Maryland Tidewater Administration

ABSTRACT

During 1980, adult American shad (Alosa sapidissima) were collected at the head-of-the-Chesapeake Bay with various commercial fishing gears. Of the 399 fish observed, 147 were successfully tagged and released. Based on 13 recaptures, a population estimate of 2,675 American shad (UL=4,740, LL=1,607 @ 95% CL) was made utilizing Chapman's modification of the Petersen formula. Analysis of length, weight, sex ratios, age, and spawning history indicated that the 1979 and 1980 head-of-the-Bay shad runs were similar and could be characterized as a population supported by two remnant age classes with approximately 11% repeat spawners. Major differences were noted with other east coast shad stocks particularly the stable and increasing runs on the Delaware and Connecticut Rivers. Only one American shad was reported captured during the 1980 Susquehanna River sport fishing survey. 1980 sport catches for other clupeid species were also well below previous reported levels. White perch, channel catfish, and striped bass made up 81% of the estimated sport angling harvest in 1980. No young-of-the-year American shad were captured by haul seine or otter trawl from 10 upper Chesapeake Bay sampling stations in 1980. Severe declines in numbers and standing crop for all Alosa species from the late 1960's through 1980 in the Susquehanna estuary was noted. An American shad literature review was initiated to broaden Maryland's biological and management data base. Comparison of this state's present situation with the successful management practices of other areas was undertaken in hopes of restoring the severely depleted shad stocks to levels allowing for the perpetuation of the species and eventual consumptive use of the resource.

ACKNOWLEDGEMENTS

We would like to acknowledge the assistance of Bill Hogans and Tim Sughrue who provided tireless field help under arduous conditions. Thanks are due those people who also helped as creel clerks; John Foster, Mike Burch, Howard King, Rudy Lukacovic, John Williams, and Bob Lunsford. We extend our gratitude to Captains Frank and Henry Pratt, Howard Sexton, and Alvin Price and their respective crews in helping us obtain adult American shad for tagging. Special thanks are due Nick Carter, Harley Speir, and Steve Early for their field help and acute editorial assistance. We also thank Rose Safford for typing the manuscript.

LIST OF FIGURES

INTRODUCTION

Historically, the principal shad river in Maryland has been the Susquehanna (Mansueti and Kolb 1953). Prior to 1980, a commercial shad fishery had existed there for over 200 years. Similarly, a successful sport fishery had existed in this region since the early 1930's. Because of the sharp, continuous statewide decline in the numbers of adults harvested since the early 1970's the 1980 Maryland shad season was closed. The most precipituous decline occurred in the Susquehanna drainage: The 1971 reported commercial catch of American shad from the Susquehanna River and Flats combined was 184,221 pounds while the reported 1979 catch for this same area was 14,319 pounds (Maryland Tidewater Administration MTA in-file data).

Concerned by the seriousness of this situation, the Tidewater Administration of Maryland's Department of Natural Resources proposed a long term investigation of American shad in the upper Chesapeake Bay. The primary objective of this study is to assess the status of head-of-the-Bay shad stocks, specifically those utilizing the Susquehanna River drainage. The information obtained will be used to formulate management policies to restore American shad to stable, harvestable levels. To meet the primary objective, five separate jobs were initiated: tagging and population estimate, population characterization, creel census, juvenile recruitment survey, literature review and survey. The five year project, initiated in February, 1980, is funded under The Federal Aid in Fish Restoration Act, PL 81-691, and the Power Plant Siting Program of the Maryland Department of Natural Resources.

JOB I. TAGGING AND POPULATION ESTIMATION

INTRODUCTION

A prerequisite to effectively manage an exploited fish stock is to determine how many individuals comprise the population under investigation. Since 1965, the state of Connecticut has been utilizing a mark-recapture program in estimating the numbers of American shad ascending the Connecticut River each spring to spawn (Crecco 1979). The data accumulated from this procedure has been one of the major factors in that state's efforts to effectively manage their shad stocks. Similar efforts on the Delaware River by New Jersey and Delaware state conservation personnel have also aided in effective management of that river's American shad stocks (Lupine 1980).

Few population estimates for American shad in Maryland waters have been made. Walburg (1954) estimated the American shad population (in pounds) in Maryland waters from 1944 to 1952 based on a single tagging experiment conducted in 1952 and the commercial catch records from 1944 to 1952. These estimates appear below:

YEAR	COMMERCIAL CATCH (lbs.)	ESTIMATED POPULATION (lbs.)
1944	661,005	2,412,427
1945	556,141	1,951,372
1946	653,868	1,841,882
1947	768,830	1,800,539
1948	892,852	1,988,535
1949	949,690	2,168,242
1950	1,342,401	3,274,149
1951	1,486,616	3,046,344
1952	1,487,085	2,836,193

St. Pierre (1978) estimated the average annual population of American shad in the Susquehanna River and the extreme northern portion of Chesapeake Bay from 1890 to 1904 to be

1,790,000 fish. This computation was based on the average annual commercial harvest for this 15 year period plus the estimate that approximately 24% of the total population was harvested during this time.

Because of the time lag between past and present population estimates of American shad and the inadequacies of previous efforts, a tagging experiment was undertaken to determine the numbers of American shad utilizing the Susquehanna River, Susquehanna Flats, and Northeast River to spawn. An extensive population evaluation would aid the Maryland Department of Natural Resources in its attempts to monitor the American shad in what was historically its most important spawning/nursery area, and in using the accrued data for future management decisions.

METHODS AND MATERIALS

Tagging of adult American shad was undertaken at various sites within the Susquehanna River, Susquehanna Flats, and Northeast River between April 22 and May 31, 1980 during the peak of the spawning run for this species (Figure I, p. 14). Fish were captured in commercially operated pound nets and anchor gill nets. Drift gill nets were also employed but were unsuccessful in catching shad. Three pound net sites were located along the shore of the Northeast River at its juncture with the Susquehanna Flats. A fourth pound net site was located at the mouth of the Susquehanna River near Perryville. Drift gill nets were fished along the east shore of the Northeast River and in the Susquehanna River near Port Deposit and Havre-de-Grace. Gill net dimensions (both anchor and drift) were 1,000' x 6' and ranged from five to five and one half inch stretched mesh. All gill net sampling was done between 12:00 AM and 6:00 AM. Pound nets were sampled every day from 6:00 AM to 12:00 PM. All tagging was done with a Dennison Floy Tagging Gun, Model # FD-67, using plastic anchor tags four inches in length.

Fish were taken from the nets, measured for length, scale samples taken, sex determined, and tagged as expeditiously as conditions would allow. Under certain circumstances, to minimize stress, the fish were only tagged and immediately returned to the water. Data from dead shad found in the nets, including weights, was also collected. Tags were inserted into the dorsal musculature posterior to the dorsal fin at an angle conducive to streamlining. Tag retention appeared to be satisfactory and did not seem to affect tag return data. A $5.00 reward was offered for each tag returned.

RESULTS

A total of 399 American shad were examined during the 40 days of sampling. Breakdown of collection by gear types is presented in Table 2, p. 12. Figure II, p.15 illustrates the time frame in which pound net and gill net captures were made. Of the 399 fish examined, 147 were tagged successfully and released from the four pound nets and two anchor gill nets. Stress among captured fish may have caused some post-release mortality. Fish taken from the four pound nets were tagged and released with good success and did not seem to exhibit the degree of stress that was observed in fish captured by, tagged, and released from the anchor gill nets. Mortality for fish captured in the anchor gill nets appeared to be higher than those captured in the pound nets.

Another problem encountered with the use of the anchor gill nets was that of immediate recapture of the newly marked fish from the same net. Fish were initially released on the downstream side of the gill net but since this gear is fished under no flow river conditions there was no current to carry the tagged fish downstream away from the nets. The use of a holding tank to transfer the newly marked fish to deeper water away from the tagging area was moderately successful.

Initially, population estimates were to be made using multivariate population models such as the Jolly-Seber stochastic and Bailey triple catch deterministic models (Ricker 1975). However, since there were only thirteen recaptures, these population models could not be utilized. An estimate for the adult spawning population of American shad in this area was attained, to an acceptable degree, by using Chapman's version of the standard Petersen estimate (Chapman 1951). Appropriate confidence limits were set by using tabulated limits for a Poisson distribution as set forth by Ricker (1975). These computations are presented in Table 3 while recapture data is summarized below:

Of the 13 recaptures-

a) 10 were made by commercial fishermen
2 were made by sport anglers
1 was made by the Conowingo Dam Fish Lift

b) 9 were originally tagged from pound nets
4 were originally tagged from anchor gill nets

c) 5 fish were recaptured from the same location
5 fish were recaptured upstream from their tagging locations
3 fish were recaptured downstream from their tagging locations

d) shortest recovery 1 day
longest recovery 21 days
average recovery 6.4 days

Of the three shad recaptured downstream of their tagging location, two were recaptured one day after tagging by a commercial fisherman from Rock Hall, Maryland, approximately 30 nautical miles south of their tagging location. Leggett (1976) found that a majority of the American shad he tagged with ultrasonic tags (both internal and external) on the Connecticut River initially moved downriver as a possible

result of physiological shock and disorientation related to capture and tagging. The third downstream recovery was that of a spent individual tagged 19 days previously and recaptured at the most southerly pound net, possibly indicating it was returning to the ocean. Specific information concerning each of the 13 recaptures is presented in Table 1, p. 11.

DISCUSSION

Several problems were encountered in both collecting and analyzing the data needed to estimate the number of American shad in the head of Chesapeake Bay.

1. A lack of sufficient capture sites within the specific spawning area combined with a lack of time synchrony between netting effort and adult fish spawning waves caused the number of fish captured to fall below what was originally anticipated. Anchor gill nets, which ultimately caught a majority of the fish, were not successfully used until the latter part of the run. American shad are not as hardy as other fish and it was feared that those caught in the anchor gill nets would be unfit for tagging. Pound nets on the other hand, permit the continuous movement of captured American shad thus minimizing much of the stressing conditions imposed on gill net caught fish. As a result of trial and error, however, it was found that by fishing only one or two boxes of gill net at a time, continuously checking the nets for fish, and using an aerated holding tank this gear would be used to collect shad for tagging. The majority of the shad lost in the anchor gill nets occurred before these techniques were employed and perfected, and most of the fish captured by this gear during the latter part of the run were successfully tagged and returned to the water. Of the 31 fish lost in the pound nets, 19 were the result of the late arrival of the tagging team to the pound nets on April 22. Table 2 presents a comparison of gear types employed to catch American shad and their relative success.

2. As stated previously, the lack of sufficient numbers of recaptures eliminated the use of multivariate population models such as the Jolly-Seber which are specifically designed for use with open populations that are subject to immigration and emmigration. Ricker (1975) states that if the number of recaptures is small, say less than four for any of the several recapture periods (ie. one week) the population estimate is subject to bias.

