boats in the fleet. Between 1935 and the early 1950s harvest doubled from 200,000 to 400,000 fish per year. Harvest then declined dramatically in the late 1950s and early 1960s. Fewer than 100,000 fish were taken in 1965 (US Dept of Commerce 1976). Harvest numbers have varied widely in recent years (8,636 in 2008 to 55,313 in 2015). Some stocks are still quite abundant and can sustain harvest, whereas others are severely depressed and are now protected under the US Endangered Species Act (ESA). Despite those declines in some stocks, the Washington Chinook Salmon fishery overall remains an important economic asset to the State and the entire region ($2.6M ex-vessel value; TCW Economics 2008), yet the troll fishery presents some acute management challenges. The 1976 Environmental Impact Statement/Preliminary Fishery Management Plan for the troll salmon fishery of the Pacific Coast described the difficulty inherent in managing this mixed-stock fishery and foretold the increasingly thorny problem of protecting sensitive stocks while targeting abundant stocks for harvest,

> "The mobility of the troll fleets, plus the fact that the salmon stocks upon which the fleets fish are highly migratory, makes management of the fishery extremely complicated. This combination results in both the fisheries and the resources crossing interstate and international boundaries. In addition to the international problems, management of the salmon resource is further complicated by the presence of large net fisheries and sport fisheries also fishing on many of these same salmon stocks" (US Dept of Commerce 1976:12).

The commercial Chinook Salmon fishery off the US West Coast, including Washington State, is managed using the Fishery Regulation Assessment Model (FRAM) as the primary analytical and evaluation tool (PFMC 2008). The FRAM is dependent on historical and contemporary coded-wire tag (CWT) recoveries and provides a discrete, time-step, age-structured, deterministic model used by the Pacific Fishery Management Council (PFMC) for annual pre-season and post-season estimates of impacts of ocean and terminal fisheries on particular stock groups of Chinook Salmon and Coho Salmon *O. kisutch*. For Chinook Salmon, impacts are modeled for most stock groups from California Central Valley (Sacramento River), north-central Oregon Coast, Columbia River, Willapa Bay, north Washington Coast, Puget Sound, and southern British Columbia. The FRAM is used to evaluate proposed annual regulation scenarios in specific fisheries for compliance with harvest allocation, US Endangered Species Act (ESA) compliance, and domestic and international legal obligations. The latter includes providing treaty tribes with the opportunity to harvest specific shares of individual Chinook Salmon stocks, as well as meeting obligations for stock-specific management associated with the Magnuson-Stevens Fishery Conservation and Management Act (16 U.S.C. 1801 - 1891(d)) (2014). It is important to note that the FRAM and other CWT-based fishery management models on the West Coast are integral elements of both international and regional management structure. Tribal, state, provincial, and federal fishery management agencies in the eastern Pacific contribute to and benefit from the Regional Mark Information Systems database, the international repository of CWT marking and recovery data.

FRAM base period for inference of current exploitation rates

The Chinook FRAM depends on CWT recoveries to estimate contemporary stock-specific abundance and exploitation rates, as inferred from a historical "base period" (see PFMC 2008 for a detailed, quantitative description of the FRAM, including flow charts and formulas for individual processes). The base period 1979 - 1982 is a critical element of the Chinook FRAM and is currently being updated to the period 2007 - 2013. Contemporary post-season abundance and observed catches, applied to the base period data in FRAM, produce annual exploitation rate estimates as well as stock-composition estimates that are comparable to genetic mixture analysis. That comparison of stock-composition estimates allows an independent evaluation of the Chinook FRAM. The base period is important because those historical exploitation rates are used to infer contemporary stock-specific exploitation. Managers then set regulations to allocate harvest and control exploitation rates on sensitive stocks.

