# Report of the 17th Northeast Regional Stock Assessment Workshop 

Stock Assessment Review Committee (SARC)
Consensus Summary of Assessments

NOAA/National Marine Fisheries Service Northeast Fisheries Science Center Environmental Processes Division

Woods Hole, MA 02543-1097

The 17th Northeast Regional Stock Assessment Workshop is documented in seven separate reports, listed below. The Northeast Fisheries Science Center Reference Documents are a series of informal reports produced by the Center for timely transmission of results obtained through work at NEFSC labs. The documents are reviewed internally before publication, but are not considered formal literature. The National Marine Fisheries Service does not endorse any proprietary material, process, or product mentioned in these reports. To obtain additional copies of this report or other Center Reference Documents contact, Information Services Unit, Northeast Fisheries Science Center, Woods Hole, MA 02543 (508-548-5123, ext. 260 or 378).

The correct citation for this document is: NEFSC. 1994. Report of the 17th Northeast Regional Stock Assessment Workshop: Stock Assessment Review Committee (SARC) Consensus Summary of Assessments. NOAA/NMFS/NEFSC: Woods Hole, MA. NEFSC [Northeast Fisheries Science Center] Ref. Doc. 94-6.

## MEETING OVERVIEW

The Stock Assessment Review Committee (SARC) Meeting of the 17 th Northeast Regional Stock Assessment Workshop (17th SAW) was held during 29 November - 4 December 1993 at the Northeast Fisheries Science Center, Woods Hole, Massachusetts. Dr. Vaughn Anthony (NEFSC) chaired the 14-member SARC (Table 1). Two SARC members were from outside the region (Seattle, Washington and Canada). Nearly 50 other individuals also attended (Table 2). The agenda for the meeting is presented in Table 3.

## OPENING

The Chairman reviewed the current SAW structure (Figure 1) and functions of the SAW Steering Committee (Table 4), clarified the responsibilities of the SARC and its Subcommittees (Table 5), and discussed how he planned to conduct the meeting. He reviewed the SAW documentation and when material would be due. In addition to carefully reviewing the species/stock assessments, the SARC would produce a "Consensus Summary of Assessments" document (SARC Report), that would include research recommendations for each species reviewed, designate any materials for publication, draft an "Advisory Report on Stock Status" (Advisory Report) for managers, and review the terms of reference for the Assessments Methods Subcommittee.

The Chairman reviewed the responsibilities of the Subcommittee chairs, rapporteurs, and the editor of the Advisory Report (Terry Smith), as well as the responsibilities of the SARC Leaders. The Subcommittee chairs are responsible for the presentation of assessments, selection of rapporteurs for Subcommittee reports, the first draft of their section of the SARC Report, and the first draft of the Advisory Report (especially tables and figures). The rapporteurs are responsible for both drafts of the SARC Report, including research recommendations, and the first draft of the Advisory Report. The editor is responsible for two drafts of the Advisory Report. SARC leaders were designated to ensure that the final documents appropriately reflect the consensus of the SARC. The SARC Leaders would work with Rapporteurs to develop the final draft of the SARC Report and with Terry Smith and Rapporteurs to develop the final draft of the Advisory Report. The Leaders would also make sure that all research recommendations for assigned species would be properly documented.

The SAWs Coordinator is responsible for the organization and overall coordination of the meeting, meeting materials, and meeting reports. The Coordinator also drafts the meeting overview and other business section of the SARC report.

To insure that all procedures and timing were well understood, the SARC Chairman tabled a 20 page document concerning the above topics.

## AGENDA AND REPORTS

The SARC agenda included nine species/ stocks (seven first priority and two second priority) and the terms of reference for the Assessments Methods Subcommittee. Reviewed were analyses for two stocks of silver hake (Gulf of Maine - Northern Georges Bank and Southern

Georges Bank - Middle Atlantic), Southern New England yellowtail flounder, bluefish, butterfish, and long- and short-finned squid. Time, however, was insufficient to allow a review of the second priority species. A chart of U.S. commercial statistical areas used to report landings in the Northwest Atlantic is presented in Figure 2.

Analyses were submitted to the SARC in the form of Subcommittee Reports developed in a
series of meetings (Table 6). Material from Subcommittee reports form the basis of this report. In addition, the SARC reviewed separate working papers containing detailed supporting material for the Subcommittee reports. Five of the working papers reviewed were recommended for publication in the NEFSC Reference Document series (Table 7).

In addition, the SARC prepared a draft Advi-

sory Report on Stock Status for the species/ stocks reviewed. Information in the Advisory report was compiled according to the format approved by the SAW Steering Committee. The draft Advisory Report will be provided to the Steering Committee two weeks prior to the SAW Plenary Meeting scheduled to be held on 24-25 January 1994, in conjunction the Mid-Atlantic Fishery Management Council meeting in Ocean City, MD. The final version of the Advisory Report will be included in the Report of the 17th SAW Plenary (NEFSC Reference Document 94-07).

## GENERAL DISCUSSION HIGHLIGHTS

## Assessment Methods

The SARC thoroughly discussed the terms of reference for the Assessment Methods Subcommittee. The summary on pages $121-122$ of this report is based on that discussion. As the ADAPT framework is adaptive to a variety of data on particular species and has a central role in agebased assessments performed in the region, it is critical to convene an ADAPT tutorial to explain the method and use of the program to all who may wish to use it. Members of state fisheries organizations, in particular, should participate in the tutorial. The NEFSC should take the responsibility to convene the tutorial, as it would not be productive to have this activity among the terms of reference of the Assessment Methods Subcommittee. It was agreed that the documentation of some basic version of the ADAPT software should be a "high priority" and recommended that the Assessment Methods Subcommittee specify what should be included in a standard user-friendly, version of the software so that action could be taken to develop such a package as soon as possible.

## Silver Hake

The silver hake assessment addressed the juvenile fishery in addition to the stated terms of reference. However, the analyses, for both the southern and northern stocks, were plagued by a number of problems which are reflected in the research recommendations. Some of these recommendations must be met in order to make progress in the assessment of these stocks.

Figure 1. SAW structure.

## Bluefish

Only three out of five of the terms of reference for bluefish were met. Although several approaches to the assessment of bluefish were discussed at the Subcommittee level, none was tabled for SARC review. After considerable debate, it was concluded that it would be worthwhile for the Subcommittee to meet once again to try to develop an agreed-upon assessment before the Plenary Meeting. This Subcommittee had met twice already (see Table 6) but, after discussion, members felt that considerable progress could be made, given one more meeting. Such a meeting in the midst of a SAW process is an exception to the procedure developed by the Steering Committee. To guarantee joint assessment and solid peer review, however, the Steering Committee did agree that another meeting should be held, because of the importance of the bluefish at this time and the promise of success made by the scientists. The Pelagic/Coastal Subcommittee met at Woods Hole on 5 January and a special SARC meeting was arranged for 11 January 1994. The scientists could not agree, however, even on the basics of an assessment and the special SARC meeting was canceled.

## Yellowtail Flounder

A new diagnostic approach and smoothing procedure were implemented in the assessment on Southern New England yellowtail flounder. A

Table 4. Steering Committee functions

- Attend the SAW Plenary and discuss management advice
- Set priorities for review of the 48 stocks in the region, allocate resources (people and funding), and oversee the assessment and advice process
- Select species/stocks to review at the next SARC
- Set terms of reference for assessments
- Set dates and places for SARC and SAW Plenary meetings
- Evaluate sufficiency and style of SARC Advisory Reports and additional communication required
- Set Subcommittees in force and functioning

Table 5. Clarification of responsibilities of the SARC and its Subcommittees as well as the SARC procedure in general

- Subcommittee reports should be drafted as sections for the SARC Report, to be approved by the SARC.
- Subcommittee working papers should be forwarded to SARC members two weeks before the SARC meeting. More lead time may be needed for SARC members not familiar with specific species under review.
- Relative to Subcommittee workloads, in addition to the species terms of reference, the general guidance is to do what can reasonably be done on the basis of a "normal" workday. The Steering Committee is not always the best judge as to how much work is involved or how to handle the workload.
- As the SARC is responsible for all assessment advice, the review of details is contingent on the particular assessment.
- If there is no indication that stock status has changed from a previous assessment, or is not about to change, then the SARC could report this as the only advice for that stock.
- Subcommittees should submit all tables and figures required for the Advisory document in the standard format.
- It is not desirable for Rapporteurs to be SARC members. Rapporteurs from outside the SARC (NEFSC or states) may be appointed to allow the SARC members to fully participate in all SARC discussions. Although Rapporteurs use their ability to interpret, SARC members make the final judgement. An additional Rapporteur (editor) will coordinate the production of the Advisory Report to assure continuity from stock to stock within the agreed-upon format.
detailed description of the approach and methods can be found in the Northeast Fisheries Science Center Reference Document 94-02.

## Squid

Recent research on the age and growth of long-finned (Loligo) squid indicates that the life span of the species is less than one year. Unlike
previous assessments, which assumed a longer life span, the assessment of this species was based on the new findings. For short-lived species such as long- and short-finned squid and butterfish, the SARC concluded that a real-time assessment/management system should be contemplated to ensure that adequate levels of spawning stock are achieved for these species. A Plan Development Team approach was suggested for the development of such a system. In connection

Figure 2. U.S. commercial statistical areas used to report landings in the Northwest Atlantic.
with this issue, the Report of the Working Group on Methods of Fish Stock Assessment (ICES 1993) was summarized for the SARC's information. The ICES report provides examples of successful assessment and management procedures for short-lived species.