3. A number of problems were associated with the use of a Petersen population estimate. Ricker (1975) notes six conditions that should be satisfied to obtain a valid Petersen estimate;

   a. the marked fish suffer the same natural mortality as the unmarked fish
   b. the marked and unmarked fish are equally vulnerable to fishing
   c. the marked fish do not lose their marks
   d. the marked fish become randomly mixed with the unmarked fish
   e. all marks are recognized and reported on recovery
   f. there is only negligible recruitment to the catchable population during the time the recoveries are being made.

   Tagging equipment and procedures were quite similar to those employed on the Delaware (Lupine 1980) and on several rivers in South Carolina (Crochet et al. 1976). Data from these studies indicated little tag induced mortality and good tag retention. Because of the thinness of the spagetti tag used and its placement at a streamlined angle, tag-induced excess fishing mortality from these areas was found to be virtually non-existent. These same observations were also noted for the 1980 Susquehanna tagging operation. It would be difficult to prove or disprove whether the tagged fish become randomly distributed with the untagged individuals but it seems reasonable to

assume that if the tagged fish were released in good physical condition their ability to keep up with the untagged fish should not be impaired. No mention of this problem was made in other shad tagging studies (Crochet et al. 1976, Minta et al.1980, Lupine 1980). The offering of a $5.00 reward for each tag returned was thought to provide sufficient incentive for reporting the recapture of American shad during the present study.

Violation of assumption f interjects a source of bias into the Petersen estimate. Since American shad enter their natal rivers in several spawning waves or pushes, they are not all available for possible capture, tagging and recapture at one time. The general trend on the Susquehanna River during previous years has been for the shad run to begin during the last two weeks of April and continue until the end of May, depending on water temperatures and river conditions. Figure II indicates that during the course of the 1980 tagging experiment possibly three different spawning pushes were noted. Ricker's assumption f may possibly be met if one considers the fact that once the migrating American shad reach the Susquehanna area they can go nowhere else because of the presence of the Conowingo Dam. Since all of the fish that were observed and collected by the various gear types were fish homing to this area, one is dealing with only Susquehanna fish regardless of the time frame in which they were observed. This problem of timing with respect to the various spawning pushes does not seem to deter the use of the Petersen statistic in estimating populations of American shad in other east coast rivers (Lupine 1980, Crecco 1979).

Ricker (1975) states that the violation of assumption f will produce a population estimate that is too high assuming that the other five assumptions are satisfied. It seems probable then, that using the modified Petersen formula

overestimated the 1980 spawning population of American shad in the Susquehanna drainage. Since the estimated population was only 2,675 spawning adults, the overestimated figure further emphasizes the severely depleted shad stocks utilizing the upper Chesapeake Bay.

4. Another source of bias associated with a Petersen estimate is the low number of recaptures. Bailey (1951) states that a large scale recapture effort may be necessary to make a reliable population estimate. Ricker (1975) noted that lower numbers of recaptures cause the Petersen estimate to become biased and, therefore, less reliable, although some confidence is gained through the use of a Poisson distribution as was done for the Susquehanna data (Table 3, p. 13).

   The sources of recaptures during the 1980 study were to have been the local sport and commercial fisheries. However, the progresive, drastic decline in the spawning stocks of American shad necessitated a statewide closure of Maryland waters for the 1980 season. Because of this closure, the incidental sport and commercial fishing effort for American shad produced a limited number of returns, with the bulk coming from commercial watermen specifically hired by the Department of Natural Resources to capture fish for tagging. Admittedly, this made for a somewhat limited population estimate, but in analyzing the current situation the Department considered the protection of the remaining brood stocks to be of greater importance than extreme precision of estimates. Although overall stock size is greatly reduced, sufficient numbers of American shad may be present in this area to allow for a more reliable population estimate, provided the number of recaptures increases. This will be attempted in 1981 through greater utilization of local commercial watermen in an effort to improve sampling techniques and timing. It is hoped that these changes will increase data reliability and allow the use of more sophisticated statistical techniques to provide more accurate information.

SUMMARY

1. Of the 399 American shad collected at the Head-of-the-Bay, 147 were tagged and released. Thirteen of these were recaptured.
2. A population estimate of 2,675 American shad was made utilizing the Petersen formula.
3. Stress and mortality problems associated with the use of anchor gill nets to capture shad for tagging were encountered. After corrective measures were implemented, these problems were reduced, allowing for the successful tagging of gill net caught shad.
4. Increased tagging and recapture efficiency may permit the use of more accurate population models in estimating future Susquehanna shad populations.

TABLE 1. Capture-recapture dates, locations and gear types for thirteen recaptures of tagged American shad during 1980.

Date Tagged	Date Recaptured	Tagging Location	Gear Type	Recapture Location	Gear Type

Con. Te. = tailrace

TABLE 2. Comparison of total catch, number tagged, number lost, and % net mortality by location and gear type for American shad captured in the Susquehanna River, Susquehanna Flats, and Northeast River during 1980.

		Location	Total Catch	No. Tagged	No. Lost	% Net Mortality
A.	Pound Nets	TP	50	29	21	
		CC I	8	7	1	
		CC II	17	16	1	
		PP	45	37	8	
	Sub Totals		120	89	31	26
B.	Anchor Gill Nets	NE R.	0	0	0	
		Sus. R.	144	65	79	
	Sub Totals		144	65	79	55
C.	Conowingo Fish Lift	Dam	135	0	?	
D.	Drift Gill Nets	NE R.	0	0	0	
		Sus. R.	0	0	0	
E.	Grand Totals		399	154*	110	42**

* # tagged used in Petersen estimate = 147: 7 fish were recaptured in anchor gill nets immediately after tagging, died, and were not included in number tagged but as lost in population estimate.

** figure based on pound net and anchor gill net totals only

TABLE 3. Population estimate of adult American shad utilizing the Susquehanna River, Susquehanna Flats, and Northeast River for 1980.

FROM CHAPMAN (1951):

$$N = \frac{(M + 1)\ \ (C + 1)}{R + 1}$$

where: N = population estimate
C = number of fish examined for marks
R = number of fish recaptured
M = number of fish marked

For the 1980 Survey -

C = 252
R = 13
M = 147

Therefore -

$$N = \frac{(147 + 1)\ \ (252 + 1)}{13 + 1}$$

$$= \frac{148 \times 253}{14}$$

$$= \frac{37,444}{14}$$

$$= 2,675$$

FROM RICKER (1975): Calculation of sampling error using recapture numbers in conjunction with a Poisson distribution approximation and acceptable confidence limits.

Using Chapman (1951) -

$$N^* = \frac{(M + 1)\ \ (C + 1)}{R_t + 1}$$

where: R = tabular value (from Ricker p343)

$$\text{Upper } N^* = \frac{(147 + 1)\ \ (252 + 1)}{6.9 + 1} = 4,740 \text{ @ } 95\% \text{ confidence limits}$$

$$\text{Lower } N^* = \frac{(147 + 1)\ (252 + 1)}{22.3 + 1} = 1,607 \text{ @ } 95\% \text{ confidence limits}$$