Genetic mixture analysis

Genetic mixture analysis, also known as genetic stock identification (GSI), uses genetic data to infer the source populations that most likely contributed to a particular group of fish taken in a mixed-stock fishery (Milner et al. 1985). Genetic mixture modeling based on DNA microsatellite data has been extensively tested and validated in Atlantic Salmon *Salmo salar* and multiple Pacific salmon species (Beacham et al. 2003; Beacham et al. 2008; Griffiths et al. 2010). There are generally two components to these studies, the unknown fishery mixture and the baseline dataset of known-origin fish. Each of these datasets consists of a list of fish with their associated multilocus genotypes, typically coded as a string of paired character states (alleles) at each genetic locus (chromosomal location). GSI is the process of fitting a model of potential source populations to the multilocus genotypes of the fish in the observed mixture (Koljonen et al. 2005).

Our study had two principal goals: 1) compare GSI and FRAM stock composition estimates for different times and areas in the commercial troll fishery, and 2) describe apparent trends or patterns in the spatial and temporal distribution of stocks. Our hope was that genetic results from this fishery would improve our understanding of stock

distribution and contribute to the power and utility of current CWT-based fishery management as implemented using the FRAM. We examined the relative distribution of different stocks among time/area strata; however, our primary focus is on fishery impacts. Because stocks can have different exploitation rates, our fishery dependent study design is ill suited to address the more academic question of how each stock is actually distributed at sea in time and space.

MATERIALS AND METHODS

Sample collection

We genotyped Chinook Salmon tissue samples randomly drawn from all rayed fin clips collected by commercial fishermen participating in Washington Chinook Salmon troll fisheries conducted during 2012 through 2015 (Table 1). On average in each year we analyzed 3.2% of total harvest collected by roughly 35% of the fleet (range 26 – 44%). Although there are around 150 permit holders, not all of them fish, and many of them fish only a small portion of the season. Most of our samplers caught their trip limits regularly, so, based on review of trip limits caught per week over a 10-year period, 34 is a reasonable estimate of average fleet size for active, commercial trollers on the Washington Coast. Samples were collected opportunistically, as time permitted and might not represent an ideal random sample. However, we offered a per-fish monetary incentive to ensure sampling during busy periods, so we believe collections represent a reasonable approximation of the fish taken in the fishery in each time and area. Collection location and date were recorded (GPS time stamp), as well as fork length and mark status (many hatchery-origin fish are marked with the removal of the adipose fin).

Fin-clip samples were folded in Whatman 3MM chromatography paper, dried, and stored in barcoded coin envelopes at ambient temperature. Samples were deposited into the Northwest Fisheries Science Center (NWFSC) Conservation Biology Division's Genetic Tissue Archive (accession numbers in Table 1). Collection data were downloaded from GPS units provided to fishermen and transcribed from forms printed on the collection envelopes. Fin clips were collected each year during the normal commercial fishing season that occurred between May and September. In our analyses, we refer to the May-June period as spring and July-September as summer (Table 1). No

Chinook Salmon harvesting is permitted at other times in the open ocean off Washington. Samples were analyzed from the southern Area 2 (Gray's Harbor Area: Leadbetter Point to the Queets River at 47.5° latitude on the Washington Coast) and more northerly Areas 3 (Quillayute Area) and 4 (Cape Flattery Area) that were combined and referred to as Area 3 & 4 for our study (Queets River to the US/Canadian border; Fig. 1).

Genotyping and reference baseline

Washington Department of Fish and Wildlife (WDFW) and Northwest Fisheries Science Center (NWFSC) cooperated in processing Chinook Salmon tissue samples. In 2012, samples were divided between NWFSC and WDFW genetics laboratories. From 2013 to 2015, all genotyping was carried out by NWFSC. In both laboratories, DNA was extracted and purified by using Qiagen® DNeasy™ membrane capture kits. Purified DNA samples were amplified and genotyped for 13 internationally standardized microsatellite loci (see below for inter-laboratory genotyping standardization). Amplified microsatellite products were size fractionated on an Applied Biosystems 3730 Genetic Analyzer in the WDFW Molecular Genetics Laboratory and a 3100 Genetic Analyzer at NWFSC. Genotypic data produced by WDFW and NWFSC were combined to create a single, 4-year dataset for mixture analysis.