## General

Several other items, common to a number of species, were noted during the meeting:

- As sea sampling data are used for discard estimation, it was suggested that the SARC address the issue of sea sampling coverage generically, for all species, rather than on the species by species basis. This would, most importantly, involve a formal examination of the sea sampling survey design.
- The age structure approach to developing assessments was discussed in connection with at least two species before the SARC. The method requires much more complete biological data base than is currently available for these species, so attention should be paid to the caveats in the reports.

CRD 94-07 Report of the 17th Northeast Regional Stock Assessment Workshop, The Plenary

- In some cases, major assessment difficulties were directly related to the fact that the ADAPT framework was not accessible to most assessment scientists outside NEFSC. This emphasized the point that an ADAPT tutorial is badly needed along with the development of user-friendly ADAPT software.
- Compatible management, in addition to cooperative research, with Canada was recommended for transboundary species such as silver hake and short-finned squid.
- Some meeting participants indicated concern about how the transfer of the Statistics Program from NEFSC to NERO would affect stock assessments since the program plans to stop biological sampling at the ports.

Two fishermen attended the meeting and contributed to discussion of butterfish and the squids.

The timing of and species to review at SAWs 18 and 19, as well as the conduct of SARC meetings was discussed. These discussions are summarized under other business.

## SILVER HAKE

## A. GULF OF MAINE-NORTHERN GEORGES BANK STOCK B. SOUTHERN GEORGES BANK-MIDDLE ATLANTIC

## TERMS OF REFERENCE

The following terms of reference were addressed:
a. Update the analytical assessments of the Gulf of Maine-Northern Georges Bank and Southern Georges Bank-Middle Atlantic silver hake stocks through 1992. If possible, include estimates of discards in the catch-atage matrix.
b. Evaluate catchability differences for silver hake between the ' 36 Yankee' and ' 41 Yankee' survey trawls, and determine the most appropriate conversion factor between the two nets. Standardize the spring survey indices and use the standardized indices in the VPA tuning.
c. Provide any new information on the natural mortality rate of silver hake, with reference to whether the natural mortality rate used in previous assessments ( $\mathrm{M}=0.40$ ) is still reasonable.
d. Review past biological reference points.
e. Examine the effects of a newly developed fishery on juvenile silver hake ( $<18 \mathrm{~cm}$ ).

## OVERVIEW

The silver hake stocks off the northeast coast of the United States have followed a trajectory typical of fish stocks that have been heavily exploited. Before 1960, silver hake fishery was exploited only by U.S. fleets. Exploitation intensified with the arrival of distant-water fleets (DWF) in 1962, and stock biomass declined sharply between 1965 and 1970. Total international landings fell by the late 1970s to historic lows. In addition, the age composition became highly truncated to younger ages: from a fishery whose landings were dominated by ages 3 to 5 with ages up to 10 years, to one in which more than 64 percent of the landings comprised age 2 to 3 fish. While DWF fishing activity for silver hake in
U.S. waters was either greatly reduced or ceased altogether by the late-1970s, U.S. landings have not increased and remain at low but stable levels compared to earlier years of the fishery. A smallmesh fishery, restricted seasonally (June through October) and spatially (SA 522), has been conducted over an area of northern Georges Bank known as Cultivator Shoals. Provisions in Amendment 4 of the Multispecies Fishery Management Plan (FMP) allow the use of small mesh in a region that has minimum mesh size restrictions of 5.5 in. More recently, a "juvenile whiting" fishery has developed for small silver hake as an export product to Spain and Portugal. Unlike the U.S. whiting market, where product demand is for larger silver hake (age 2 and 3), the export market demand is for small silver hake ( 7 to 9 in.) presumably in their first or second year of life. By exploiting younger ages of fish in the stocks the question of concern to management focuses on the affects of a "juvenile whiting" fishery on the long-term yield of the silver hake stocks. Because discards in the domestic silver hake fishery may be significant (Anderson 1975) an important consideration deals with estimating the selection pattern of the current fishery (total catches) and determining whether a directed fishery for smaller silver hake increases the selectivity towards younger ages. Simultaneously, we considered whether increased effort and, therefore, fishing mortality will likewise be directed into this emerging fishery.

The silver hake population in U.S. waters is presently assumed to comprise two major stocks (Figure AB1): 1) Gulf of Maine-Northern Georges Bank (Div. 5Y; 5Ze, SA 521-522, 561) and 2) Southern George Bank-Middle Atlantic (Div. 5Ze, SA 525-526, 562; Div. 5Zw, 6A-6C). These stock definitions represent a change from assessments prior to 1987 and are based on research bottom trawl surveys, U.S. and distant-water fleet commercial fishery statistics, and morphometric data collected during bottom trawl surveys in 19781979 (Almeida 1987). Other studies suggest similar distinctions between silver hake populations in the northern and southern regions of the northeast U.S. continental shelf, but have placed the dividing line further south (Conover et al. 1961; Konstantinov and Noskov 1969). Although the present definition is generally accepted, it is

Figure AB1. Stock definition of the Gulf of MaineNorthern Georges Bank and the Southern Georges Bank-Middle Atlantic silver hake population in U.S. waters.
unlikely that these stocks are reproductively isolated nor is it known to what extent exchange between the two stocks occurs.

Juvenile and adult silver hake distributions from U.S. research vessel surveys during 19821992 (Figure AB2) suggest that silver hake may seasonally migrate across the presently assigned stock boundaries. Distributions vary seasonally by size/age and probably in response to hydrographic changes. During the spring, dense concentrations of juveniles are observed on northern Georges Bank and in the Gulf of Maine just east of Cape Ann, while during the autumn they are widely distributed over all of Georges Bank. Also during the spring, large concentrations of adults occur along the continental slope of the southeastern rim of Georges Bank. Distributions shift significantly by the autumn; the large concentrations of adults, formerly on southern Georges Bank. are absent and adults appear in significant numbers on northern Georges Bank and in the Gulf of Maine (Figure AB2). In addition, silver hake show a general northward movement from the southern and middle Atlantic into southern New England waters which occurs during the summer and autumn. Thus, it may be equally likely that silver hake migrate across Georges Bank.

The impact of the boundary used to separate the northern and southern silver hake stocks on the respective landings at age matrices is greatest in the area of the Cultivator Shoals fishery on Georges Bank. In this area of likely mixing between the northern and southern stocks, all of the catch is allocated to the northern stock under the present definition. Therefore, it may be important to investigate further the question of where to divide the stocks or whether the stocks can be assessed as one unit.

## A. GULF OF MAINE-NORTHERN GEORGES BANK STOCK

## The Fishery

## Commercial Landings

Before 1955, silver hake in the Gulf of Maine and Georges Bank were only lightly exploited. Between 1955 and 1961, an "industrial fishery" developed in Southern New England and landings of silver hake increased, averaging 62,000 mt , most of which was taken from the Gulf of Maine-Northern Georges Bank Stock (Table A1). Exploitation intensified between 1961 and 1965 with the arrival of the DWF (principally the USSR), and total international landings increased to historic highs, reaching $94,500 \mathrm{mt}$ (Figure A1). Total international landings from the Gulf of Maine-Northern Georges Bank stock subsequently declined to a time series low of $3,400 \mathrm{mt}$ in 1979. Since the late 1970s, silver hake have been taken exclusively by U.S. vessels and landings have been fairly stable but at low levels compared to earlier years of the fishery, averaging $6,000 \mathrm{mt}$.

Total commercial landings in 1992 were 5,302 $\mathrm{mt} .12 \%$ lower than reported in 1991 and $17 \%$ lower than 1990 (Table A1). Short-term trends in U.S. landings between 1980 and 1992 show a steady increase to $8,500 \mathrm{mt}$ in 1986, but a decline in more recent years, approximately $37 \%$, between 1986 and 1992.

## Recreational Fishery

No estimates of the recreational catches are available for this stock, but these catches are considered to be insignificant.

Figure AB2. Distribution of juvenile ( $<18 \mathrm{~cm}$ ) and adult ( $>18 \mathrm{~cm}$ ) silver hake in the NEFSC spring and autumn bottom trawl surveys during 1982-1992. Values shown are numbers of fish per tow.

## Sampling Intensity

United States length-frequency sampling in the Gulf of Maine (SA 51) averaged one sample per 130 to 160 mt landed during 1985-1990 (Table A2), but prior to and after this period sampling has been at a much lower intensity (1982-1983: 1 sample per 800 to 960 mt ; 1991 to 1992: I sample per 660 to 990 mt ). Lengthfrequency sampling of commercial landings from northern Georges Bank (SA 52) averaged one sample per 160 to 350 mt during 1982-1989, but since 1990 sampling intensity has decreased substantially (l sample per 500 mt in 1990-
1991). In 1992, only two length-frequency samples were taken from 3,300 mt landed from northern Georges Bank.

## Commercial Landings at Age

Strong shifts in the predominant age of commercial landings have occurred since 1955. During 1955-1971, commercial landings were dominated by age 3 and 4 silver hake (Table A3) with significant contributions from age 5, after which the age composition shifted to younger

ages during 1972-1974, largely due to the DWF concentrating on the strong 1971 and 1972 year classes. Since 1979, the age composition has shifted toward ages 2 to 3 , which have generally composed at least $64 \%$ of the total annually. Since 1955, the age composition of the commercial landings has become highly truncated, with a gradual decrease in the numbers of fish age 6 and greater during 1972-1986, and a complete disappearance since 1989.

Figure Al. Total landings of silver hake from the Gulf of Maine-Northern Georges Bank stock, 1955-1992.

## Commercial Mean Weights at Age

Mean weights at age in the commercial landings for ages 1 to 6+ during 1955-1992 are given in Table A4 and, based on landings patterns, are considered mid-year values. Only slight variations in mean weight at age are apparent among years during 1955-1992 and are related to variations in year class strengths as they become recruited to the fishery. No trends in mean weights during the 1955-1992 period are evident.