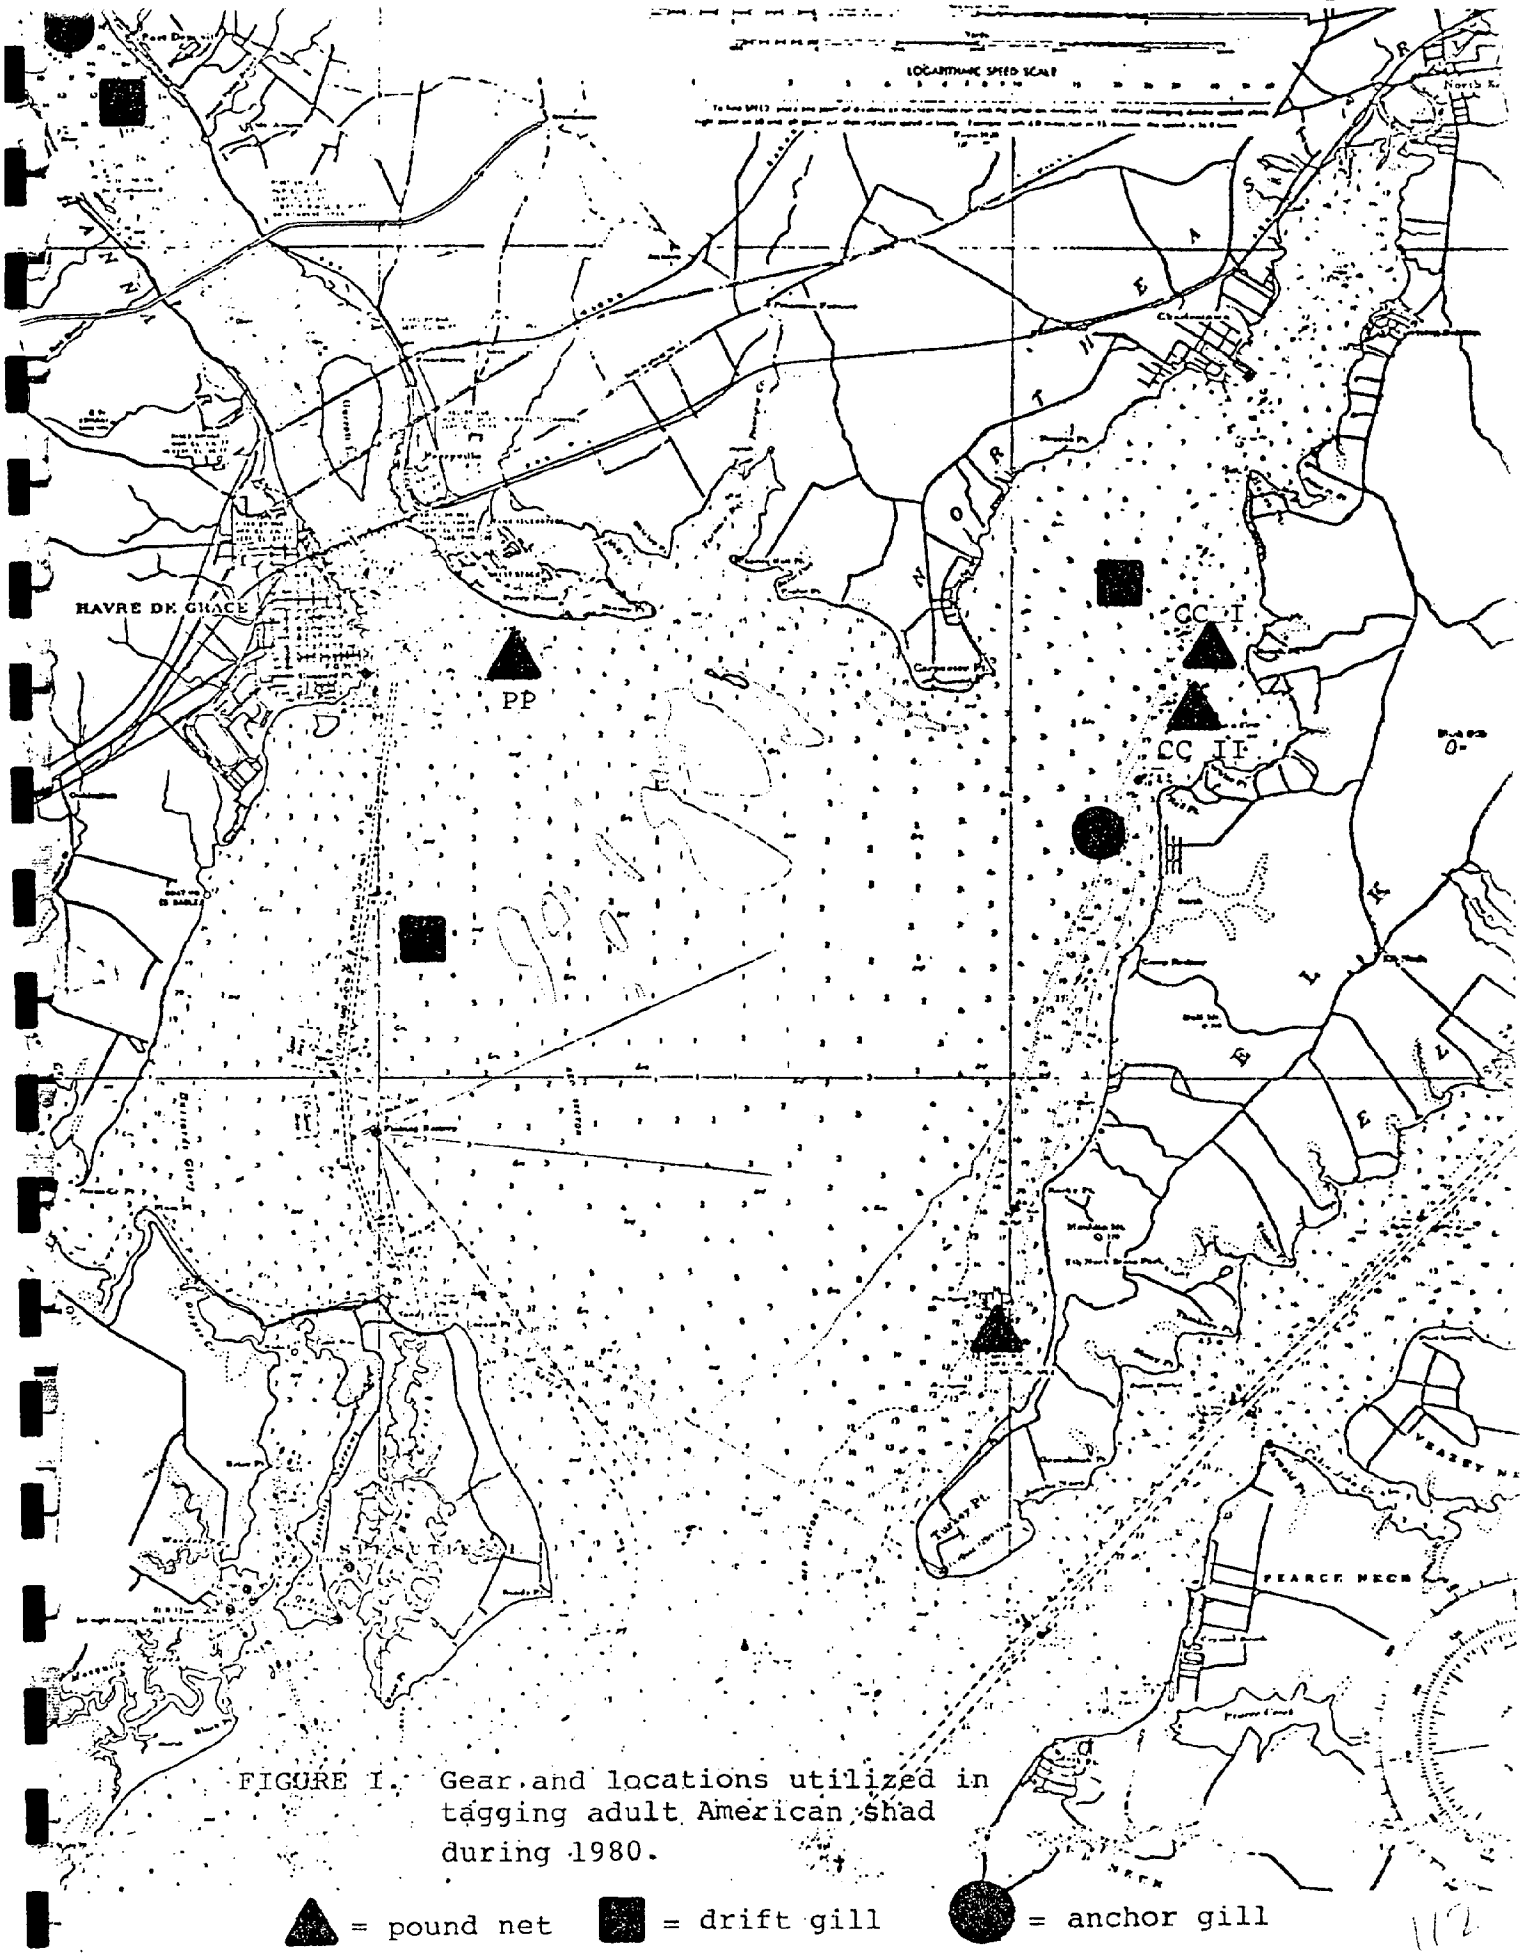

FIGURE I. Gear and locations utilized in tagging adult American shad during 1980.