The genetic mixture models we employed depend on complete representation in the baseline of all potentially contributing populations. In this study, we used the internationally standardized, microsatellite, baseline dataset (same loci and allele designations; Moran et al. 2006) produced by the Genetic Analysis of Pacific Salmonids consortium (GAPS; Moran et al. 2005; Seeb et al. 2007). This dataset was designed explicitly for eastern Pacific coastal fishery mixtures, and geographic coverage is excellent for the fisheries examined here, including more than 20,000 known-origin fish from 167 representative populations. The GAPS Chinook Salmon baseline is the most comprehensive of its kind. It includes all Evolutionarily Significant Units and Wildlife Species listed under the ESA and the Canadian counterpart, Committee on the Status of Endangered Wildlife in Canada, and is believed to represent principle genetic lineages from all significant production areas over that geographic range. The GAPS Chinook Salmon database is thoroughly vetted with the salmon genetics research community on

the Pacific West Coast of the US and Canada (Seeb et al. 2007). The 13 microsatellite loci that make up the coast-wide baseline are highly variable, with almost 500 alleles observed. Extensive simulations and leave-one-out jackknife analyses show excellent power to allocate mixed-stock fisheries to origin, either as single individuals or as modeled proportions (Seeb et al. 2007; Anderson et al. 2008). The GAPS Chinook Salmon baseline has been used widely in studies of harvest and bycatch impacts (Satterthwaite et al. 2014; Bellinger et al. 2015) as well as ecological genetic studies (e.g., Rhodes et al. 2011; Roegner et al. 2012; Johnson et al. 2013). The current study provides an opportunity to independently evaluate Chinook Salmon stock composition estimates from the FRAM over the 4-year period from 2012 through 2015.

Single nucleotide polymorphisms (SNPs) have been used for other GSI studies (Narum et al. 2008; Hess et al. 2011). However, no current SNP baseline was available with the geographic breadth (Central Valley California to Southeast Alaska) and depth (multi-year samples from multiple populations from each genetic stock group) necessary to characterize contributing populations observed in Washington coastal Chinook Salmon fisheries.

Data analysis

To estimate stock compositions, we used conditional maximum likelihood mixture modeling (CMLMM) as implemented in the computer software package ONCOR (Kalinowski et al. 2007), including bias correction (Anderson et al. 2008). Allele frequencies were estimated to assign non-zero population-specific frequencies for all alleles observed in the mixture samples but not observed in the source populations (Rannala and Mountain 1997). The CMLMM uses the expectation-maximization algorithm (Dempster et al. 1977) to estimate the most likely proportions of contributing populations. We used the CMLMM approach to derive modeled proportions because those are better suited to our application and more robust than tallied individual assignments, especially where mixture proportions are non-uniform (Koljonen et al. 2005).

We first examined overall stock composition for each of the 4 years, irrespective of time and area. We estimated 95% confidence intervals around the point estimates for each stock using100 bootstrap replicates, re-sampling both the mixture and the baseline (Kalinowski et al. 2007). We felt comfortable using this number of bootstrap replicates because preliminary analyses of 2012 and 2013 data demonstrated that 100 bootstrap replicates generated confidence limits that were indistinguishable from 1000 replicates. These estimates represent the proportional stock composition of fish in the mixture samples collected. Genetic stock composition estimates were compared to post-season estimates from FRAM (PFMC 2012 to 2016) that reflect all fishery-related mortality, including post-release mortality of sub-legal-size fish. These comparisons imply that non-retention mortality was uniform across stocks. Departures from uniform mortality rates might result from stock-specific differences in age structure or size-at-age; however, these effects would be limited to sub-legal encounters and were unlikely to be of sufficient magnitude to confound our results.