## Stock Abundance and Biomass Indices <br> Commercial Landings Per Unit Effort

United States commercial landings per unit effort indices (LPUE, expressed in metric tons landed per day fished) were calculated by tonnage class from otter trawl trips in which silver hake constituted $50 \%$ or more of the total trip landings by weight. These values are considered "directed trips." They have been calculated for the Gulf of Maine (SA 51) and northern Georges Bank (SA 52) separately because the fisheries differ between these areas. and because of regulated Cultivator Shoals fishery on northern Georges Bank established in 1988.

Directed U.S. LPUE indices for the Gulf of Maine have generally exhibited an overall declining trend during the 1973-1992 period, but two

${ }^{1}$ Values in parenthesis for annual samplin gintensity indicate no samples taken for landings given.
distinct peaks occurred; one in 1976-77 and another in 1984-85. The LPUE indices on northern Georges Bank exhibit a slightly more varied trend, and values from tonnage class 3 (which have dominated directed landings) declined slightly between 1973 and 1987. Since 1988, however, LPUE has increased substantially with rates approaching values not observed before in the time series ( $60.1 \mathrm{mt} /$ day fished in 1991). This is particularly notable in the ton class 4 fleet and suggests a significant change in the fishing power of those vessels, which have participated in the regulated small-mesh Cultivator Shoals fishery since 1988 .

To account for changes in the fishing power of the ton class 4 fleet on northern Georges Bank,
the relative fishing power between the various tonnage classes were standardized by applying a three-factor (year, tonnage class, and area) GLM to $\log$ LPUE data for all directed otter trawl trips.

Standardized LPUE indices appear to show relatively consistent trends between the different ton classes and within the different regions (Figure A2). The overall trend between the different regions (average of all ton classes weighted by landings) shows relatively consistent peaks in the standardized LPUE values, although the magnitude was greater on northern Georges Bank (Figure A2). The standardized mean (weighted by landings) indices for the entire Gulf of MaineNorthern Georges Bank stock show distinct peaks in LPUE during 1975-1977 and during 1983-

1985. Most recently, standardized mean LPUE has steadily increased since 1987, but declined in 1992.

## Research Vessel Survey Indices

Spring and autumn survey indices were calculated using Delta distribution estimators for offshore strata only and spring 1973-1981 indices were adjusted to the \#36 Yankee trawl as the standard gear. Stratified mean catch-per-tow in number and weight from U.S. spring and autumn bottom trawl surveys are given in Table A5 and
estimates of number-per-tow at age since 1973 in Table A6.

The autumn offshore number per tow index (0+) declined in the mid- and late 1960s during the period of heavy exploitation by the DWF (Figure A3). Between 1969 and 1975, number per tow increased in both the spring and autumn surveys due to above average recruitment in the mid 1970s, but subsequently declined during the late 1970s. These trends in population abundance from the NEFSC surveys were largely consistent with standardized commercial LPUE indices (Figure A2). Number per tow in the spring survey varied without trend during the early- to

mid-1980s, but increased since 1987, although estimates have been highly variable. The spring index for 1992 is the highest on record, at 196.4 fish per tow. The autumn survey index in 1992 is also the largest on record and is strongly influenced by the 1989, 1990, and 1991 year classes.

## Mortality

## Natural Mortality

Instantaneous natural mortality (M) for the Gulf of Maine-Northern Georges Bank stock is
assumed to be 0.40 . Substantial changes in the age composition of the stock (i.e. substantial numbers of age 8 and $9+$ during the earlier history of the fishery) may suggest that M has also changed. Although an adult M of 0.40 is high compared to other gadids, given the extensive cannibalism in this stock it is possible M could be even higher and that the natural mortality rates varies significantly with age.

## Total Mortality

Pooled estimates of instantaneous total mortality ( $Z$ ) were calculated for four time periods

Figure A2. Landings per unit effort (LPUE) standardized for differences in vessel tonnage class fishing power for the Gulf of Maine-Northern Georges Bank silver hake stock. Calculated standardized LPUE indices compared by a) two-digit statistical area (51 and 52) and vessel tonnage class; and b) by statistical area weighted by tonnage class landings.
encompassed by the NEFSC autumn and spring offshore bottom trawl surveys: 1974-1977, 19791982, 1984-1987, and 1989-1992 (Table A7). Total mortality was calculated from survey catch-per-tow in numbers at age for fully recruited age groups (age $2+$ ) by the $\log _{e}$ ratio of the pooled age $2+$ /age $3+$ indices in the autumn surveys, and the pooled age $3+$ /age $4+$ indices in the spring surveys.

Table A5. Stratified mean number-per-tow (delta estimate) and weight-per-tow (kg) for silver hake from the Gulf of Maine-Northern Georges Bank stock (strata 20-36, 36-40) from NEFSC autumn and spring bottom trawl surveys

[^0]

Figure A3. Stratified mean number and weight (kg) per tow of Gulf of Maine-Northern Georges Bank silver hake from the NEFSC spring and autumn bottom trawl surveys.

ADAPT runs were made using the same formulation but with different combinations of spring and fall indices. Two causes for concern from these analyses were: 1) the indices' q's for the autumn and the spring showed inconsistent patterns. with q's increasing at age in the autumn and q's decreasing at age in the spring, and 2) the autumn survey indices (ages 2 to $5+$ ) showed strong residual patterns that were negative in the earlier years (1973-1975) and positive in more recent years.

These ADAPT results indicated that the estimated F's in 1992 were largely invariant to the different sets of tuning indices, ranging from $\mathrm{F}=0.10$ to 0.14. Regardless of which ADAPT results are chosen, F on the fully recruited ages was estimated to decrease by an order of magnitude since 1988 (from $\mathrm{F}=1.6$ to 0.14 ). Since landings have declined only slightly since 1988 and there is no real indication that effort has declined, it seems improbable that $F$ could have declined as drastically as indicated by these results.

The reasons for the extremely low values of F in 1992 are not completely clear. However, a number of possible explanations include: 1) recent increasing trends in survey population abundance in combination with the temporal trends in the residuals from the ADAPT results, may have inflated stock sizes (as seen as high positive residuals in recent years from the ADAPT results) and therefore artificially lower F's; 2) uncertainty in the landings-at-age matrix from the use of survey age-length keys to age the commercial

Figure B1. Total landings of silver hake from the Southern Georges Bank-Middle Atlantic stock, 1955-1992.
landings and poor sampling of commercial landings, particularly in recent years which required the use of sea samples; and 3) mixing of the Gulf of Maine-Northern Georges Bank and the Southern Georges Bank-Middle Atlantic stocks and its effect on the survey indices that are used to tune the VPA.

## B. SOUTHERN GEORGES BANKMIDDLE ATLANTIC

## The Fishery

## Commercial Landings

Landings from the Southern Georges BankMiddle Atlantic silver hake stock were taken exclusively by U.S. vessels before 1960. Exploitation intensified between 1961 and 1965 with the arrival of the DWF (principally the USSR) and total international landings increased to 307,000 mt (Figure B1), the historic high. Total international landings from the Southern Georges BankMiddle Atlantic stock dropped markedly between 1965 and 1969, increased again during the early 1970s, and subsequently declined. While foreign fleets fishing for silver hake in U.S. waters were either greatly reduced or eliminated altogether by the late-1970s, U.S. landings have not increased
and remain at lows levels compared to earlier years of the fishery.

Total commercial landings from this stock in 1992 were $10,300 \mathrm{mt}$, a slight increase over 1991 and approximately $24 \%$ lower than the $13,600 \mathrm{mt}$ reported for 1990 (Table B1). In 1990 the U.S. commercial fisheries had the largest landings since 1966, and international landinds were the largest since 1982. Since 1980, the U.S. commercial fishery has accounted for at least $80 \%$ of the total, which has remained without trend, averaging $12,000 \mathrm{mt}$ (Figure B1).

## Recreational Catches

Recreational catches of silver hake have been reported for this stock but have been generally a minor component of the total, averaging 777 mt per year and ranging from 0 to $1,974 \mathrm{mt}$ (Table B1). Details of recreational catch estimates can be found in Almeida (1987).

## Sampling Intensity

Length frequencies taken from Division 62 were generally oversampled (averaging 1 sample per 21 to 170 mt ), particularly since commercial landings from this area are low (Table B2). In division 61, length frequency sampling was adequate during 1982-1992, averaging one sample per 100 to 280 mt . Sampling in division 53 averaged one sample per 150 to 290 mt during 1984-1991, but decreased prior to 1984 and in 1992 (1982-1984: 1 sample per 450 to 660 mt ; 1992: 1 sample per 500 mt ). Sampling has been generally poor in division 52 , particularly since 1988, averaging one sample per 350 to 730 mt . Length frequency samples from sea sampling trips during 1989-1992 were also available and used to augment port sample length frequencies.

Sampling recommendations as discussed for the Gulf of Maine-Northern Georges Bank stock should be applied.

## Commercial Landings at Age

Similar shifts in the predominant ages composing the commercial landings have been observed for this stock since 1955 (Table B3). The commercial landings in the 1950s and 1960s were predominantly composed of age 2 to 4 fish (averaging about $86 \%$ of the total each year). During 1972-1974 the age composition shifted to

younger fish (ages 1 to 3), due to several strong year classes recruiting to the fishery. As those year classes grew through the fishery during 1975-1978, the age composition again shifted toward older fish (age 2 to 4), which constituted approximately $90 \%$ of the total. Since 1979, the commercial landings have been made up primarily of age 2 to 3 fish (about $65 \%$ of the total each year), and since 1988 significant contributions have been made by age 4 fish.