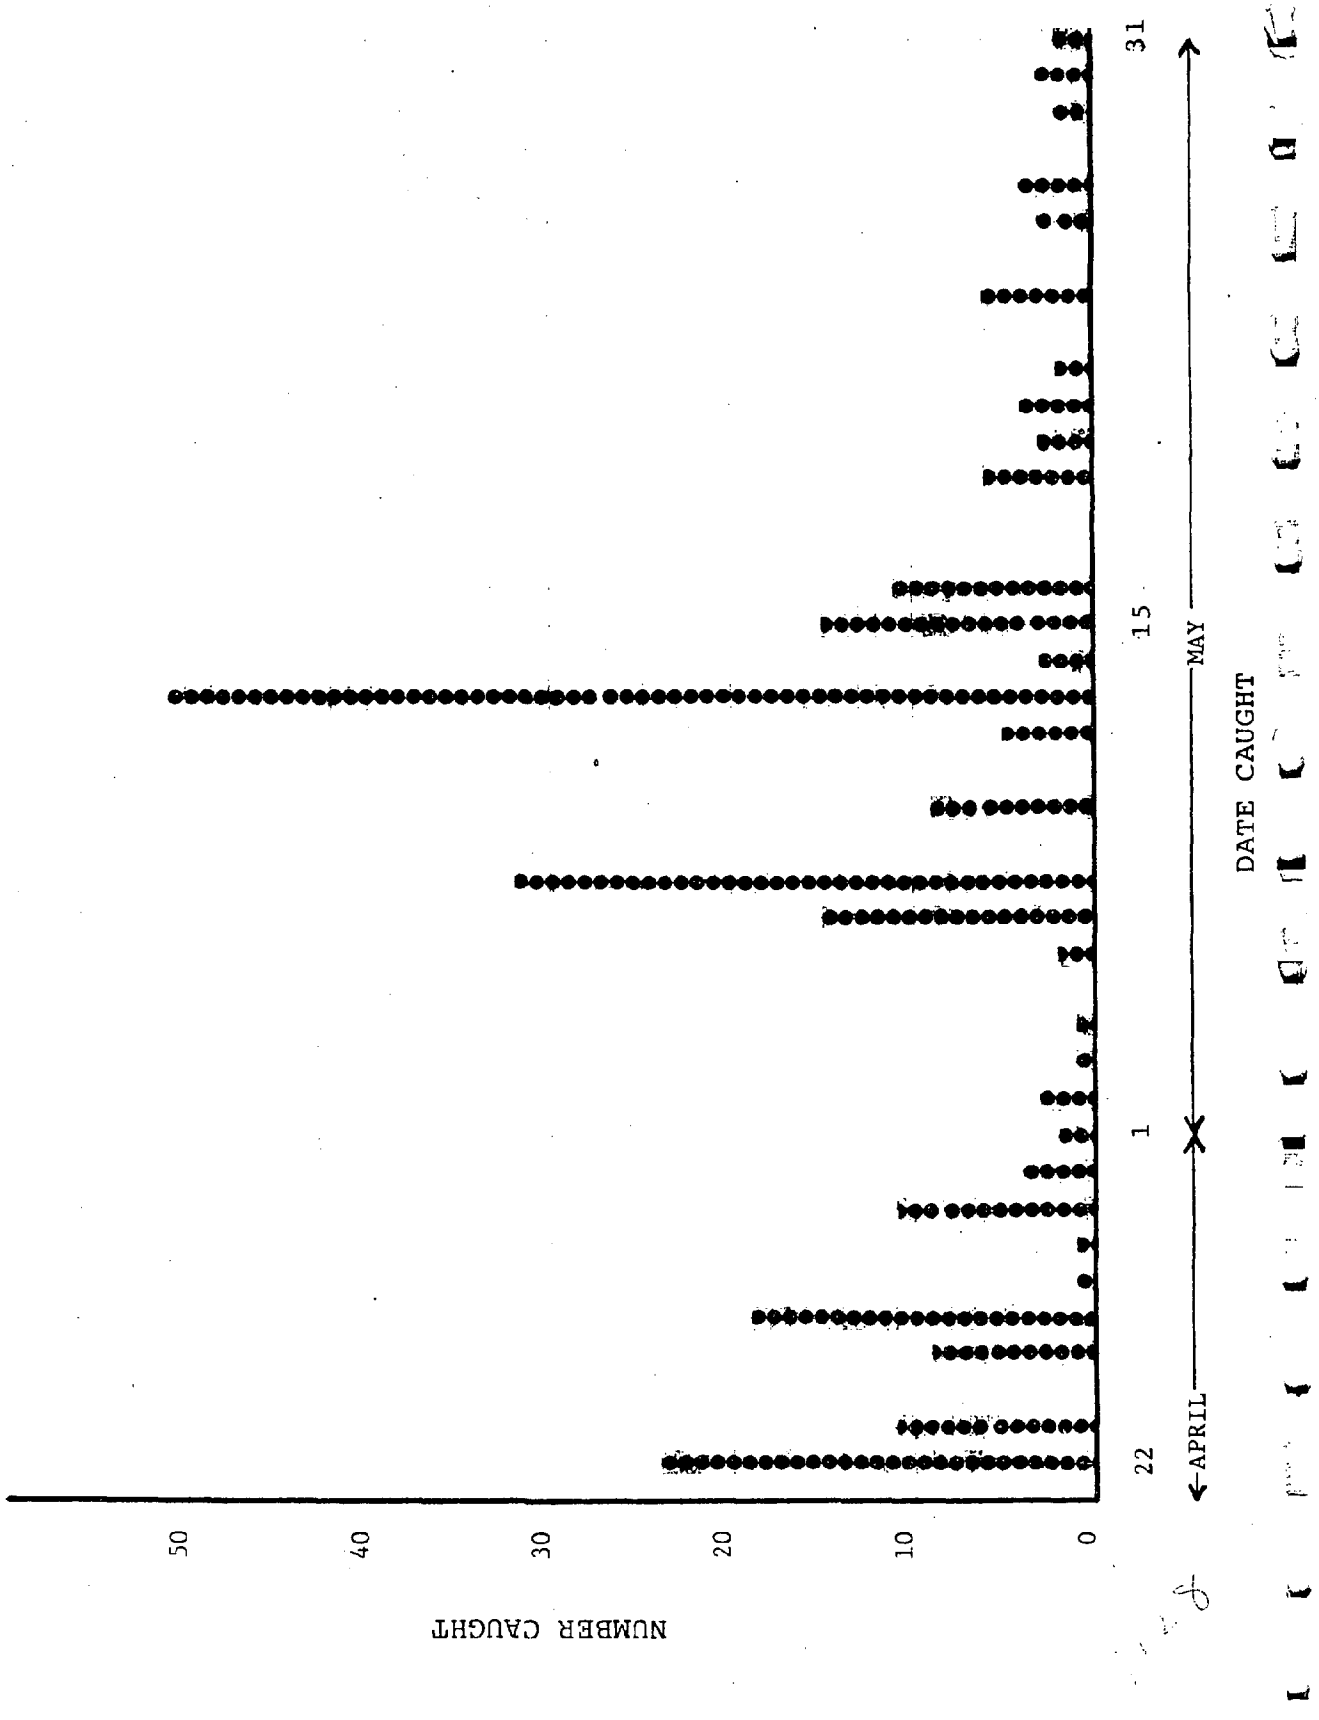

FIGURE II. Numbers of American shad caught for tagging by all gear types and by date from the Susquehanna River, Susquehanna Flats, and Northeast River during 1980.

JOB II. POPULATION CHARACTERIZATION

INTRODUCTION

Effective management policies can only be implemented when an extensive data base exists from which to draw information. Such a data base exists in Connecticut where the population characteristics of American shad have been monitored for many years (Fredin 1954, Judy 1961, Jones et al. 1976, Leggett 1976, Crecco 1979, Minta et al. 1980). In this system such parameters as growth and survival rates, total, fishing and natural mortality rates, and annual fishing rates have been determined from length and weight frequencies, sex and age composition, adult spawning history, and commercial and sport fishing data since 1966 (Crecco 1979). Other estimates made for Connecticut River shad include recruitment, escapement, and return per spawner based on adult age structure. The accumulated data are then utilized for determining different yields associated with changes in fishing effort for the exploited shad fishery. A stable shad population has been the result of this research and subsequent management which allows sufficient escapement while permitting a viable economic harvest.

Most of the literature concerning Maryland American shad stocks discusses historical overviews of the commercial fishery, catch records, and catch-per-unit-effort (CPUE) estimates of those landings (Mansueti and Kolb 1953, Walburg 1955, Mansueti 1958, Walburg and Nichols 1967, Forester and Reagan 1977, St. Pierre 1978). Very little is known about the fluctuations in American shad stocks for the Susquehanna River other than these historical reviews. There has been no long term monitoring program of the population characteristics of Susquehanna River American shad. La Pointe (1958) presented sex ratios, age class, spawning history and length data for Susquehanna shad. RMC (1979) summarized sex and age composition data for shad collected at the Conowingo Dam fishlift and from sport anglers between

1972 and 1979. In that eight year period, however, only 451 fish were examined, and in one year, as few as six fish were collected (Table 4, p. 24).

In 1979, a pilot study of Susquehanna River American shad stocks was made. The study, designed to gather information concerning population characteristics of upper-Bay shad, was expanded in 1980 to measure length and weight frequency distributions, sex and age composition, and adult spawning history data for five years. This will allow estimation of the parameters needed for effective management of Maryland shad stocks. For example, since the gear used by upper Chesapeake Bay shad fishermen is highly size selective, accumulation of length-weight data would allow the Department of Natural Resources to better protect a safe number of virgin spawners who make up the majority of the adult population and older, more fecund repeat spawning individuals through limitations in net mesh sizes.

METHODS

American shad were collected at various locations in the Susquehanna system as described in JOB I. A sample of approximately 12 or more scales was taken midway between the dorsal fin and the midline on the left side of each fish and placed in a scale envelope. The date and location of capture, net type, fork length (mm), sex, and weight (grams) were recorded on each envelope. Weight measurements were taken from dead fish only. On occasions when it appeared that a fish was stressed due to handling or confinement in the sampling gear, scale samples were not taken so as to minimize handling and possible mortality, since the fish were being tagged for use in a population estimate.

Scale samples were prepared for age and spawning history determinations by selecting 4 to 6 non-regenerated scales from each envelope and cleaning each one thoroughly with soap and

water. Clean scales were impressed on 25 mm by 76 mm acetate slides with a roller press. The slides were then placed in a microprojector and read at 2.5X magnification. Two biologists read each scale for age and spawning marks according to the techniques developed by Cating (1953). If the two readers were in disagreement, the slide was set aside to be re-read later. If agreement could not be reached after reading the slide a second time, that sample was discarded. Age was determined by the number of true annuli present plus the outer edge of the scale (Cating 1953). Spawning history was indicated by the presence or absence of a spawning mark near the scale periphery.

RESULTS

To reduce stress-induced mortality of captured American shad, not all physical measurements were taken for each fish collected. Consequently, sampling sizes for such measured parameters as length, weight, age and spawning marks are not equal. The sample sizes for sex, length, weight, and age of male, female, and spent shad are presented below:

	SAMPLE SIZE		
Variable	Female	Male	Spent
Sex	160	97	
Length	124	69	5
Weight	57	16	
Age	117	67	4

The sex ratio of 257 shad examined was 1.6:1, female to male (Table 6, p. 28). The mean fork length for females was 461 mm, while that for males was 428 mm (Table 5, p. 26). The mean weights for female and male shad were 1,580 grams and 1,240 grams, respectively (Table 5, p. 26). Figures III and IV present the length frequency distributions by sex for adult shad.

There were 196 scale samples collected for age structure data and spawning history. Because some scale samples were discarded as unusable, there were 188 slides from which age and spawning history could be determined. Table 6, p. 28, presents scale analysis data. The dominant age class, age IV, comprised 57.4% of the shad examined, while age V individuals made up 33% of all shad collected. Only 11.7% were determined to be repeat spawners (Table 6). The percentage of male shad which were virgin fish was 83.6%, while the female population consisted of 90.6% virgin recruits.

DISCUSSION

Tables 6, 7, and 8 (p. 28, 30, and 34) present characterization data collected from Susquehanna American shad captured in 1979 and 1980, and for other east coast shad rivers. Of note are the following:

1. Little age structure change was noted for upper Chesapeake Bay shad captured in 1979 and 1980; the dominant age class for both years was IV. The incidence of repeat spawners increased slightly in 1980, although this level was far below the 37% reported by LaPointe (1958) for Susquehanna River American shad. Slight increases were noted in mean length for both males and females in 1980 while length at age ranges were similar for both years. The most noticeable change between the two year's catch was in the sex ratio which changed from strongly female in 1979 to slightly female in 1980. During 1979, approximately 90% of the American shad examined from the Susquehanna River and Flats were collected by gill nets. In 1980, nearly 50% of the fish sampled were taken from commercial pound nets, a less selective gear. This change in sex ratios appears to be an artifact of the various sampling gears employed for the two years.
2. 1978 sex ratios for Chesapeake Bay shad stocks from the York, James, Rappahannock, and Pamunkey Rivers, Virginia were similar to 1979 Susquehanna sex ratios. This similarity may, again, be due to the fact that fish collected

in all the Virginia rivers in 1978 and from the Susquehanna in 1979 were taken with size selective gill nets. Age structure, however, appears to be different between the two with age class VI individuals dominating the Virginia runs as opposed to age IV for the upper Chesapeake Bay population. Few age III and IV individuals were collected from these Virginia rivers in 1978. No data on repeat spawning was available from these Virginia caught fish.

3. Age structure of 1978 caught shad from Albemarle Sound North Carolina was similar to age structure of Virginia shad. However, certain differences between the two were noted: a) the dominant age class for the North Carolina fish was V instead of VI, b) the numbers of younger age classes (III and IV) was much greater for North Carolina shad. Sex ratios of Albemarle Sound fish were quite different from Maryland and Virginia Chesapeake Bay stocks and more closely represented the 1:1 ratio reported by Leggett (1976). The percentage of repeat spawners for 1978 Albemarle Sound fish was lower than for Susquehanna shad. This agrees with the findings of Leggett and Carscadden (1978) who concluded that the incidence of repeat spawners decreased with decreasing latitudes and was virtually non-existent in South Carolina, Georgia, and Florida.

4. Delaware River American shad captured in 1978 and 1979 exhibited a similar age structure to upper Chesapeake Bay fish with age IV individuals dominating. Beginning in 1978, however, an influx of three year old males occurred on the Delaware which increased greatly in 1979. Both mean length and length ranges at age were usually greater for 1979 Delaware shad as opposed to their 1979 and 1980 Susquehanna counterparts (Table 6, p. 28). Numbers of repeat spawners were significantly less for Delaware River shad due primarily to adult mortality during seaward migration (Sykes and Lehman 1957, Chittenden 1969).

113

5. Mean length and length ranges by age for both male and female Connecticut River American shad collected in 1979 were greater than 1979 and 1980 Susquehanna fish. However, the differences between 1979 Connecticut and 1979 Susquehanna shad were very slight for all age groups. The 1979 Connecticut River sex ratio was also quite similar to that found for 1980 Susquehanna fish. The greatest difference between the two stocks appears to be in the spawning history. The percentage of repeat spawners utilizing the Connecticut River in 1979 was 20%, with a 15 year average (1965-1979) of 36% (Minta et al. 1980). Susquehanna River American shad exhibited only a 10.4% and 11.7% incidence of repeat spawning during 1979 and 1980, respectively.