For each year, we stratified our stock composition estimates by time and area to facilitate comparisons with the FRAM. Forty-six genetic stock groups were aligned with 12 FRAM stocks (Appendix 1). As stated earlier, we examined two areas off the Washington Coast (Area 2, in the south; Area 3 & 4, in the north; Fig. 1) and two time periods (spring and summer). Mean square error (MSE) was used to evaluate the fit of FRAM stock composition estimates to those from GSI. Recognizing the bias for large contributing stocks, we also calculated mean absolute percent error (MAPE), which is more sensitive to small contributing stocks. Because results were similar, only MSE values are presented.

RESULTS

Sample collection

Of the total 8,219 samples collected in the course of this study, most included complete and internally consistent collection data (e.g., time and location). However, we observed some problems with at-sea georeference data due to a malfunction with one of our GPS units that resulted in a large number of duplicated waypoints (collection time

and location). Also, some waypoints were from the Westport Boat Basin (Grays Harbor) or the site where the GPS units were configured in Olympia, WA, an urban center 100 km inland from the study area. In total, 1,186 samples were missing valid latitude/longitude coordinates, so those specific location and timestamp data were omitted from analyses. Despite discarding faulty GPS data, sample batches allowed confident assignment to time period (spring or summer) and area stratum (Area 2 or Area 3 & 4). Finally, 45 samples were omitted that were found to have been collected outside the study area, in Area 1, south of Leadbetter Point (Fig. 1).

Laboratory analysis

Sample quality was excellent. Only about 1.4% of processed samples were later omitted from analyses due to sparse genotypic data and excessive homozygosity, which are typical of degraded DNA from poor quality tissue samples. For example, a sample scored as homozygous for three highly polymorphic loci but failing amplification for all others would be omitted. Of the remaining samples, more than 80% were successfully typed for all 13 loci, and more than 99% were typed for 10 or more loci. In each year, 1 to 5 pairs of fish (12 pairs total) were observed with identical multilocus genotypes. The variability of the GAPS Chinook Salmon microsatellite loci is such that identical genotypes for six or more loci, with no mismatches, is almost certainly the result of multiple tissue samples taken from the same individual (individual-specific DNA "fingerprints"). In our case, members of each pair occurred within the same time/area stratum; therefore, we omitted one member of each pair. Our final sample size after filtering was 5,344 fish taken as a random sample from a total of 8,219 tissue samples collected (Table 1).

Nearly half the samples were taken from fish marked with an adipose fin clip, which identified them with near certainty as hatchery-produced individuals. Unmarked fish can be either hatchery or wild origin, but almost no wild fish are marked by clipping the adipose fin. All except eight fish sampled were of legal size (>66 cm), and average fork length was 77.2 cm (SD = 6.4 cm).

Genetic mixture modeling

Genetic mixture analysis showed that the Washington Chinook Salmon troll fishery is primarily supported by two Columbia River fall-run stocks: Mid-Columbia River Tule and Upper Columbia River Bright. On average, 44% of our sample was attributed to those two stocks (27% and 17%, respectively; Fig. 2). Other important contributors included the Lower Columbia River Bright and Tule stock (9.7%) and the Fraser River/West Coast Vancouver Island/ Georgia Strait stock (a FRAM stock comprised of three genetically distinct regions; 9.5%). With the exception of 2013, overall stock composition showed little variation among years. Despite that relative uniformity, there was a general trend toward increasing abundance of Mid-Columbia River Tule through time, resulting in a narrower distribution of contributing stocks. Stock composition in 2013 was unusual in having a very high percentage of Central Valley Sacramento stock (fall run; 14% in 2013, 2 – 7% in other years studied) and a smaller contribution from the Mid-Columbia Tule stock (14% in 2013, 31 – 50% in other years studied).