## Commercial Mean Weights at Age

Mean weights at age in the commercial landings for ages 1 to 6+ during 1955-1992 are given
in Table B4 and, based on landings patterns, are considered mid-year values. During the 19551992 period, mean weights at age varied annually, but without consistent trend.

## Stock Abundance and Biomass Indices

## Commercial Landings Per Unit Effort

United States commercial LPUE indices (landings per unit effort; expressed in metric tons landed per day fished) were calculated, by ton-

nage class, from otter trawl trips in which silver hake constituted $50 \%$ or more of the total trip landed by weight. These values are considered "directed trips" and have been computed for those divisions in which significant silver hake landings occur. United States landings from directed trips in divisions 53 and 61 have varied annually but generally without trend since the late 1970s. However since the early 1980s, commercial landings from directed trips have increased in the southern Georges Bank area (SA 52), primarily from the ton class 4 fleet.

United States directed commercial LPUE in-
dices from divisions 53 and 61 have gradually declined since the late 1970s, with peak values during 1981-1984 and another smaller peak during 1988-1990 (Figure B2). Despite decreases in these areas, LPUE in the southern Georges Bank region (SA 52) has increased since 1980.

Commercial LPUE indices were standardized by applying a three-factor (year, tonnage class, and area) General Linear Model (GLM) to log LPUE data for directed trips otter trawl trips from 1973 through 1992. Standardized indices that have accounted for area and ton class effects show an overall declining trend (Figure B2).

Figure B2. Landings per unit effort (LPUE) standardized for differences in vessel tonnage class fishing power for the Southern Georges Bank-Middle Atlantic silver hake stock.

## Research Vessel Survey Indices

Spring and autumn survey indices were calculated using Delta distribution estimators for offshore strata only and spring 1973-1981 indices were adjusted to the \#36 Yankee trawl as the standard gear. Stratified mean catch per tow in number for both spring and autumn surveys are given in Table B5 and estimates of number per tow at age in Table B6.

The spring and autumn survey number per tow indices have been variable and have generally shown inconsistent trends in population abundance, except during 1973-1978. During this period, the number per tow indices increased, reaching a series high in 1974 and in 1977 for the spring and autumn surveys, respectively, after which both set of indices subsequently declined (Figure B3). This resulted from strong year classes during the mid-1970s and was consistent with trends occurring in the Gulf of MaineNorthern Georges Bank stock during the same period. The spring index increased again during 1985-1989, but declined through 1992; since 1980 autumn indices have generally varied without trend except for an unusually high index in 1985.

## Mortality

## Natural Mortality

Instantaneous natural mortality (M) for the Southern Georges Bank-Middle Atlantic stock is
assumed to be 0.40 . Changes in natural mortality rates over time and varying by age as was discussed for the Gulf of Maine-Northern Georges Bank stock also applies here.

## Total Mortality

Estimates of instantaneous total mortality $(Z)$ were calculated in the same manner as for the Gulf of Maine-Northern Georges Bank stock and values were obtained for the same time periods. Pooled estimates indicated that total mortality on this stock increased from 0.7 to 0.8 during 1974 1982, to 1.1 during 1984-1987 and further to 1.6 during 1989-1992 (Table B7). Estimates of total mortality were roughly equal between spring and autumn surveys.

## Estimates of Stock Size and Fishing Mortality

## Virtual Population Analysis Calibration

The ADAPT framework (Parrack 1986; Gavaris 1988; Conser and Powers 1990) was used in an attempt to calibrate VPA stock sizes and derive estimates of terminal F values in 1992. As with the Gulf of Maine-Northern Georges Bank stock, temporal trends in the residuals were observed in both surveys in earlier years (1973-1976); however, the spring survey indices (ages 2 to $5+$ ) showed particularly strong trends. Additionally. the spring and autumn surveys have shown inconsistent trends in recent years; observed spring indices were larger than expected (resulting in large positive residuals) while the observed autumn indices were smaller than expected (resulting in large negative residuals).

The above ADAPT results indicated that the estimated F's in 1992 were extremely variable to different sets of tuning indices and formulations, ranging from $\mathrm{F}=0.79$ to 4.8 . The variability in the fully recruited $F$ in 1992 is not only driven by the inconsistency between the spring and autumn surveys, but by the within survey variability in the observed indices. It is not clear whether one index should be chosen over the another; i.e., omission of spring indices which showed strong temporal trends in the residuals lead to extreme values of $F$ in 1992. The reasons for the extremely high values of F in 1992 are not completely clear; however, a number of possible explanations include: 1) large positive residuals on age 2 indices

Table B5. Stratified mean number-per-tow and weight-per-tow (kilograms) for silver hake from the Southern Georges Bank-Middle Atlantic stock (offshore strata 1-19, 61-76; inshore strata 1-46, 52, 55) from NEFSC autumn and spring bottom trawl surveys

[^4]and large negative residuals on age 4 indices in recent years from ADAPT results, may have inflated stock sizes at age 1 and deflated stock sizes at age 4 and, therefore, artificially increased Fs; 2) uncertainty in the landings-at-age matrix from the use of survey age-length keys to age the commercial landings composition and poor sampling of commercial landings, particularly in recent years, which required the use of sea samples; and 3) mixing of the Gulf of Maine-Northern Georges Bank and the Southern Georges BankMiddle Atlantic stocks and its effect on the survey indices that are used to tune the VPA.

## Effects of Discarding onYield and Spawning Stock-Biomass-PerRecruit Analyses

## Methods

To estimate the selection pattern of the current fishery for silver hake, the landings-at-age matrix was augmented to account for the numbers of silver hake at age discarded at sea. This required: 1) a discard estimator for each cell within defined temporal and spatial strata; 2) an

Table B6. Stratified mean number-per-tow (linear estimate) at age for silver hake from the Southern Georges Bank-Middle Atlantic Stock (offshore strata 1-19, 61-76; inshore strata 1-46, 52, 55) from NEFC autumn and spring bottom trawl surveys.

Figure B3. Stratified mean number and weight (kilograms) per tow of Southern Georges Bank-Middle Atlantic silver hake from the NEFSC spring and autumn bottom trawl surveys.
expansion factor to adjust the cell's discard estimates to fleet wide estimate of discards by strata; and 3) samples of the size composition of discards by strata from which the average weight can be used to estimate numbers of fish discarded by length and age. It is assumed that fishing patterns and recorded weight and size composition of discards from observed trips in the Domestic Sea Sampling Program (DSSP) are representative of the overall fishing fleet.

Statistical areas and meshes were aggregated into large enough categories to obtain minimum adequate samples to stratify temporally and spatially, because discard rates are likely to vary owing to the size composition of the fish in the population and operations of the fleets (i.e. mesh size). In addition, meshes were aggregated into mesh categories as follows: mesh category 1 (mesh cod end $<=3.5$ inches), mesh category 2 ( $3.5<$ mesh cod end < 5.5), mesh category 3 (mesh cod end $=>5.5 \mathrm{in}$ ). Tables A8 and B8 show data on discarded silver hake in the DSSP data base: the number of individual length samples and numbers of fish measured by strata (year, quarter, region, and mesh).

## Discard Estimate Expansion

The weight (in pounds) of silver hake discarded to days fished was chosen as the ratio

Table B7. Estimates of instantaneous total mortality $(Z)$ and fishing mortality $(F)^{1}$ for the Southern Georges Bank - Middle Atlantic silver hake stock derived from NEFSC offshore spring and autumn bottom trawl survey data ${ }^{2 .}$

| Time Period | Spring |  | Autumn |  | Geometric Mean |  |

${ }^{2}$ Estimates derived from: Autumn, $\ln \left(\Sigma\right.$ age $2^{+}$for year $1-1$ to $j-1 / \Sigma$ age $3^{+}$for year $i$ to $j$.
Spring, $\ln$ ( $\Sigma$ age $3^{+}$for year $i$ to $j / \Sigma$ age $4^{+}$for year $i+1$ to $j+1$.
${ }^{3}$ Provisional estimate; does not include spring 1993 survey abundance estimates.
discard estimator for the silver hake fishery (Helser 1993). Only those sea sampling trips for which some silver hake were landed were used to compute the discard rates, i.e., trips in which all silver hake were discarded were excluded from the calculations.

The discard rates so estimated were derived from only a fraction of the total number trips made by vessels within each stratum. To derive fleet-wide discard estimates, the discard rate was raised by the expansion factor, $E$, defined as the total days fished of trips that landed silver hake within a given stratum (Helser, 1993). Total effort was defined as the summation of all days fished for those trips during which silver hake were landed. Because some trips that catch silver hake discard $100 \%$ of them (i.e., landings are 0 ), the present discard rates are considered minimum estimates.

The total discards (in weight) of silver hake by stratum were obtained using:

$$
\begin{equation*}
W_{i j k t}=R_{i j k l} * E_{i j k} * P_{i j k l} \tag{1}
\end{equation*}
$$

where:
$W_{i j k l}=$ total weight of discards (lb) in year iregion $j$ quarter $k$ and mesh $l$
$R_{i j k t}=$ mean discard estimator in year $i$ region $j$ quarter $k$ and mesh $l$
$E_{i j k}=$ the total effort (days fished) in year $i$ region $j$, and quarter $k$, and
$P_{i j k l}=$ proportion of total effort from interviewed trips in yeariregion $j$, quarter $k$, and mesh $l$.