The data presented in Tables 6, 7, and 8 and summarized above were from American shad collected with various commercial gear types; therefore, some degree of sampling bias has been introduced. Measured parameters reflect characteristics of the commercially harvested sample and not the entire spawning population. The mesh size of commercial gill nets fished in the non-Maryland areas is unknown. However, it seems reasonable to assume that the mesh size employed by each system's commercial fishermen does not drastically change within that system. This is because a river's watermen are all fishing on the same stocks. Upper Chesapeake Bay gill net fishermen select large net sizes (5¼ to 5 3/4 inch stretch mesh) designed to capture the larger, more robust shad. Males, which are normally smaller than females at any given age are less likely to be captured by these larger mesh nets. An extra economic incentive also exists for taking females because of their roe. Preliminary pound net samples from the Connecticut River (Minta et al. 1980) indicated that there were major differences in the sex ratios of pound net vs gill net captured American shad in 1980. Connecticut DEP personnel theorize that the probability of tagging and recapturing small adult shad was reduced by gill net fishing that is highly size selective. Adult collections of American shad from the Delaware River are made with less size selective haul seines (Friedersdorff and Baren 1978, Lofton 1979, Lupine

1980). The 1979 Delaware sex ratio, 53% males and 47% females is very similar to the 1:1 proportion as reported by Leggett (1976).

It would appear from analysis and comparison of the 1979 and 1980 Susquehanna shad data that this stock can be characterized as a run primarily supported by two very small, virgin age classes with relatively few repeat spawners. These conditions provide little buffering against man-induced and natural environmental problems. The situation on the Connecticut River is such that each year's run is supported by more than one large year class and a large number of more fecund repeat spawners. Consequently, this is the most stable shad fishery of all major east coast rivers. With few repeat spawners present, the recent increases in Delaware River shad runs are due primarily to the presence of several strong year classes that have successfully passed through the Philadelphia pollution zone. Chittenden (1975) found that large increases in the 1962 and 1963 Delaware shad runs were the result of extremely large year classes produced in 1958 and 1959. Chittenden noted a shift in the sex ratios from strongly female in 1960 to strongly male in 1961 and 1962. He concluded that since males tend to enter the fishery one year before females, a sudden large increase in the proportion of male fish appears to be a strong indicator of year class strength and hence run size for the following year(s) as the females return to spawn. The 1963 Delaware shad run was one of the largest in the previous 45 years. Similar increases in the proportion of males in 1978 and 1979 indicated strong year class production in 1974 and 1975. Subsequent Delaware River sport and commercial catches of American shad for the past four years have also increased dramatically.

As previously stated, the shift in the sex ratio of Susquehanna shad (Table 6) from 1979 to 1980 was probably due to changes in the gear types employed to capture adults. If an actual increase in male fish did take place a significant increase in 1980

Susquehanna age III male fish should have occurred as it did on the Delaware in 1978 and 1979. However, this did not happen on the Susquehanna and it appears that two very reduced, virgin age classes, with little help from stronger year classes and more fecund repeat spawners will continue to support the already limited upper Chesapeake Bay American shad runs.

SUMMARY

1. General similarity was noted between 1979 and 1980 upper Chesapeake Bay American shad runs.
2. Although similarities existed for some characteristics, Susquehanna stocks exhibited definite differences with other east coast American shad populations.
3. The 1979-1980 upper Chesapeake Bay runs may be characterized as being supported by two remnant virgin age classes with a small percentage of repeat spawners.
4. Comparison with both Connecticut and Delaware River American shad runs indicates that with no significant increase in the numbers of virgin males, an indicator of increased year class strengths, and in the numbers of more fertile repeat spawners, the present reduced levels of American shad utilizing the head-of-Chesapeake Bay will continue for the forseeable future.

JOB III. SPORTFISHING SURVEY

INTRODUCTION

A non-uniform probability creel census (Pfeiffer 1966) was conducted from 3 May through 30 June 1980 in the area of the Susquehanna River from Conowingo Dam south to the river's mouth at Havre de Grace. The non-uniform probability sport angling survey makes use of prior fishing knowledge on a particular body of water, in this case the Susquehanna River (Whitney 1961, Carter 1973, RMC 1979). Selection of sampling probabilities, locations, and interview days and times is proportional to expected intensity as determined from these previous surveys. The non-uniform probability census also provides more reliable information with less expenditure of effort and money (Pfeiffer 1966). The purpose of this survey was to determine fishing pressure, catch per unit of effort, harvest, and catch composition. Data from this survey is compared with previous surveys (Carter, 1973; RMC, 1979) to assess trends that have taken place in the sport fishery of the lower Susquehanna River.

METHODS AND MATERIALS

Thirteen access points were utilized in the 1970 survey but the present survey dropped the Riverside site because of low fishermen usage (Fig. V). Probabilities for the twelve access points, time blocks, time units and associated sampling probabilities utilized in the 1980 survey are presented in Tables 9 and 10. The probabilities were the same as those used by RMC in 1979. The day and time probabilities were changed slightly to reflect the differences in fishing pressure during weekday holidays.

Interviews were conducted with fishermen who had completed their fishing trips during the assigned time interval at a

given access point. Anglers were canvassed concerning their mode of fishing, number in their party, state of residence, hours spent fishing, species catch composition and catch disposition. The survey questionnaire is presented as Figure VI. Observed angler catch was expanded using the assigned probabilities for day, time and location. The expanded values estimated number of anglers, angler hours, harvest (fish kept), and total catch for the Susquehanna River during the survey period.

Anglers were also asked their opinion of the possible construction of a fishway at the Conowingo Dam and of the 1980 American shad fishing closure.

RESULTS

A total of 314 party interviews, comprising 749 individual anglers, were conducted on 27 census days between 3 May through 30 June, 1980. Of these, 565 (75%) were Maryland residents and 184 (25%) nonresidents. The average party trip length was 5.0 hr with 2.5 anglers per party. Interviewed shore and boat anglers spent 3,668 hours fishing and caught 4,741 fish of 19 different species. Catch, harvest, and success rate data are presented in Table 11. Anglers kept approximately 40% of their total catch. The dominant species caught was white perch (Morone americana). Channel catfish (Ictalurus punctatus), striped bass (Morone saxatilis), and carp (Cyprinus carpio) were also commonly taken. Sixty-one percent of the carp caught were retained, and anglers kept twice as many striped bass as they released. However, twice as many white perch and channel catfish were released as were kept. American shad were released because of the closure of the commercial and sport shad fisheries by the Maryland Department of Natural Resources.

Catch per angler hour (CPUE) for selected species caught during this creel survey are found in Table 12. The CPUE for

white perch was 0.7375, while the CPUE for channel catfish and striped bass were 0.1892 and 0.1270, respectively. American shad CPUE was 0.0003.

Estimated harvest of fish kept for the survey period was 50,432 with nearly half consisting of white perch (Table 13). Striped bass comprised 18% of the estimated harvest while channel catfish and brown bullheads comprised 16.2% and 7.4%, respectively. The CPUE for boat fishermen was greater (1.38 fish caught per angler hour) than that experienced by shore anglers (1.21 fish caught per hour).

Of the 547 anglers responding to the opinion question, 68% favored construction of a fish ladder at Conowingo Dam while 30% had no opinion. Fifty-six percent of the anglers agreed with the imposed ban on commercial and sport fishing for American shad, while 38% offered no opinion.

DISCUSSION

Estimated sport fishing pressure in 1980 was similar to that observed in 1979 (RMC, 1979). There were 26,291 anglers in 1979 that fished 107,503 hours (Table 11). In 1980, the number of anglers (21,063) was 20% fewer than the previous year while the number of hours fished (109,764) increased by 21%. Susquehanna anglers caught 1.12 and 1.29 fish per hour during 1979 and 1980, respectively.

Estimated sport fishing pressure in 1970 was greater than in 1980 (Table11). There were fewer estimated anglers and less estimated fishing time expended in the present survey, but the success rate, a possible measure of angler satisfaction, was greater than that observed a decade earlier. There was a 62% decrease in hours fished between 1970 and 1980, and a 63% decrease in the number of anglers. However, the success rate for 1980 was 1.29, 38% greater than the 1970 survey success rate of 0.93.

Because sport anglers were required in 1980 to release all American shad caught, there was little data concerning sport angling for this species during the present survey. Only one shad was reported caught and subsequently released. It was rumored among anglers that more shad were taken from the Susquehanna River than were reported. However, there was no evidence to substantiate or refute this rumor. In 1970, the actual reported catch of American shad by sport anglers was 694. This comprised approximately 9% of the total sampled catch. In 1980, only one American shad was reported taken by hook and line which made up less than 1% of the entire sampled catch for this year.

Observed catch per angler hour (CPUE), and species composition, both observed and expanded, for white perch, striped bass, and channel catfish can be found in Tables 12 and 13.

Approximately half of all white perch landed by anglers were recorded from the Lapidum access point; 45% by boat anglers and 5% by bank fishermen. An additional 25% of the white perch landed were caught by shore anglers in Shures Landing. These percentages are not simply an artifact of sampling intensity or sampling probability. The boat angler CPUE was 1.46 white perch caught per hour at the Lapidum site, twice the total calculated CPUE for this species in the 1970 survey (Table 11). CPUE's for shore anglers at Lapidum and Shures Landing were 0.32 and 0.52 fish caught per hour, respectively. White perch CPUE for all sites experienced a 93% increase between 1970 and 1980, although there was a 15% decline in actual numbers of fish caught.

Forty-two percent of the striped bass were landed by bank fishermen utilizing Shures Landing. CPUE for striped bass at this site was 0.15 per hour. An additional 32% were caught by boat anglers (CPUE 0.17) who had launched from Lapidum. Catch per angler hour of striped bass in 1980 was approximately 214% and 147% greater than in 1970 and 1979, respectively. There were 3.1 striped bass caught per trip with 1.8 stripers

kept per angler per trip in the present survey. In 1979, only 0.3 striped bass were kept per angler per trip. For shore and boat anglers, respectively, striped bass success rates were 450% and 27% better than in 1979.

Seventy-six percent of the channel catfish caught during the present survey were caught by shore anglers at Shures Landing. The CPUE for channel catfish at this site was 0.40 fish caught per hour which was twice the CPUE calculated for this species for the present survey over all access points. The 1980 CPUE for channel catfish increased 219% over 1970 but decreased 27% since 1979. The boat angler success rate for channel catfish in 1980 was 0.06, a 65% decline from 1979, while the shore angler success rate for this species increased by 43% from 1979 to 1980.

SUMMARY

1. Seven hundred forty-nine individual anglers were interviewed on 27 census days between 3 May and 30 June.
2. Sampled anglers spent 3,668 hours fishing and caught 4,741 fish of 19 species.
3. The four most frequently caught species were white perch, channel catfish, striped bass, and carp.
4. An estimated 26,291 anglers fished 109,764 hours and harvested 50,432 fish from the Susquehanna River.
5. Only one American shad was reported caught during the 1980 creel survey.