Comparison of GSI and FRAM

When the Chinook FRAM was developed, mid-Oregon Coast populations were poorly represented among CWT releases. Those populations were not thought to contribute substantially to the Washington coastal troll fishery and, therefore, were not included in the model. In our study, however, GSI estimates for the Mid-Oregon Coast stock were unexpectedly large (Figs. 2 and 3), substantially larger than the estimated FRAM contribution of all non-FRAM stocks (Fig. 4). The Mid-Oregon Coast stock contributed up to 29% of the harvest in Area 3 & 4 in summer of 2012, and GSI estimates were generally an order of magnitude greater than the FRAM estimates for all non-FRAM contributors combined (which should have included Mid-Oregon Coast, Fig. 5). With the Mid-Oregon Coast disaggregated from the non-FRAM GSI estimate, FRAM and GSI estimates of remaining non-FRAM-stock contributors were similarly low (GSI ~2%, Fig. 2). Other than Mid-Oregon Coast, the largest non-FRAM contributor was Upper Fraser River, which averaged 0.6% of the troll fishery (range: 0.3% to 1.1%).

Some similarities in stock composition estimates were found between GSI and FRAM, but in most cases we saw substantial differences. High concordance was observed between GSI and FRAM in only 4 of 16 time/area strata; all 4 were in Area 2 during spring 2012, spring and summer 2014, and spring 2015 (MSE < 0.0043; Fig. 5). GSI and FRAM usually diverged more substantially in Area 3 & 4 for both spring and summer time strata. Despite similar numbers of contributing stocks, FRAM estimated narrower, less diverse distributions of contributing stocks in essentially every stratum relative to GSI, especially in the more northerly Area 3 & 4.

Consistent, directional departures between GSI and FRAM were observed for particular stocks across time/area strata and across years (Fig. 5). Relative to GSI, FRAM estimates were consistently low for the Oregon North Coast stock and for the Fraser River/West Coast Vancouver Island/ Georgia Strait stock. The FRAM estimates were also lower for Upper Columbia River Brights, especially in the spring fishery. FRAM estimates were consistently lower than GSI for Columbia River summer and Washington North Coast stocks, although absolute contributions were small with both methods. By contrast, FRAM estimates for the ESA-listed Puget Sound fall-run stock were consistently higher than GSI estimates. GSI showed smaller changes in stock composition between time strata than did FRAM, but larger differences between areas (Fig. 5). The most extreme mismatch between methods, other than the Mid-Oregon Coast issue described above, was in estimates of the Lower Columbia River Bright and Tule stock and the Mid-Columbia River Tule stock. In every stratum, FRAM estimates for the Lower Columbia River Bright and Tule stock were greater than comparable GSI estimates. For the Mid-Columbia River Tules, FRAM estimates were greater than GSI in 13 of 16 time/area strata (Fig. 5).

DISCUSSION

Potentially informative differences between GSI and FRAM

Stock composition estimates from GSI often differed dramatically from comparable FRAM estimates. These differences were apparent in northern and southern areas and spring and summer time periods but especially in northern Area 3 & 4. In particular, FRAM estimates were consistently greater than GSI estimates for the sensitive,

ESA-listed Lower Columbia River Tule stock. Although our genetic analysis did not discriminate Lower Columbia River Tule from Lower Columbia River Bright, FRAM results suggested the Bright contribution was very small, and most of the fish in this combined group were likely from the Lower Columbia River Tule stock. This difference in stock composition between methods is particularly important because Lower Columbia River Tule stock is the limiting stock in the coastal troll fishery (and also protected as threatened under the US Endangered Species Act). Our results suggest that the stock might be consistently over-estimated under the current management regime. The PFMC attempts to structure fisheries between Cape Falcon (Oregon) and the Canadian border to limit marine and freshwater exploitation rate on Lower Columbia River natural Tule populations to no greater than 41% (Pacific Fishery Management Council 2015). That objective was the primary constraint for ocean fisheries in this area between 2012 and 2015. It might be that Tule contributions estimated from GSI were less than those predicted by FRAM because these stocks were less abundant than current FRAM estimates, or because exploitation rates were lower than estimated by the FRAM. Preliminary FRAM composition estimates using the updated base period appear to be closer to current GSI estimates, e.g., lower estimates for Tule stocks and Puget Sound, but greater for Upper Columbia River Brights (based on ongoing recalibration efforts). It is not clear whether improved concordance is a result of updated exploitation rates that might be more accurate, or other factors, including chance. Estimated proportions for the Fraser River/West Coast Vancouver Island/Georgia Strait stock are slightly greater under the new FRAM base period, but those estimates are still substantially less than GSI estimates. FRAM estimates of Canadian stocks are important because total harvest is first allocated between nations, then between tribal and non-tribal fishers, next between sport and commercial fishers, and finally among time/area sectors. Errors made in allocating the total catch between the United States and Canada propagate downward and influence the equitable distribution of this important cultural and economic resource among all fishers.