## Numbers of Discards at Length and Age

The age composition of discarded silver hake in the fishery was estimated by applying estimated numbers of discards at length derived from DSSP length frequency samples to agelength keys derived from NEFSC research vessel surveys, pooled by calendar quarter. Discarded numbers were estimated by dividing mean weights obtained by applying a length-weight equation ( $W=.00000593 L^{3.05}$ ) to DSSP length frequency samples into the total discard estimate. Total numbers discarded were then multiplied back into proportions at length by stratum to derive numbers at length. Numbers at length were summed across mesh categories, across regions, and across quarters 1 to 2 and across quarters 3 to 4 and applied to age-length keys (quarters 1 to 2 applied to the spring survey key; quarters 3 to 4 applied to the autumn survey key) and summed again over quarter to derive estimates of the
numbers of discards at age. Total numbers discarded at length are shown in Figures A4 and B4 and numbers at age in Figures A5 and B5.

Estimated discards of silver hake ranged from $26 \%(1,695 \mathrm{mt}$ in 1991$)$ to $156 \%(7,236 \mathrm{mt}$ in 1989) of total Gulf of Maine-Northern Georges Bank landings over the 19891992 period for which data were available. In the Southern Georges Bank-Middle Atlantic silver hake stock discards ranged from $12 \%$ ( $1,249 \mathrm{mt}$ in 1991) to $76 \%$ ( $10,000 \mathrm{mt}$ in 1989) of total landings. Numbers of silver hake discarded ranged from $47 \%$ ( 16.6 million in 1990 ) to $296 \%$ ( 75.6 million in 1989) of the total numbers landed in the fisheries in the Gulf of Maine-Northern Georges Bank stock. In the Southern Georges Bank-Middle Atlantic stock fisheries, numbers discarded ranged between $18 \%$ ( 9.7 million in 1991) to $108 \%$ ( 80.7 million in 1989) of the total numbers of silver hake landed.

In the Gulf of Maine-Northern Georges Bank stock significant discards in numbers occurred generally between 15 and 25 cm (Figure A4) and represented the greatest proportion of age 1 and a smaller but still significant proportion of age 2 fish (Figure A5). The size composition of discarded silver hake in the Southern Georges BankMiddle Atlantic fisheries, although slightly larger in size compared to the northern stock, were clearly of a smaller size composition than the landings; with significant numbers between 21 and 30 cm (Figure B4). Discarded silver hake dominated in number at age for age 1 with significant numbers at age 2 and in some years even age 3 (Figure B5).

## Selection Pattern at Age

Estimated numbers of discards-at-age (from 1989-1990) were added to the numbers landed-at-age to develop an estimated catch-at-age matrix for those years. An untuned Virtual Population Analysis (Gulland 1965) was applied to the silver hake landings-at- age and catch-at-age matrices to determine the effect of discarding on the exploitation pattern. Since discard estimates were only available for the years 1989-1992, the VPA was run and examined to determine the extent to which estimates of fishing mortality at age had converged over the 1989-1992 period. For both stocks, natural mortality (M) was assumed to be 0.4 and VPA runs were performed with varying levels of terminal fishing mortality. In all cases, from low to high terminal F's, convergence was achieved across ages 1 to 3 by 1989 and to some extent by 1990. In the northern

stock (see table in the next column ), inclusion of the discards in the catch at age increased the $F$ at age 1 from about 5 to $7 \%$ of the age 3 F (assumed full) to about $45 \%$ (see $200 \%$ column) of the age 3 F . In the southern stock, F at age 1 remained low relative to the age 3 F , but F at age 2 increased from about $25 \%$ of the age 3 F to about $42 \%$ of the age 3 F .

Sensitivity runs at various terminal F's indicated a flat-topped exploitation pattern from age 3 and older. The exploitation pattern given below, indicated as the reference pattern, reflects the average conditions in 1989 and 1990 for each stock. To examine possible results from effort being redirected toward younger ages associated with a "juvenile" whiting fishery, these reference patterns were compared to patterns representing $25 \%$ and $200 \%$ of this estimate in yield and spawning stock biomass per recruit analyses.

Yield-per-recruit and spawning stock biom-ass-per-recruit analyses (Thompson and Bell 1934) were conducted to determine the affect on the long-term yield of the silver hake stocks. Yield and spawning stock biomass (SSB) per recruit were accumulated separately over both the "juvenile" and the "adult" life history phases of a cohorts entire life span and used to examine the likely outcome of harvesting for both a juvenile (ages 0 through 2 ) and adult (age $3+$ ) silver hake fishery. Yield and SSB was calculated for the reference exploitation pattern at age obtained with and without discard estimates (taken from the untuned VPA results) as described earlier, using the 1989-1990 discard estimates.

Mean weights at age were calculated as the average of the mean weights from the landings and discards at age matrices weighted by numbers at age over the 1989-1992 period. Stock weights used in the subsequent analysis were taken as the weight from the length-weight equation applied to mean lengths at age derived from von Bertalanffy growth equations Pentilla et al. 1989). Input mean weights for yield per recruit analyses are given in the table at the bottom of page 29.

Figure A4. Estimated numbers of landed and discarded silver hake by length from the Gulf of Maine-Northern Georges Bank stock over the 1989-1992 period.

The maturation ogives at age of northern and southern silver hake stocks for application of the spawning stock biomass-per-recruit analyses were taken from O'Brien et al. (1993). All initialization parameters were set equal for each stock and for the landings and catch analyses: 1) natural mortality ( M ) was assumed to be 0.40 and equal for all ages; and 2) proportion of F and M before spawning was set to 0.66 and 0.50 for the northern and southern stocks, respectively.

Figure A5. Estimated numbers of landed and discarded silver hake at age from the Gulf of Maine-Northern Georges Bank stock over the 1989-1992 period.

Examination of yield per recruit from exploitation patterns obtained from the VPA indicated a significant trade off between increasing harvest on younger ages of fish in the population andloss of yield per recruit to the "adult" fishery (Figures A6 and B6). Increasingly higher selection (exploitation) of ages 1 and 2 resulted in increasingly greater yield per recruit from a "juvenile" fishery, with maximum yield per recruit being obtained from lower levels of $F$ as exploitation was in-

Figure B4. Estimated numbers of landed and discarded silver hake by length from the Southern Georges Bank-Middle Atlantic stock over the 1989-1992 period.
creased to $200 \%$ of the reference pattern. Yield per recruit becomes more asymptotic as exploitation was increased. Although yield per recruit increased from the "juvenile" component with increasing exploitation on younger ages, it resulted in a significant adverse effect on an "adult" fishery; as selection on ages 1 and 2 was increased to $200 \%$ of the reference pattern maximum yield per recruit decreased by nearly $35 \%$. In addition, $F$ required to achieve maximum yield per recruit from the fishery decreased from around 0.6 to 0.3 .

These results suggest that a harvesting strategy directed toward younger ages of fish (as might occur in a "juvenile" whiting fishery) may be

Figure B5. Estimated numbers of landed and discarded silver hake at age from the Southern Georges Bank-Middle Atlantic stock over the 1989-1992 period.
incompatible with objectives to maintain an "adult" component which has traditionally supported the silver hake fishery. While overall yield to the "adult" fishery was significantly reduced using the different series of exploitation scenarios in this analysis, percent maximum spawning potential (currently used as the overfishing definition) did not decrease as much as might be expected, probably because most of the stock has matured by age 2 (Figures A7 and B7). Fishing mortality rates at $31 \%$ and $42 \%$ MSP declined from 0.51 to 0.36 and 0.39 to 0.34 , for the northern and southern stocks respectively, when discard mortality was taken into account using the reference exploitation pattern. If effort is targeted on con-

Figure A6. Yield and percent maximum spawning potential (MSP) per recruit from fisheries on "juvenile" and "adult" components of the Gulf of Maine-Northern Georges Bank silver hake stock. Graphs compare yield and MSP per recruit obtained from exploitation pattern derived from catch at age under two assumed vectors of natural mortality at age: top graph, $\mathrm{M}=0.4$ constant over all ages; bottom graph, $\mathrm{M}=0.8$ on age $0, \mathrm{M}=0.6$ on age 1 , and $\mathrm{M}=0.4$ on ages 2 and above.

Figure B6. Yield and percent maximum spawning potential (MSP) per recruit from fisheries on "juvenile" and "adult" components of the Southern Georges-Bank-Middle Atlantic silver hake stock. Graphs compare yield and MSP per recruit obtained from exploitation pattern derived from catch at age under two assumed vectors of natural mortality at age: top graph, $\mathrm{M}=0.4$ constant over all ages; bottom graph, $\mathrm{M}=0.8$ on age $0, \mathrm{M}=0.6$ on age 1 , and $\mathrm{M}=0.4$ on ages 2 and above.
gram. Further, it shouid be noted that reliable discard estimates can only be obtained from a statistically based sampling program.

Sampling of commercial landings since 1982 was reviewed. Sampling has frequently been spotty, particularly during 1992 when only 4 samples for the entire year were available from port samples. Also, age structures were not available directly from port samples, but agelength keys were derived from survey-captured fish. Both of these factors contribute to variability and potential bias in landings at age for recent years. The length frequency of silver hake measured in the sea sampling program were compared to that obtained in port sampling. Although good agreement was seen in some years (e.g., statistical area 52 in quarter 2 of 1989),

Figure A7. Yield and percent maximum spawning potential (MSP) per recruit from the Gulf of Maine-Northern Georges Bank silver hake stock under $25 \%$ and $200 \%$ of the reference (Ref.) exploitation at age 1 and 2: 25\%) 0.070 and 0.123 ; Ref.) 0.280 and 0.490 ; and $200 \%$ ) 0.50 and 1.00 .
some disparity was observed in other years (e.g., statistical area 52 in quarter 4 of 1991). The subcommittee also notes that because the sea sampling data are unaudited, the data must be scrutinized prior to use.

Regarding the landings at age matrix, the subcommittee noted that cohorts that appeared strong in the survey did not appear to track well through the landings matrix. The cause of this problem is unknown, but could result from imprecision due to sampling variation, errors introduced by using survey-derived age length keys for the commercial landings, or to other factors such as mixing between the two stocks.