JOB IV. JUVENILE RECRUITMENT SURVEY

INTRODUCTION

Numerous authors have noted a possible significant relationship between numbers of juvenile American shad and the numbers of spawning adults three to five years later (Chittenden 1975, Marcy 1976, Minta, Crecco, and Jacobs 1980). Chittenden (1975) investigated year class strengths by studying age and sex composition data and comparative run sizes for adult populations of Delaware River American shad between 1963 and 1965. He back-calculated by age class to determine the year class which exerted the greatest influence on the adult population for a particular year. Marcy (1976) collected juvenile American shad from the Connecticut River and calculated their yearly abundance between 1967 and 1973. He then developed an equation which indicated a significant relationship between juvenile shad, adults potentially available to spawn, water temperature, and river flow. Marcy stated that this equation could be successfully used to predict juvenile shad production in a particular year. From data derived by Marcy (1976), Minta, et al. (1980) regressed the realtive young-of-the-year and adult abundances of Connecticut River American shad and noted a strong positive correlation indicating year class strength is established before the juvenile stage. From further analysis of Marcy's 1965-72 juvenile index data and corresponding numbers of age V virgin females collected between 1970 and 1977, Minta also noted the apparent influences that the juvenile year classes exerted upon yearly abundances of adult American shad. He concluded that relative young-of-the-year abundances could be a useful management tool in forecasting adult year class strength five years in advance. Management strategies can be developed from a historic data base; therefore, beginning in 1979 an extensive juvenile recruitment survey was initiated in the Susquehanna River, Susquehanna Flats, and Northeast Rivers to provide an adequate

juvenile data base for developing management policies for Maryland shad stocks.

METHODS AND MATERIALS

To measure the spawning success of clupeid species at the head-of-Chesapeake Bay during 1980 a detailed young-of-the-year sampling survey was conducted on the Susquehanna River, Susquehanna Flats, and Northeast River. Sampling was carried out on a bi-weekly schedule from late June through October (Table14).

Ten shallow water shore sites were sampled with one of two different haul seines during each sampling period. At seven locations below Port Deposit, a 200'x10'x1/2" stretch mesh haul seine was set by boat in a semi-circular shape. The area swept by this seine set was calculated to be 0.0591 hectares. Because of the rocky nature of the Susquehanna River above Port Deposit, the three upper river sites had to be sampled with a 100'x6'x1/2" stretch mesh haul seine. The corresponding area swept by this gear, also set in a semi-circular shape, was calculated to be 0.0148 hectares. Locations and descriptions for each seine site can be found in Figure VII and Table 15, respectively.

Six open water sampling stations were established in the Susquehanna Flats and Northeast River as close to their corresponding seine sites as water depths and the presence of bottom snags would permit (Figure VII, Table15). Open water sampling was done with a modified 16' headrope semi-balloon shrimp (otter) trawl with 1/2" stretch mesh open end, 1 1/2" stretch mesh cod end, and 1/2" stretch mesh cod end liner. The area swept by this gear was calculated as:

$$\frac{3.0175\ m^{*} \times \text{trawl run length (m)}}{10{,}000\ m^2} = \text{area swept in hectares}$$

*3.0175 m = effective trawl mouth opening

Starting and stopping points for each run were determined from compass sightings of nearby fixed shore and navigational structures. Appropriate compass bearings are found in Table 16.

Trawl and seine samples were collected nearly simultaneously with replicate seine pulls and trawl runs made at each station per sampling period except where precluded by inclement weather or equipment failure. Tables 17, 18, 19, and 20 present sampling effort data by site and period for all gear types.

RESULTS

A total of 182 seine hauls and 101 trawl runs were made at sampling stations on the Susquehanna River, Susquehanna Flats, and Northeast River from 24 June through 31 October 1980. This effort captured 44,321 fish of 33 species (Table 21). Numbers and weights for each species caught by gear type by period and station are presented in Tables 23through 29.

Calculations of standing crop arranged by period and station for each gear type for all species combined are detailed in Tables 30, 31, 32, and 33. Of note -

1. Standing crop for haul seine effort was greatest
   - during Periods II and VII for number and weight per unit area, respectively
   - at Station 2 for both number and weight per unit area
2. Standing crop for otter trawl effort was greatest
   - during Period V for both number and weight per unit area
   - at Station 2 for both number and weight per unit area
3. For the six common seine and trawl stations mean standing crop
   - was 49% greater (#/ha) for haul seine vs. otter trawl captures
   - was 18% greater (kg/ha) for otter trawl vs. haul seine captures

4. For the nine common seine and trawl sampling periods mean standing crop
   - was 40% greater (#/ha) for haul seine vs otter trawl captures
   - was 39% greater (kg/ha) for otter trawl vs haul seine captures

Young-of-the-year catch and catch per unit of effort for four important commercial and sport species, blueback herring (Alosa aestivalis), alewife herring (Alosa pseudoharengus), striped bass (Morone saxatilis), and white perch (Morone americana), by gear type, sampling period, and station are presented in Tables 34 and 35. General trends indicated by this data were:

1. The haul seine caught more juvenile alewife and blueback herring and striped bass than the otter trawl.
2. A large total catch and catch-per-unit-of-effort (CPUE) of young-of-the-year herring and striped bass by one gear type was generally not accompanied by a corresponding large catch by the otner gear type.
3. The haul seine captured young-of-the-year blueback herring, striped bass, and white perch in all sampling periods except X.
4. Of the four species, only juvenile striped bass were captured upstream from Station 6.

In the Susquehanna River, standing crop calculations (numbers/ha only) by gear type, period, and station for these four species are presented in Tables 36 and 37. Each of these four species were generally more prevalent during the middle sampling periods. Both young-of-the-year blueback and alewife herring were more abundant at one particular station (Wild Duck Cove and Camp Rodney, respectively) while juvenile striped bass and white perch were concentrated in at least three different sampling locations.

No young-of-the-year American or hickory shad were captured during the 1980 Juvenile Recruitment Survey. However, a yearling

American shad was captured by otter trawl at Havre de Grace, Station 6 on 22 July 1980.

Of the 302 juvenile herring captured by haul seine, 64% (194) were alewife. The species ratio for otter trawl captures was 58% (38) alewife and 42% (27) blueback herring. Haul seine catches of blueback herring indicated a bi-modal capture distribution, for both total numbers caught and CPUE, with peaks in Periods I and VII/VIII (Figure VIII, Table 34). Following Period I, otter trawl catches of bluebacks, however, were greatly reduced (Figure IX, Table 34). Haul seine and otter trawl catches of alewife herring were concentrated more during the survey's middle periods, peaking in Period V for haul seine and Period VI for otter trawl captures (Figures VIII and IX, Table 34). Site specificity for haul seine catches of both herring species was also noted (Figures X and XI, Table 35). Station 4 had 66% of all alewife herring haul seine catches while Station 1 had 46% of all blueback herring captured by this gear type. Site specific differences in trend of catch by otter trawl for both species were less obvious due to the small numbers captured, although alewives appeared to be more evenly distributed over the open water stations than bluebacks.

DISCUSSION

No young-of-the-year American shad were captured during the 1980 juvenile survey. The failure of the two gear types employed to capture any juvenile shad could be due to a number of factors. These include poor sampling techniques (i.e., poor timing, improper sampling locations, etc.), insufficient sampling, and a general recruitment failure.

With regard to the first two, poor sampling techniques and inadequate sampling, the sampling design for the 1980 survey was based upon a study carried out in the late 1960's by Carter (1973) in the same Susquehanna region. Carter's conclusions

were that the sampling techniques and gear he used were effective in capturing juvenile American shad. Data gathered over the past twenty-two years by the Maryland Estuarine Fish Recruitment Survey, Federal Aid Project F-27-R-6, show that no young-of-the-year American shad have been captured from any of ten upper Bay stations since 1972 (Boone 1980). Four of these ten sites are located close to four of the 1980 survey sites. Boone found that prior to 1972, juvenile shad were frequently taken by haul seine and that catch rates had been as high as 17 juveniles per haul during years of good reproduction. During 1980, the Maryland Anadromous Fish Stream Survey Program (AFC-8) conducted extensive sampling in the Susquehanna area with a bow-mounted push trawl. This apparatus, developed by the Virginia Institute of Marine Science has proved successful in collecting juvenile American shad in Virginia waters (Kriete and Loesch 1980). Push trawl sampling on the Susquehanna was initiated in June and continued through September on a tri-weekly basis. All sampling was conducted at night. No young-of-the-year American shad were collected by this gear during 1980 although two juvenile hickory shad were captured at Station 4, Port Deposit, during June (MTA infile data).

It appears that the 1980 sampling in the Susquehanna region by these various projects was adequate in both technique and magnitude to note the presence of juvenile American shad. The lack of juveniles, then, is the result of a near total recruitment failure during the 1980 spawning season. This failure to reproduce may be the result of certain chemical, physical, and biological conditions, some of which are briefly discussed below.

Chemical contaminants from nearby locations and upstream in the Susquehanna watershed may derive from urban non-point source runoff, agricultural runoff, and sewage treatment plant (STP) discharges, particularly chlorine. Colston (1974) found that COD and BOD from urban non-point sources averaged 91% and 67%, respectively, that of raw sewage. He also noted that

concentrations of heavy metals were from two to fifty times greater than in raw sewage. Increased sedimentation as a result of greater agricultural and urban land use can be highly detrimental to fish eggs. Morgan et al. (1973) found that only 0.5 to 1.0 mm of sediment cover caused greater than 50% mortalities in white perch eggs and that 1.2 mm of deposited sediment resulted in 100% mortality. Concerning chlorine, Middaugh et. al. (1977) found that larval development in striped bass, white perch and blueback herring was inhibited by increased chlorine concentrations; the length of larval fish hatched decreased, and that the incidence of larval deformities also increased with increases in chlorine concentrations. A delay in hatching or a change in the number of eggs hatching or nearing hatch may be very detrimental to a larval population. A delay in hatching may cause changes in the distribution and density of larvae both in time and space, plus a possible desynchronizing of larval food availability. Deformed larvae are less able to capture food or avoid predation. In an attempt to mitigate some of these problems the Maryland Departments of Natural Resources and Health and Mental Hygiene have selected certain STP's in the upper Chesapeake Bay and asked that their chlorine discharges be reduced or eliminated during the spring spawning season.

A number of biological factors may be adversely affecting American shad reproduction. Contamination of the eggs and milt by pesticides, heavy metals, and PCB's through accumulation in the adults could result in abortion/reabsorption of eggs, production of non-fertile eggs and milt, and deformities in eggs and larvae. During 1979 the Maryland Department of Health and Mental Hygiene analyzed body tissue and gonadal samples from six adult American shad taken from the Susquehanna River. This testing showed generally low levels of metals, pesticides, or PCB's in either flesh or reproductive organs (MTA infile data). Also during 1979, in a controlled lab experiment, Susquehanna River shad eggs were artificially fertilized to determine egg viability and hatching success. Examination of both fertilized eggs and developing

larvae revealed no discernable physical deformities that suggested gonadal deficiencies. Although these data are not conclusive, they suggest that reproductive organ failure is not the major factor contributing to the lack of recruitment.