Differences not due to misalignment of genetic groups and FRAM stocks

To make comparisons between GSI and FRAM stock composition estimates, we had to align FRAM stocks to our 167 genetic baseline populations comprised of reference

samples of known-origin individuals (Appendix 1). In most cases, alignment was a straightforward process because hatchery collections in our baseline were often exactly the same FRAM indicator stocks. However, in some cases different FRAM stocks are genetically similar and cannot be easily distinguished, even stocks that show morphological differences (e.g., Lower Columbia Bright versus Lower Columbia Tule stocks). In other cases, FRAM stocks are made up of multiple individual populations that belong to genetically distinct groups (e.g., Canadian stocks in Georgia Basin). After years of hatchery stock transplantation and propagation of mixed-origin brood stocks, some populations have been partially homogenized and genetic differences diminished. Incongruities between GSI baseline populations and FRAM stock groups were mitigated partly by the allocate-sum procedure used in genetic mixture analysis to aggregate local populations into population groups (Wood et al. 1987). In this procedure, proportional allocations to local populations are summed hierarchically to estimate the contributions of population aggregates. Ideally population aggregates are based on genetic similarity (Wood et al. 1987), so population allocation errors occur primarily within aggregates and not among them. Whereas some genetically similar local populations were aggregated into separate groups to satisfy non-genetic FRAM stocks, resulting allocation errors should have been restricted to the implicated FRAM groups. We do not think there are substantial misallocation errors in our data, although we are aware of two potential sources of this type of error. First, allocation estimates for FRAM OR North Coast stock might have decreased due to misallocation of Siuslaw River Chinook (GSI: Mid-Oregon Coast; FRAM: OR North Coast) to other populations in the Mid-Oregon Coast GSI stock, which was not included in the FRAM. Second, allocation estimates for FRAM U Columbia R summer/fall stock might have been decreased due to misallocation of Hanford Reach Chinook (GSI: U Columbia R summer/fall; FRAM: Upper Columbia Fall Bright) to other populations in the U Columbia R GSI stock. Neither of these misallocation errors to FRAM group would substantially change our findings.

Opportunities and limitations for GSI and refined time/area management

We hoped that results from our GSI study would increase the power and utility of current CWT-based Chinook Salmon fishery management as implemented using the FRAM. We succeeded in a number of important ways. Overall, our results support

current recalibration of the Chinook Salmon FRAM to a more recent base period. This is important to management because the base period is used to determine stock abundance and exploitation and, by extension, post-season stock composition. One of our most important findings was the contribution of Mid-Oregon Coast populations to harvests. Previously, those populations were not thought to contribute substantially to Washington commercial troll harvest and were not originally included in the Chinook FRAM when it was developed. Because genetic data showed a substantial contribution from Mid-Oregon Coast populations, we reviewed historical data for this fishery and found tag recoveries that support results of genetic mixture analysis. Unfortunately, the options for CWT release programs in this region are extremely limited. The only tagging program with a sufficient time series is in the Elk River, which is at the southern end of the Mid-Oregon Coast region and, according to our genetic data, is not necessarily representative of other populations in the region in terms of overall contribution to the fishery. Elk River contributes less than 7% of all Mid-Oregon Coast fish, whereas the Umpqua River contributes 41%.