Commercial LPUE indices derived from nominal landings over days fished by ton class, as well as GLM analyses of LPUE indicated different trends between different size vessels. In particular, the LPUE of ton class 4 vessels in recent years has increased greatly relative to ton class 2 and 3 boats. This increase is nnevident beginning in 1988, coincident with the initiation of the Cultivator Shoals fishery. As such, the reliability of commercial LPUE measures as indices of abundance was questioned.

Spring and autumn research survey indices for both stocks show considerable interannual variability resulting in difficulty in tracking cohorts through time. For both surveys, the subcommittee noted a strong decline in catch/tow between ages 3 and 4, suggesting high mortality on these age groups or changes in catchability to the survey. Mortality rates estimated from the surveys show conflicting trends between the two seasonal surveys for the northern stock. Esti-

Figure B7. Yield and percent maximum spawning potential (MSP) per recruit from the Southern Georges Bank-Middle Atlantic silver hake stock under $25 \%$ and $200 \%$ of the reference (Ref.) exploitation at age 1 and 2: 25\%) 0.025 and 0.104; Ref.)0.099 and 0.417 ; and $200 \%) 0.35$ and 1.00 .
mates of $Z$ from the spring survey have been high since 1974 (i.e., $Z>1.0$ ), and have declined during the past four 4 -year time periods. Estimates of $Z$ from the autumn survey, however, were less than 1.0, and have shown a steady increase since 1974.

Discussions of ADAPT results for both the northern and southern stocks concluded that none of the results were reliable in estimating current stock size and fishing mortality. Further, the subcommittee felt that the problems observed could occur for a number of reasons including:

- The boundaries between these stocks are uncertain. Evidence presented on the geographical distribution of survey catches of silver hake, particularly juveniles in the autumn, suggests that considerable mixing between these stocks may occur. The distribution of adult fish also suggests that the stock boundary may shift seasonally, potentially resulting in a misallocation of landings to the stocks and a mismatch between stock boundaries and survey strata sets between seasons.
- Sampling variation in the landings at age matrix, and possible errors introduced by using survey-captured fish for commercial age-length keys in recent years could be significant. Since the ADAPT procedure assumes that errors in the landings at age matrix are negligible, violations of this assumption may result in patterns among the residuals and unreliable results.
- Variation in the distribution of silver hake in bottom trawl surveys and changes in gear used could result in trends in residuals.

## General Comments

## Biological Sampling

Lack of adequate biological samples affected the assessment of silver hake; problems were mainly associated with inadequate port sampling. In 1992, only four silver hake samples were taken from the commercial landings of the northern stock. In three cases, these samples were of king whiting (large silver hake), although this size group comprises a very small fraction of the total catch.

## Sea Sampling

Sea sampling data were used in the silver hake assessments to estimate discards. When the available data were stratified spatially and seasonally within each year, the number of observations within each cell in was usually quite low. Further, incomplete coverage of the commercial fishery by sea sampled trips often led to missing cells when the stratification was too fine-scale. This often led to high variance on the discard estimates and/or problems with imbalanced designs when attempting ANOVAs.

Because of the various gears and mesh sizes in use in the Northeast mixed groundfish fishery, discards within each component must be estimated separately. Expansion to total discards must be performed using some fishery-based raising factor such as total catch or effort. Often, the commercial weighout data are insufficient to allocate total catch by factors such as mesh size which is needed to determine the proportion of sea sample
coverage to total activity within each gear/mesh stratum.

Lack of sea sampling coverage prior to 1989 requires the use of other measures as a surrogate for the sea sampling data based, in part, on relationships determined from the 1989-1992 period. In some cases research vessel survey data can be used to approximate the discard, but this approach requires several assumptions regarding the distribution of fish and fishing activity with respect to the survey sampling design.

The subcommittee has reservations about the
general use of sea sampling data for discard estimation without regard to the above caveats. We would like to request that the SARC address the issue of sea sampling coverage generically for all species rather than on the species by species basis that has prevailed in the past.

## Research Recommendations

- The subcommittee strongly recommends that the stock structure of this resource be closely examined in order to determine the most appropriate aggregation of landings at age and survey data.
- The subcommittee recommends that the survey series be evaluated to 1) determine appropriate strata sets to account for possible differences in distribution between years 2) determine evidence of mixing between stocks 3) determine effect of transformations (e.g., logarithmic or delta) in reducing the impact of unusually high tows.
- The subcommittee recommends that the adequacy of the statistical design of the sea sampling program for estimating discards of silver hake be evaluated. The subcommittee notes that this evaluation should be done across several species and that sampling designs need to reflect the priorities given to each species.
- Sea sampling is not yet substitutable for port sampling. Thus, port samples for length composition are essential to estimate landings at age. Since age-structures collected in the survey do not adequately cover commercially caught fish, the subcommittee recommends that age structures be collected from either the port sampling or sea sampling programs.
- The subcommittee recommends that the spring and summer Canadian surveys be evaluated for use as tuning indices and as indicators of silver hake geographical distribution.
- The developing fishery for juvenile silver hake should be carefully monitored to establish whether it is targeting concentrations of small fish or simply landing catches that otherwise would have been discarded. From a scientific basis it would be beneficial to take observers aboard trips that target juvenile silver hake, optimally when participating in
an experimental fisheries program. This data collection effort is needed to accumulate catch statistics, measure the length composition of landings and discards, and provide adequate sea sampling to determine discard rates.
- There is a need for a market category designation and adequate sampling for small silver hake ( $<18 \mathrm{~cm}$ ) to properly quantify the magnitude of the landings of these juvenile fish.
- MARMAP data should be examined to gain information on egg and larval silver hake distribution with respect to aggregation of spawning adults.

## C. SOUTHERN NEW ENGLAND YELLOWTAIL FLOUNDER

## TERMS OF REFERENCE

After the Sixteenth Stock Assessment Workshop (SAW 16), the Steering Committee set the following terms of reference:
a. Assess the status of Southern New England yellowtail flounder through 1992 and characterize the variability of stock abundance and fishing mortality rates.
b. Provide 1994 projected estimates of catch and 1995 SSB options at various levels of F .

The SARC noted several new approaches for assessment methodology within this assessment. These include application of a cumulative logistic model for estimation of age-specific retention rates by pooled fishery years, graphical methods for examination of tuning indices and VPA model residuals, and a stochastic stock projection technique for short term forecasting. These approaches, described in Rago, et al. (in prep), may prove useful in other age-structured assessments.

## INTRODUCTION

A unit stock of Southern New England yellowtail flounder extending between Nantucket Shoals and Long Island has been defined, based on results of tagging experiments and studies of parasite infestations. Some intermixing occurs with stocks on Georges Bank and off Cape Cod (Royce, et al. 1959; Lux 1963). The stock distribution is represented by U.S. Statistical Reporting Areas 526 and 537-539 and Northeast Fisheries Science Center (NEFSC) offshore bottom trawl survey strata 5, 6, 9 and 10 .

Yellowtail flounder were managed under the International Commission for Northwest Atlantic Fisheries (ICNAF), with nationally-allocated catch quotas in 1971-1976. With the implementation of the Magnusson Fisheries and Conservation Act in 1976, yellowtail flounder were managed under the New England Fishery Management Council's Fishery Management Plan (FMP) for Atlantic Groundfish from 1977-1982. From September 1982 - September 1986, the species was managed under the Interim Plan, which included a minimum possession size of 28 cm (11 in.). The New England Multispecies FMP then imposed

Table C1. Commercial landings of yellowtail flounder (thousands of metric tons) from Southern New England (U.S. Statistical Reporting Areas $526,537-539$ ) as reported by NEFSC weighout, state bulletin and canvas data (U.S.), and by ICNAF /NAFO or estimated by Brown and Hennemuth 1971 (foreign)

minimum sizes of 30 cm ( 12 in. ), later revised to 33 cm (13 in.) under Amendment 5, effective September 1989.

Yellowtail flounder became an important component of the domestic demersal fishery in the early 1930s as abundance of winter flounder declined (Royce, et al. 1959). Total landings rose from about $10,000 \mathrm{mt}$ in 1938 to about $38,000 \mathrm{mt}$ in 1942, but declined in the 1950s, with most landings from the southern New England stock. Some recovery was observed in the 1960s, and

estimated landings from the stock peaked at $33,200 \mathrm{mt}$ in 1969, including a foreign fishery that also harvested the stock between 19651974. Landings declined to $1,600 \mathrm{mt}$ by 1976 . Although landings briefly averaged $13,500 \mathrm{mt}$ in 1982-1983, they quickly declined to a new record low level of 900 mt in 1988. A second quick increase in landings to $8,000 \mathrm{mt}$ in 1990 was also short-lived.

In 1992, total commercial landings were 1,400 $\mathrm{mt}, 500 \mathrm{mt}$ above the 1988 record-low level, and the second-lowest level in the landings history of the stock (1935) (Table C1). There is no recreational fishery for this stock.

## Landings Data

Commercial landings for 1973-1992 were derived from the NEFSC commercial landings files by stock area (U.S. Statistical Reporting Areas 526, 537-539). A landings-at-age matrix (Table C2) was developed from quarterly length samples and age-length keys from the commercial fishery as described in Conser, et al. (1990).

## Landings Per Unit Effort

A general linear model (GLM) was fitted to landings and data collected by interview from
trips reporting otter trawl landings of yellowtail flounder in the NEFSC weighout data base, 19731992 (Table C3). Year, calendar quarter, statistical area and tonnage class (one digit) were included as explanatory variables. Models including year-quarter, year-area and year-tonnage class interactions indicated that although statistically significant, addition of these interaction effects did not improve model fit substantially (e.g., changes in $\mathrm{R}^{2}$ from 0.30 to 0.34 , with $F$ levels of interaction effects one to two orders of magnitude smaller than main effects. Effort was standardized relative to tonnage class 4 , quarter 4, area 539, 1992.