A second biological factor to consider is the problem of drastically reduced spawning stocks in the upper Bay area. Leggett (1969) estimated that survival for American shad from egg to adult was approximately one in 100,000 indicating tremendous mortality for eggs and larvae. Since 1974 the commercial catch of adult American shad from the Susquehanna area dropped precipitously (Table 38) resulting in the closure of the shad fishing season for 1980. The decline in spawning stock size, as indicated by declining commercial catch, was also mirrored by the juvenile survey work of Boone (1980) and this current study. These two trends are strong indications that the number of juveniles produced by the remaining adult stocks in the Susquehanna area are not sufficient to replace individuals lost to both natural and man-induced mortalities.

Conowingo Dam at river mile 10 physically affects reproduction of American shad in several ways.

1. The area available for finfish spawning in the Susquehanna River is severely limited. Prior to the dam's completion in 1928, other dams along the river periodically restricted shad migration which historically had been as far as Binghamton, New York at river mile 218. By contrast, the Connecticut River with fish passage facilities at both Holyoke and Turners Falls Dams has 120 miles of river open for spawning, while the Delaware has approximately 270 river miles available.

2. Conowingo Dam is designed as a peaking plant, with the volume of water discharged constantly changing depending upon power demand and available water. Because

of this change in demand water depths may fluctuate as much as 15 feet while river flow may range from 0 to 86,000 cfs. These drastic fluctuations create unstable and unsuitable spawning habitat and conditions. Also, reduced flows have led to dissolved oxygen depletions which have resulted in four major fish kills and numerous minor ones below the dam since 1965.

Either of these conditions could be causative factors in the reproductive failure of American shad in the Susquehanna Region and because of the possible interrelationships behind them elimination of one may not solve this problem.

During 1979, a preliminary juvenile recruitment survey was conducted in the head-of-the-Bay region with haul seine only. This sampling utilized the same ten stations as the 1980 survey, with each station being checked every two weeks. The 1979 survey, however, encompassed only six sampling periods, resulting in 115 seine hauls or 67 less than the following year. All other sampling techniques and equipment were identical for both year's work. Results of the 1979 survey appear in Tables 39 through 44.

The 1979 seine survey captured three juvenile American shad during the six sampling periods. Young-of-the-year were captured at the Cara Cove (#3) and the Camp Rodney (#4) stations on 7/24/79 and at the Robert Island station (#9) on 8/24/79. Catch per haul was calculated as 0.03. No juvenile American shad were captured during the 1980 survey.

Catch in 1980 of juvenile blueback and alewife herring was markedly different from the 1979 catch. The total seine catch of alewife in 1980 was 194 as compared to only 18 in 1979, a 10.4 fold increase. Catch per seine haul in 1980 was 1.07 as opposed to only 0.16 in 1979, a 669% increase. For bluebacks, however, the total catch and catch per haul decreased in 1980; total catch was down by 244 individuals (326%) and catch per haul was down from 3.06 to 0.59 fish per haul, a five fold decrease. The large increase in the alewife

herring juvenile CPUE in 1980 could have been due to the increase in numbers of yoy over 1979 (Tables 43 and 44).

Total catch and catch per unit effort for juvenile striped bass was down in 1980, with 33% fewer juveniles being captured. Catch by site for both numbers and rate were greatest at Station 1 during both years.

Data for juvenile white perch captures (Tables 43 and 44) indicated that even though 672 more young-of-the-year were taken in 1980, catch per haul in 1979 was 21.3 while catch per haul for 1980 was 22.1. This indicated similar young-of-the-year populations in both years. The greatest numbers were captured from late August until the end of the survey during both years. Similarity in juvenile captures by site was also noted for the two years with the greatest numbers and highest rates occurring at Station 2.

Data gathered by Carter (1973) in 1968 and 1969 provides an adequate data base from which to note changes in the clupeid catch. Procedures and techniques used by Carter for his earlier survey were utilized during 1980. Of the 12 sites sampled in 1968-69, seven sites were resurveyed in 1980. These common sites are listed below:

NAME	SITE CODE 68-69	1980
Wild Duck Cove	12	1
Seneca Point	9	2
Cara Cove	8	3
Camp Rodney	7	4
Fishing Battery	3	5
Tydings Park	2	6
Quarry	1*	7*

*haul seine only.

Summation and comparison of the seven common sampling stations for the two surveys noted that-

1. Additional computations from Carter 1973, Table 53, page 61, indicated that a total of 281 young-of-the-year shad were captured by haul seine in 1969* and that 95 were collected by otter trawl during 1968/1969. During this study, juvenile shad were taken by haul seine at two sampling stations, Cara Cove and the Quarry. Otter trawl captures of young-of-the-year American shad for 1968/1969** were from four different locations; Cara Cove, Camp Rodney, Battery Island, and Tydings Park. Estimates for standing crop of juvenile shad by gear type derived from Carter (1973, Table 53, page 61) were 103/ha for haul seine and 4/ha for otter trawl samplings. No juvenile American shad were captured during 1980.

2. During the 1968 and 1969 samplings (Carter, 1973, Table 53, page 61) a total of 233 and 1,476 young-of-the-year alewife herring were captured by haul seine and otter trawl, respectively. Alewife herring were captured at five of the seven seine sites and at all six otter trawl stations. Standing crop, derived from Carter's data (Table 53, page 61) for alewives was calculated to be 86/ha for haul seine in 1969 and 66/ha for otter trawl captures during 1968/1969. In 1980, 194 and 38 juvenile alewife herring were collected by the same two gear types respectively. Calculated standing crop for haul seine was 23/ha and 1.4/ha for otter trawl. During 1980 this species was collected at four sites by seine and at five sites by trawl.

---

* haul seine data for 1969 only

** 1968 and 1969 otter trawl data combined

3. For blueback herring, Carter (1973, Table 53, page 61) collected a total of 5,281 by haul seine in 1969 and 520 by otter trawl for both years combined. Bluebacks were collected at all surveyed stations by both gear types during the earlier survey. Standing crops calculated for the 1969 seine haul captures was 1,944/ha and 23/ha for the 1968/1969 otter trawl. The 1980 seine sampling captured 108 young-of-the-year blueback herring from five different stations while the otter trawl collected 27 from three separate sites. Numbers per hectare in 1980 were calculated to be 13 and 1 for haul seine and otter trawl captures, respectively.

Comparisons of the results of these two surveys indicate a drastic decline in abundance of American shad, alewife and blueback herring during the 1970s (Table 45). The magnitude and severity of this decline is also mirrored by the commercial catch of these three species from the Northeast and Susquehanna Rivers and the Susquehanna Flats combined for the previous 12 years (Table 38). The numbers of American shad upper bay brood stock may continue to decrease simply because there are not enough recruits to replace dying adults. This condition will necessitate further intensive management to insure that the number of mature adults does not fall below a level where natural recovery is impossible, a level that may have already been attained.

SUMMARY

1. One hundred eighty-two seine hauls and 101 trawl runs were made at 10 seine and six trawl stations on the Susquehanna River/Flats and Northeast River. There were 44,321 fish of 35 species captured.
2. No young-of-the-year American shad were captured in 1980.
3. Among the 35 species captured, juveniles from four important commercial and sport species were represented; blueback and alewife herrings, striped bass, and white perch.

4. Comparisons with previous studies indicate drastic declines in total numbers and standing crop of juvenile American shad and alewife and blueback herrings in the Head-of-the-Bay between the late 1960's through 1980.

TABLE 14. Sampling periods during the 1980 Juvenile Recruitment Survey.

SAMPLING PERIOD	DATES
Period I	June 23, 24, 25, July 1
Period II	July 7, 11, 12
Period III	July 21, 22, 23
Period IV	August 4, 5, 6
Period V	August 18, 19, 20
Period VI	September 2, 3, 4
Period VII	September 17, 18, 19
Period VIII	October 1, 2, 3
Period IX	October 15, 16, 17
Period X	October 30, 31

TABLE 21. Species caught during the 1980 Juvenile Recruitment Survey.

SCIENTIFIC NAME	COMMON NAME
Alosa aestivalis	Blueback herring
Alosa pseudoharengus	Alewife herring
Alsoa sapidissima	American shad
Anchoa mitchilli	Bay anchovy
Anguilla rostrata	American eel
Brevoortia tyrannus	Atlantic menhaden
Carassius auratus	Goldfish
Carpiodes cyprinus	Quillback
Cyprinus carpio	Carp
Dorosoma cepedianum	Gizzard shad
Etheostoma olmstedi	Tesselated darter
Fundulus diaphanus	Banded killifish
Fundulus heteroclitus	Mummichog
Hybognathus nuchalis	Silvery minnow
Hypentilium nigricans	Northern hogsucker
Ictalurus nebulosus	Brown bullhead
Ictalurus punctatus	Channel catfish
Leiostomus xanthurus	Spot
Lepomis auritus	Redbreasted sunfish
Lepomis gibbosus	Pumpkinseed
Lepomis macrochirus	Bluegill
Lepomis megalotis	Longear sunfish

TABLE 21 , con't.

SCIENTIFIC NAME	COMMON NAME
Membras martinica	Rough silverside
Menidia beryllina	Tidewater silverside
Micropterus dolomieui	Smallmouth bass
Micropterus salmoides	Largemouth bass
Morone americana	White perch
Morone saxatilis	Striped bass
Notropis hudsonius	Spottail shiner
Notropis spilopterus	Spotfin shiner
Perca flavescens	Yellow perch
Pomatomus saltatrix	Bluefish
Pomoxis nigromaculatus	Black crappie
Strongylura marina	Atlantic needlefish
Trinectes maculatus	Hogchoker

JOB V. LITERATURE REVIEW AND SURVEY

A. Extensive literature concerning the biology and management of American shad exists primarily due to the species' sport and commercial value and its widespread range along the entire Atlantic coast. Mansueti and Kolb (1954) cited 1,314 literature sources in their publication "A Historical Review of the Shad Fishery of North America" while Dr. Timothy Robbins (pers. comm.) estimates that approximately 800 literature sources have been produced on the American shad since 1954.

In order to upgrade Project staff familiarity with both published and unpublished material, a literature search was undertaken by the Maryland Tidewater Administration. Accumulation and analysis of pertinent literature and subsequent comparison with Maryland's situation is a prime requisite for improvement of the state's ability to rationally manage its shad stocks.