Stock composition analysis is used to monitor and evaluate fishery impacts on Chinook Salmon stocks, and to increase understanding of spatiotemporal distribution of these stocks, including their associations with oceanographic conditions. Our efforts were focused on fishery impacts and improving the ability of resource managers to allocate harvest of abundant stocks among fisheries while protecting sensitive stocks, especially those listed under the US Endangered Species Act. However, because abundant and sensitive stocks co-occur in coastal ocean fisheries, more detailed information on sensitive stock distribution might not improve managers' abilities to increase harvests of abundant stocks while still holding impacts on sensitive stocks to acceptable levels. Nevertheless, improved distributional information will provide more accurate estimates of relative impacts and should better inform safe harvest levels.

GSI provides a powerful, independent opportunity for cross validation of the Chinook FRAM. With GSI, every fish is genetically marked and can be included in the mixture model. With CWTs, tag recoveries vary in each fishery, depending on the stocks contributing to the fishery and tagging rates for hatchery releases, which can vary

between 0% (none tagged) and 100% (all tagged). Expanding CWT stock composition estimates to include wild fish would require information not available for this complex fishery, including age-specific escapement and exploitation rates of wild populations. Therefore, the number of tagged fish in a mixed-stock fishery is not easily related to the total number of fish originating from natural production areas surrounding hatcheries that tag fish. In contrast to CWT retrieval, GSI sampling is non-lethal, although some delayed mortality undoubtedly results from capture and handling. Non-lethality provides an opportunity to sample non-retained, sublegal-size fish and obtain empirical, stock-specific estimates of those encounters. GSI estimates of stock origin for individual fish also include assignment error that has been well characterized (Anderson et al. 2008).

Unlike CWT-based methods, neither conventional GSI mixture modeling nor individual assignment provides age-specific exploitation rates or discrimination of different hatchery release groups (e.g., different ages or experimental treatments) among fish from the same or genetically similar populations. Age can be inferred from otoliths or scales, but collection and analysis require significant additional effort and expense. Age is also obtainable using an alternative genetic method referred to as parentage-based tagging (PBT), which requires genotyping all (or nearly all) potential parents in a "marked" population so that offspring can be assigned to specific parent pairs. PBT is often used for characterizing relative reproductive success of hatchery fish spawning in the wild (Ford et al. 2012), and can provide nearly all of the information currently obtained from CWTs, including time and location where the parents were spawned as well as family-specific performance (Hankin et al. 2005; Anderson and Garza 2006). Although PBT has been proposed as an alternative to CWTs (Anderson et al. 2012; Steele et al. 2013), it is thought to be logistically intractable and cost prohibitive on a coast-wide scale (Hankin et al. 2015). Instead, managers have suggested using radio-frequency identification (RFID) micro tags to replace or augment CWTs (Hankin et al. 2015). However, after considering results of a contracted study on the issue, the Pacific Salmon Commission decided that, "transition to the current generation of RFID tags (microchips or PIT tags) is not warranted" (Pacific Salmon Commission 2017). A common sentiment among managers is that, "investigation of new technological approaches to provide data for salmon fishery management diverts monies that can be

used to maintain the existing CWT program" (Pacific Salmon Commission Joint CWT Implementation Team 2015). Multiple reports leave open the possibility of reconsidering RFID tags in 3 to 5 years, but for the near future, CWT-based harvest models will remain the cornerstone of West Coast salmon management.