As reflected by the low values of $\mathrm{R}^{2}$, effect of standardization of southern New England effort was minimal (Figure C1). Effort increased from low levels in 1976 to reach high levels in 19831986, before dropping sharply by 1988. A second, higher peak followed in 1990, and effort in 1992 dropped to just below 1983-1986 levels.

Retransformed year coefficients provided LPUE-based indices of abundance (Figure C2). Because the largest bias correction changed the retransformed value by only 0.1 , bias correction was omitted. The index declined to low levels between 1975-1978, increased abruptly in 1979, peaked in 1983 and then declined rapidly. It remained at very low levels from 1984-1989, increasing briefly in 1990-1991, then reaching the second lowest level in the series in 1992.

Table C3. General Linear Model of commercial landings per day fished, Southern New England yellowtail flounder, 1973-1992, all otter trawl trips landing yellowtail flounder; raw and standardized effort (days fished)

## Discard Data

A wide variety of methodologies were employed to estimate numbers of yellowtail flounder discarded by age group. In many instances the estimates fluctuated widely by year and quarter within year. Such fluctuations include sampling variability and process error (or alternatively, model misspecification). To reduce these effects of this variation, Conser, et al. (1991) used nonlinear least squares to fit a cumulative logistic function to estimated discard fractions by age group within a cohort (year class). The cumulative logistic function has several attractive properties for smoothing discard data. First, it is bounded by zero and one, as are the observed input data. Second, the function is monotonically increasing, thereby modeling the general tendency of fisheries to become increasingly efficient at capturing older and larger fish. Finally, the parameters correspond to easily interpreted concepts of $50 \%$ retention and the rate of increase in retention with age.

The general logistic model for retention can

Figure C2. Standardized index of abundance from commercial landings per unit effort data, Southern New England yellowtail flounder. 1973-1992.
be written as:

$$
\begin{equation*}
R=1-\frac{1}{1+\exp \left(-\frac{K_{50}-\text { Age }}{a}\right)} \tag{1}
\end{equation*}
$$

where R is fraction of catch retained, $\mathrm{K}_{50}$ is the age at $50 \%$ retention, $a$ is the slope of the regression and Age is the age group.

Equation 1 was fit to cohorts (year class) in Conser, et al. (1991) for the 1970 to 1988 year classes. Smoothing along cohorts was based on the general premise that strong year classes tend to "attract" fishing effort, thereby increasing the rate of discarding at earlier ages. In other words, high rates of discarding become feasible for fishermen when high levels of landings can be obtained from a cohort. When estimated discard proportions from the 1991 and 1992 fishery years were appended to the cohort-based approach, the statistical fitting procedure produced erratic results. In some instances the retention proportions were lower in 1991 and 1992 than in
previous years for the same cohort. These results suggested that a fishery year approach would be more appropriate. In particular, the implementation of a 13 in . size limit in 1989 would be expected to have a marked effect on discarding rates. Equation 1 was applied to pooled years and generalized to allow for testing of differences among pooled fishery years.

To compare two groups the model was generalized as :

$$
\begin{equation*}
R=1-\frac{1}{1+\exp \left(-\frac{K_{50}+\beta X-\text { Age }}{a+\gamma X}\right)} \tag{2}
\end{equation*}
$$

where X is dummy variable equal to 0 for observations in group 1 and equal to 1 for group 2, $\beta$ and $\gamma$ are parameters related to the group effect on $\mathrm{K}_{50}$ and a, respectively. Equation 2 can easily be generalized to more than two groups by adding more dummy variables. Equation 2 was applied to pooled data for the 1985-1988 and 1989-1992 fishery year groups. Statistical significance of the $\mathrm{K}_{50}, \mathrm{a}, \beta$, and $\gamma$ parameters was approximated by computing the $95 \%$ confidence bounds using the asymptotic standard error of the estimates. Reduced parameter models were selected when the approximate confidence interval overlapped with zero. The following text table summarizes the model estimates and approximate confidence intervals.

| Corrected <br> $\mathbf{R}^{\mathbf{2}}$ | Para- <br> meter | Est. | Approx. <br> $\mathbf{9 5 \%}$ C.I. |
| :--- | :---: | :--- | :---: |
| 0.83356 | K | 2.234 | $[2.1281,2.3393]$ |
|  | $\beta$ | 1.238 | $[1.0054,1.4702]$ |
|  | a | 0.2029 | $[0.1186,0.2872]$ |
|  | $\gamma$ | 0.6435 | $[0.4139,0.8731]$ |

Results suggested that the four-parameter model, with a significant period effect on both $K_{50}$ and a, was appropriate. Changes in minimum size regulations, growth rates, or fishing patterns may have effected significant changes in $\mathrm{K}_{50}$ and a. The statistical fit for this stock is summarized in Figure C3. Analyses of residuals suggested no significant departure from normality.

Overall, the cumulative logistic function was judged to be an effective means of aggregating and smoothing the age specific retention rates. Additional work is needed to apply the model to fishery years prior to 1985. Statistical testing of similar management measures in previous years

Figure C3. Observed age-specific retention rates and smoothed values for 1985-1992 for the Southern New England stock of yellowtail flounder. Circles denote observations from 1985-1988: the solid lijne is the smoothed prediction from the nonlinear fit of the cumulative logistic distribution function: Reten $=1$ - $1 /(1+\exp (-(2.2368-A g e) /$ 0.2029 )). Triangles represent observed retention rates for 1989-1992. Rates for the 1987 year class within this period are indicated by stars. Retention function is: Reten $=1-1 /(1+\exp (-(3.47-$ Age $) / 0.8464))$.
should also be conducted. Smoothing models are appropriate for discard rates in view of the noisy and potentially biased estimates associated with nonrepresentative sea-sampling, imprecise interview data, and reliance on the survey data for estimation of the true population length at age.

The SARC discussed potential reasons for the change in retention pattern in 1989-1992 relative to 1985-1988. The decline in proportion retained at age in 1989-1992 could be due to implementation of higher minimum fish size (13 in. vs 12 in .) after 1989, a change in growth patterns, or a combination of the two factors. Although a decline in mean length at age was observed from research survey catches, mean weights at age in landings do not appear to be changing. But of course, mean weights in the landings should increase for age groups not fully vulnerable to the length limit, unless the lengthweight relationship has changed over time. Consequently, further study of the potential interaction between fishing mortality and growth rates is warranted.

When landings ( L ) were available for a given age class, the smoothed retention function was

used to estimate discards (D) as $\mathrm{D}=\mathrm{L} / \mathrm{R}-\mathrm{L}$. When landings data were not available, other procedures incorporating research length distribution data (Conser, et al., 1991; Rago, et al., in
prep.) were used to impute the number of fish caught, but not landed.

Commercial landings (Table C2) and discard at age (Table C4) were summed to provide a total

Figure C4. Age composition of commercial landings and discards, Southern New England yellowtail flounder, 1988-1992.

Figure C5. Proportion of total catch aged 1 to 3 discarded quarterly, Southern New England yellowtail flounder, 1973-1993.
catch-at-age matrix (Table C5, Figure C4). The proportion of catch derived from discards is summarized in Figure C5. From 1989-1991, landings were dominated by the 1987 year class. Age 1 fish were absent from landings since 1988, which may have been reinforced by minimum size regulations implemented in 1989. The age structure of the landings has continued to become more truncated. Between 1977 and 1986. landings of fish age 5 and older averaged 665,000 annually ( $3.25 \%$ of total landings, average). Between 19871992, an average of 143,000 fish age 5 and older were landed per year ( $1.57 \%$ of total landings, average). Mean weight in the landings is summarized in Table C6.

## STOCK ABUNDANCE INDICES

Indices of age-specific stratified mean catch per tow (Figure C6) were available from NEFSC spring and autumn bottom trawl surveys (Table C7, 1968-1993; Table C8, 1963-1992; respectively) and from NEFSC scallop surveys (Table C9, 1982-1992). Aggregate indices in 1992 were the lowest in the time series for autumn trawl and scallop surveys. The aggregate index in the 1993 spring survey was the second lowest in the time series. Age-specific indices generally indicated relatively weak year classes since 1989. Age distributions in trawl survey catches have become more truncated over the past ten years, with few or no catches of fish aged 5 or older. The SARC noted the absence of statistical adjustment for the effects of vessel (Albatross IV us Delaware $I$ ) and otter trawl door changes over the course of the fall and spring surveys. Although the statistical adjustment factors are small ( $<15 \%$ ), and do not affect the conclusions of the assessment, the SARC suggested adjustment

in future assessments. A newly-released version of the survey analysis program (SURVAN 6.0) will make these adjustments automatically.

The SARC also noted that comparisons among age-specific survey indices revealed highly significant correlations within and between years, especially for the fall and spring surveys (Rago, et al. in prep). These results suggest that the NEFSC survey data provide a coherent set of tuning indices for Virtual Population Analysis (VPA).

## Northeast Fisheries Science Center Winter Trawl Survey

The NEFSC winter trawl survey, implemented in early 1992, is designed to improve sampling of flatfishes through gear modification (elimination of roller gear, use of longer sweeps in front of doors) and survey timing (during period of potential offshore concentration). For yellowtail flounder, winter survey performance varied widely between the two years examined, 1992-1993, as well as when compared with other surveys (Table C 10 ). The total number of stations within survey strata was comparable to that for spring and fall surveys for Southern New England. However, the placement of stations in 1993 appeared to

leave areas southeast of Nantucket unsampled. These areas may provide higher catches, based on some spring survey distribution information. Consequently, some differences between years (e.g., the higher proportion of stations with yellowtail flounder in
1992 vs 1993) may be due to station distribution, although the continued decline in stock size may also be important.