B. Queried information sources during the past 12 months include:

1. Journals/Periodicals -

Transactions of the American Fisheries Society
Canadian Journal of Fisheries and Aquatic Sciences
Ecology
Estuaries
Progressive Fish Culturist
Scientific American
Biological Conservation
Fisheries
Limnology and Oceanography
Natural History
American Midland Naturalist
Marine Fisheries Review
Fishery Bulletin, National Marine Fisheries Service
Fishery Bulletin, Fish and Wildlife Service

Research Reports, Fish and Wildlife Service

National Marine Fisheries Service Commercial Landings

Fish and Wildlife Service Computer Reference System

2. State Governmental Agencies-

Florida Department of Natural Resources, Division of Marine Resources

Georgia Department of Natural Resources, Coastal Resources Division

South Carolina Wildlife and Marine Resources Department, Marine Resources Division

North Carolina Department of Natural Resources and Community Development, Division of Marine Resources

Virginia Marine Resources Commission

Maryland Department of Natural Resources, Tidewater Administration

Delaware Department of Natural Resources and Environmental Control, Division of Fish and Wildlife

New Jersey Department of Environmental Protection, Division of Fish, Game and Shellfish

New York Department of Environmental Conservation, Division of Fish and Wildlife

Connecticut Department of Environmental Protection, Marine Region

3. Federal Government Agencies-

Department of Interior, Fish and Wildlife Service

Department of Commerce, National Marine Fisheries Service

4. Private Consultants -

Radiation Management Corporation

Environmental Resources Management, Inc.

Martin Marietta Corporation

National Environmental Services, Inc.

Lawler, Matusky, and Skelly

5. Academic Institutions

University of Maryland, Sea Grant

Johns Hopkins University, Applied Physics Laboratory

University of Maryland, Center for Environmental and Estuarine Studies

College of William and Mary, Virginia Institute of Marine Science (VIMS)

6. Personal Communication

A great deal of information was obtained through personal contact with various individuals and groups. Discussions with the Maryland Watermens Association and their various county chapters, individual commercial fishermen, and seafood processors provided insight into the Maryland shad fishery and market system. Further direct contact with specific watermen was invaluable to the Project's field operations as well as providing useful supplemental data such as catch-per-unit of effort.

Personal communication with various state conservation agencies was helpful to all aspects of Maryland's program. The Connecticut DEP assisted in the difficult job of ageing American shad scales. New Jersey DEP personnel provided information concerning the resurgence of Delaware River shad runs. This information may well be applicable to Maryland's problem. Agreement was reached with the VIMS to tag adult American shad in the Virginia portion of the Chesapeake Bay during 1981 so that their movements into Virginia tributaries and the Maryland Bay would become better understood.

C. To better understand the value of this literature survey to Maryland's American shad investigation, a brief discussion concerning one aspect of the survey is presented below.

Table 46 presents the reported commercial catch of American shad by state or major tributary along the east coast from 1962 to 1980. Analysis and comparison of any commercial catch data can be tenuous at times due to differences in effort, gear types employed, gear selectivity, and the accuracy of the reported totals. Because these conditions

which influence this data were unknown, specific conclusions could not be drawn from simple comparisons. However, certain trends appeared obvious with respect to Maryland and warranted mention.

All east coast states have experienced both increases and decreases in reported American shad landings from 1962 to 1980. The most dramatic declines appear to be from the Chesapeake Bay south. With the exception of South Carolina, these southern states have experienced declines from their average catch ranging from 434,000 pounds in Georgia to 1,557,100 pounds in Maryland during this 19 year period. Catches from the three northern rivers and South Carolina, however, appear to be stable and increasing. The declining shad catch from the Delaware River during the late 1960's through the mid-1970's can be attributed to the pollution block created by the cities of Philadelphia and Trenton (Chittenden 1975, Lupine pers. comm.) Poor water quality greatly restricted upstream migration of spawning adults in the spring and downrunning juveniles in the fall. Extensive pollution control measures in these problem areas have shortened the duration of this block, thus permitting more nearly unaltered movements of both adults and young-of-the-year. Consequently, Delaware River American shad catches by both commercial watermen and sport anglers have experienced a sharp increase during the past five years. The 1980 Hudson River totals were expected to substantially exceed the record 1979 totals (Blossum pers. comm.)

In each of these three northern rivers and South Carolina a continuous research program has resulted in effective regulations and management policies for their shad fishery (Fredin 1954, Talbot 1954, Walburg 1963, White and Vurtis 1969, Curtis 1974, Leggett 1976, Marcy 1976, Chittenden 1974, Crochet et al. 1976, Crecco 1979, Lupine 1980, Minta et al. 1980). This has

been one of the major factors contributing to stabilized runs and commercial catches in these locations. Specifically, American shad in the Connecticut River have been extensively studied and managed for over 20 years, and the corresponding commercial harvest has been the most stable of any major east coast river.

The ability to return Maryland's American shad population to stable harvestable levels is directly related to the state's continued study and monitoring of both the fish and its various limiting factors (pollution, stream blockage, habitat alteration, overfishing). Synthesis of this information along with that obtained from outside sources into an effective management policy, strengthened by enforceable regulations should logically follow.

TABLE 46. Reported commercial catch of American shad from all waters in Florida, Georgia, South Carolina, North Carolina, Virginia, Maryland, and the Delaware, Hudson, and Connecticut Rivers from 1962 through 1980.

CONCLUSIONS AND RECOMMENDATIONS

The major conclusion derived from the 1980 data is that American shad stocks in the upper Chesapeake Bay are in a precarious condition. Prior to 1972, it was common for commercial fishermen to catch as many shad in a week as the estimated upper Bay population for 1980. Sport angling success during the 1960's and early 1970's was among the best along the east coast. Though never as plentiful as other species, young-of-the-year American shad were regularly collected in various head-of-the-Bay juvenile surveys through 1972.

Closing Maryland's waters to all American shad fishing in 1980 was a serious but necessary step to protect the remaining brood stocks. Mansueti and Kolb (1953) noted that the evidence from the majority of previous investigations clearly indicated that overfishing was the primary cause of reduced and declining shad runs in Maryland. Overfishing was also identified as a major factor in declining shad runs on the Hudson River (Talbot 1954), the Connecticut River (Fredin 1954, Marcy 1976, Leggett 1976, Crecco 1979), and in South Carolina (Crochet et al. 1976).

Other factors have been cited as major reasons for Maryland's shad decline. Sidell (1979) stated that barriers preventing anadromous species from reaching their spawning grounds has been the primary cause of fishery declines in the Susquehanna River. Beginning in 1830, construction of dams precluded American shad from ascending the river to their uppermost spawning area, Binghamton, New York, river mile 318. With completion of Conowingo Dam in 1928 all migratory fish were restricted to only the lower 10 miles of the Susquehanna River.

The effects of pollution and habitat alteration pose serious threats to spawning adults, eggs, and larvae. These conditions probably operate to make reproduction less successful for already depleted brood stocks. However, insufficient data indicating changes in pollution levels and habitat alterations for specific

spawning and nursery areas over time makes quantitative relationships difficult, if not impossible, to ascertain.

On the basis of the information presented in this report, the following management recommendations are presented.

I. Continuation of Closed Fishing Season

The scarcity of both spawning adults and juvenile American shad precludes any recreational or economic incentive to reopen the fishery. Continuation of the fishing ban through 1984 would maximize protection of the remaining brood stocks and allow their quickest rebuilding. As mentioned in Job IV, several authors have noted a relationship between the numbers of juvenile American shad and the numbers of spawning adults three to five years later (Chittenden 1975, Marcy 1976, Minta et. al. 1980). Because recruits would not return to Maryland waters for three to five years after being spawned a minimum closure of five years is required to permit the return of at least one unfished generation. A five year closure would also eliminate the problem of immediate "fishing up" whereby individuals who would not normally enter the fishery do so because of nominal increased catches by regular fishermen, thereby overfishing the stocks before they have a chance to rebuild to safe harvestable levels. If the number of spawners in one generation is overfished, thus reducing juvenile recruitment, numbers of fish returning three to five years later as adults will be decreased. This condition is further compounded if this returning cohort is itself overfished. One successful year class will not restore Maryland shad runs to harvestable levels.

II. Chemical Monitoring

Overfishing is probably not the only adverse condition limiting Susquehanna brood stocks and successful recruitment. The effect of pollution on both adults and juveniles (see Job IV) needs to be investigated. Analysis of water samples collected at various locations throughout the Susquehanna drainage would be beneficial in determining the types of pollutants present,

concentrations, and in certain instances their origin. In addition, chemical analysis of both tissues and gonads from Susquehanna shad is needed to determine if contaminants accumulated in the adults are limiting successful reproduction. Adult contamination may result in production of non-fertile eggs and larvae and in hatching deformed, diseased, or weakened larvae incapable of survival. A simple and inexpensive method to test the viability of upper Bay American shad eggs and milt would be to place fertilized eggs in shad hatching boxes stationed throughout the area and monitor their hatching and development.

III. Project Continuation and Expansion

Few specific trends and conclusions can be drawn from one year's data. Successful management practices such as those for the Connecticut River involve the accumulation and analysis of data gathered over many years. Since this data is non-existent for any Maryland shad stocks, continuation of the present investigation is of paramount importance. Effective management policies are only possible with a comprehensive data base.

Data expansion during 1981 centers on a proposed tagging experiment of American shad in the Virginia portion of Chesapeake Bay. The effects of Virginia's fishery on Maryland shad stocks is unknown. This exercise will provide preliminary information concerning effort, the relative importance of the Potomac River as a spawning area, and the possible exploitation rates attributable to the by-catch provisions of the 1981 Maryland closure. As Walburg and Nichols (1967) state, "Successful management probably requires consideration of Chesapeake Bay stocks as units without regard to political boundaries."

IV. Supplemental Stocking

Supplemental stocking of both adults captured from other areas and hatchery reared eggs and larvae is not recommended at this time for the lower (=Maryland) Susquehanna drainage. From 1875 to 1950 over 199,000,000 shad fry were reared

and placed into nine different Maryland rivers; Potomac, Patuxent, Bush, Susquehanna, Northeast, Sassafras, Chester, Choptank, and Wicomico. These releases, however, were not successful in stopping the Maryland shad catches declining from over seven million pounds in 1890 to 1.4 million pounds in 1950. Talbot (1954) concluded that no correlation existed between hatchery operations and the estimated population of American shad entering the Hudson River from 1915 to 1950. The recent resurgence of Delaware River shad runs has been erroneously concluded by the public to be the result of stocking adults collected from various east coast rivers, particularly the Susquehanna. Chittenden (1975) stated that the dominant factor affecting the abundance of American shad runs on the Delaware River for the past 60 years was the pollution block centered around the Philadelphia area. Delaware River fishery research personnel (Lupine pers. comm.) state that the increase in both sport and commercial landings during the late 1970's is a result of a decline in both the severity and duration of this pollution block. They concluded that artificial stocking of adults into the Delaware, terminated in the late 1960's, had little if any beneficial effect on the river's native brood stock.

Until the conditions causing reproductive failure at the head of Chesapeake Bay can be defined, and corrective measures implemented, the stocking of hatchery produced eggs and larvae and transplanted adults will not solve the problem. It is unrealistic to assume that the deleterious factors presently affecting natural populations and reproduction will not produce similar results on artificially propagated and transplanted organisms.