Future directions

For various historical, logistical, and financial reasons the US West Coast fishery harvest management community has generally resisted genetic methods (Pacific Salmon Commission 2008). This is in distinct contrast to fisheries farther north in Canada and Alaska, where genetic mixture modeling is central to harvest management. West Coast salmon harvest management has instead evolved towards exploitation rate evaluation, rather than stock composition estimates in individual fisheries (Morishima and Henry 2000). Exploitation rate estimation from CWT recoveries is a straightforward calculation, but estimates from GSI data would require all fisheries to be sampled, which is unlikely with current budget constraints on existing programs. Nevertheless, GSI provides a superior method for many stock composition comparisons in selected fisheries, such as the Washington coastal troll fishery. Until now, stock composition estimates from GSI dating back to the 1980s (Milner et al. 1985; Utter et al 1987) were not used in fishery management because of the large investment in CWT assessment methods. While it is unlikely that GSI, PBT, or RFID tags, will soon replace CWTs (Pacific Salmon Commission 2008 and 2015), we expect genetic methods will increasingly be used to help mitigate problems associated with mark-selective fisheries. These problems include violating the assumption of similar exploitation rates between wild populations and hatchery indicator stocks, total marking of hatchery fish (complicating tag recovery), lethal sampling to recover CWTs, and wild populations potentially mismatching their hatchery indicator stocks with respect to habitat use or migration timing, resulting in different exploitation rates. Following the guidance of the Pacific Salmon Commission (2008), our study offers an example of the valuable role genetics can play in supporting the established management structure and the recalibration of FRAM.

ACKNOWLEDGMENTS

We thank the Washington Trollers Association, the Coastal Trollers Association, and all the individuals who helped collect fin-clip tissue samples from the commercial troll fishery. The port liaisons also played a pivotal role in the outstanding tissue and data quality we observed in this study. We thank Eric Iwamoto and laboratory staff at NWFSC and WDFW for DNA extraction and genotyping. Cheryl Dean and Todd Kassler provided superb field, laboratory, and logistical support. David Teel and Jim Myers provided immeasurable help and consultation related to genetic stock groups, especially in the genetically complicated Columbia River and Puget Sound. NOAA's Cooperative Research Fund supported the work with co-PI Peter Lawson. Finally, we thank Michael Ford, Jeffery Hard, Jim Myers, Todd Seamons, Gary Winans and other anonymous reviewers who helped substantially improve the clarity of our paper. Reference to trade names is for information only and does not imply endorsement by the US Government, the State of Washington, or the Washington Trollers Association.

Figure Captions

Figure 1. Collection locations of individual Chinook Salmon taken in the commercial troll fishery off the coast of Washington. Samples were separated between the Juan de Fuca Canyon in Area 3 & 4, north of latitude 47.5 and those taken to the south in Area 2 near Grays Harbor. These areas represent most of the Washington troll fishery.

Figure 2. Genetic stock composition estimates and 95% confidence intervals for genetic stock groups aligned to 11 FRAM coded-wire-tag indicator stocks and Mid-Oregon Coast (ordered from south to north), and a combined group of 22 non-FRAM stocks, 2012-2015. The non-FRAM Mid-Oregon Coast stock (marked with an asterisk) is disaggregated from the other non-FRAM stocks because it made an unexpectedly large contribution in all 4 study years.

Figure 3. Genetic stock composition estimates and 95% confidence intervals for 22 non-FRAM stocks (ordered from south to north). The non-FRAM Mid-Oregon Coast stock was included with the FRAM stocks in Figure 2 rather than in this figure, due to its much larger contribution in relation to other non-FRAM stocks.

Figure 4. Genetic (GSI) and coded-wire tag (FRAM) stock composition estimates for 11 FRAM stocks, Mid-Oregon Coast (ordered from south to north), and an aggregate of 22 non-FRAM stocks. Because of its large contribution, non-FRAM Mid-Oregon Coast is shown disaggregated from the non-FRAM GSI estimate and included with the FRAM stocks. Differences between FRAM and GSI were quantified by mean square error (upper right corner of each panel).

Figure 5. Time-area stratified GSI and Chinook FRAM stock composition estimates for 11 FRAM stocks and Mid-Oregon Coast (ordered from south to north), in addition to an aggregate of 22 non-FRAM stocks. Mean square error values appear in the upper right of each panel. See Table 1 for sample sizes**Appendix 1.** Listing of GAPS Chinook Salmon baseline populations with corresponding genetic stock groups (Seeb et al. 2007) and Chinook FRAM stocks.