For Southern New England, the winter survey produced higher catch rates in weight and number than spring and autumn surveys in adjoining seasons, although coefficients of variation were generally higher than for spring survey results. The survey captured some age 1 fish. Results based on the first year would appear promising, but it is difficult to determine if the change in performance in 1993 were due to inherent interannual variability for a survey in this season, lower sampling intensity, changing spatial distribution of sampling (or stock) in the second year, or declining stock conditions. This inconsistency will likewise make evaluation of this index's performance in tuning virtual population analyses difficult.

## ESTIMATES OF STOCK SIZE AND FISHING MORTALITY

## Virtual Population Analysis

Virtual population analyses were tuned by estimating numbers at age surviving after the terminal year, and age-specific survey catchabilities, using weighted non-linear least squares fitting procedures (ADAPT, Gavaris 1988; Conser and Powers 1990). Survivors at ages 1 to 3 and 5 (1993) were estimated as were catchabilities for NEFSC spring survey catch/ tow indices of age 1 to 4 and $5+$ abundance, NEFSC scallop survey catch/tow indices of age 1 to 3 and 4+ abundance, and NEFSC autumn survey catch/tow indices of age 1 to 3 and 4+ abundance. Spring survey indices were compared with 1 January stock sizes at ages 1 to 4 and 5+ while scallop and autumn survey indices were compared with mid-year stock sizes at age 1 to 3 and $4+$. The survey indices in the objective function were weighted to reduce the effect of

The above SSBs by age (a) and year (y) are calculated following the algorithm used in the NEFSC projection program, i.e.

```
    SSB(a,y)=W(a,y) < P(a,y) x N(a,y) x exp[-Z(a,y)]
where Z(a,y) = 0.4167\timesM(a,y) + 0.4167\timesF(a,y)
    N(a,y) - Jan 1 stock size estimates (males & females)
    P(a,y) - proportion mature (generally females)
    W(a,y) - weight at age at the beginning of the spawning season
```

The $W(a, y)$ are assumed to be the same as the mid-year weight at age estimates (see "wT AT AGE" table in input section).
highly variable or inconsistent survey indices. Catch at ages 7 and 8 were combined in a plus group. The input exploitation pattern reflected full recruitment at age 3 , as in previous assessments (e.g., Conser, et al. 1991). Fishing mortality for ages $7+$ was assumed equal to fishing mortality for age 6 fish. Instantaneous natural mortality (M) was assumed to equal 0.2 , as in previous assessments. The partial recruitment vector for the terminal year was taken from Conser. et al. (1991); age-specific partial recruitment values were assigned as 0.02 and 0.35 for ages 1 and 2 and 1 for ages 3 to 7 . The SARC suggested further examination of the partial recruitment vector, particularly for changes in recent years.

Fishing mortality levels obtained from virtual population analysis have remained within high ranges observed previously ( $\mathrm{F}=1.6$ from 1990 estimates, Conser, et al. 1991, Figure 7), although reliability of the estimates has deteriorated. There is no analytic evidence of any decline in fishing mortality since 1990 (Table C11). Exploitation rates may possibly be near $85 \%$ in 1992 (comparable to $75 \%$ as estimated in the 1990 assessment for 1990). The age structure in the stock and catches has been reduced
to the point that results of virtual population analyses are compromised.

Estimates of 1992 fishing mortality were fairly insensitive to alternative definitions of plus groups as ages $5+$ or $6+$. Designation of a $5+$ group implies fishing mortality for the fully-recruited portion of the stock is defined primarily by fishing mortality on age 3 in any year in these analyses. Examination of the residual errors using influence and LOWESS smoothing (Rago, et al., in prep.) revealed no significant departure from the ADAPT model assumptions.

Stock size in numbers, although imprecisely estimated, reflected a continuous decline since the appearance of the 1987 year class (Table C11). Stock numbers in 1992 were close to if not the lowest in the 1973-1992 time series. Spawning stock biomass likewlse appeared low, comparable to record-low levels in 1986-1987 (Figure C7, C8). In 1992, the contribution of the 1987 year class to the stock numbers and spawning stock biomass was negligible.

The three most recent year classes, 19891990, were the smallest of the 1973-1992 series, estimated at about 6,4 and 5.5 million, respectively (Figure C7). The abundance of the 1992 year class in 1993 was estimated using 1993

Figure C8. Spawning stock biomass (thousands of metric tons) and recruitment (millions), Southern New England yellowtail flounder, 1973-1992. Points are labeled by year class. Observations serving as the basis for high, medium. and low recruitment used in stochastic projections are separated by soild lines.

Figure C9. Precision of the estimates of spawning stock biomass for Southern New England yellowtail flounder derived from a statistical procedure known as bootstrap. The vertical bars give the range and probability of individual values within that range. The dashed line gives the probability that SSB is less than any selected value on the $x$-axis.
spring survey data and the associated catchability coefficient estimated from the ADAPT procedures. The year class was estimated to be about 2.5 million, but with extremely low precision (approximate coefficient of variation of $133 \%$ ).

Precision of estimates of survivors (1993) was low, although comparable with that of the previous assessment. Approximate coefficients of

Figure C10. Precision of the estimates of fishing mortality for Southern New England yellowtail flounder derived from a statistical procedure known as bootstrap. The vertical bars give the range and probability of individual values within that range. The dashed line gives the probability that $F$ is less than any selected value on the x -axis.
variation ranged between 50 and $55 \%$ for estimates of numbers at age, 1993, except for age 1. Previously, approximated coefficients of variation ranged between 44 and $76 \%$ (age 1 not estimated). Estimates were biased $19 \%$ high for age 2 and 5 to $6 \%$ for older ages. To address the low precision of the estimates, 500 bootstrap replicates were conducted. Bootstrapped estimates of coefficients of variation for stock sizes at ages 2,3 , and 4 to $7+$ in 1993 were $84 \%, 62 \%$ and $55 \%$, after correcting estimates for bias. The 1993 age 1 value was extremely poorly estimated, with coefficients of variation exceeding $300 \%$ and bias exceeding $100 \%$.

Spawning stock biomass at the start of the 1992 spawning season ( 1300 mt ) was estimated with little bias, and a coefficient of variation of $20 \%$. The entire distribution of spawning stock biomass estimates was below 2300 mt ., i.e, the probability that spawning stock biomass exceeded 2300 mt in 1993 less than 1 in 500 (Figure 9).

A coefficient of variation of $20 \%$ was associated with the estimate of fully-recruited $F$ in the terminal year, based on bootstrap analysis. The lowest bootstrap realization of fully-recruited $F$ was 1.20 , i.e., the probability of F being less than 1.2 was less than 1 in 500 (Figure C10). Coefficients of variation for F at ages 1 and 2 were $68 \%$ and $38 \%$, respectively.

Table C12. Input parameters and projection results for Southern New England yellowtail flounder, landings, discard and spawning stock biomass (000 mt). Stock size in 1993 is based on results of bootstrap replications. Recruitment is drawn randomly from a pool of high, medium or low observations from the virtual population time series. Results are averaged over 500 replications. Proportion of $F$, $M$ before spawning $=0.4167$ (peak spawning 1 May). Mean weights at age from 1992 landings and discard at age.

## Yield per Recruit and Spawning Stock Biomass per Recruit Analyses

Biological reference points were calculated in 1990 based on a Thompson-Bell model (Conser, et al. 1991)(Figure 7). Analyses were not revised in this assessment because the partial recruitment vector may vary over the short-term as a function of stock and year class abundance; and no trend in weight at age was observable. Based on the 1990 analysis, $\mathrm{F}_{0.1}=0.22, \mathrm{~F}_{\max }=0.48$ and $\mathrm{F}_{20 \%}=0.49$. Proportion discarded at age was based on fitted retention curves (Figure C3).

## Short-Term Projections

Because of the uncertainty in estimates of numbers at age in 1993, a stochastic projection was undertaken. Each of the 500 realized population vectors at age in 1993 from ADAPT bootstrap runs was projected forward through 1995 under an F option of interest. Three levels of recruitment were considered for each F option. For the high recruitment option, recruitments in 1993-1995 for each iteration were drawn randomly from a pool of the top $33 \%$ of estimated recruitment values from 1973-1992 (Figure 8), consisting of seven values between 41.9 and 126.9 million. For medium and low recruitment, recruitment was drawn randomly from pools containing middle and lower $33 \%$ of observed recruitment values, each containing seven values between 14.0 and 30.0 million and 2.5 and 12.9 million, respectively.

Four F options were considered:

|  | $\mathbf{F}_{1993}$ | $\mathrm{F}_{1994}$ | $\mathrm{F}_{1995}$ |
| :---: | :---: | :---: | :---: |
| 1. Status quo | 2.3 | 2.3 | 2.3 |
| 2. Status quo, reduced $10 \%$ in 1994-95 | 2.3 | 2.1 | 2.1 |
| 3. Status quo, reduced $50 \%$ in 1994-95 | 2.3 | 1.1 | 1.1 |
| 4. $\mathrm{F}_{20 \% \mathrm{MSP}}$ in 1994-95 | 2.3 | 0.5 | 0.5 |

Mean landings, discard and spawning stock biomass resulting from the 500 realizations are summarized by F option, recruitment level and year in Table C12.

Partial recruitment for the projection was set equal to that used in VPA (described in Conser, et al., 1991). Weights at age were based on observed values for 1992. Total catch at age was apportioned between landings and discard based on estimated ratios of discard to catch, 1989-1992, estimated from the retention curve (Figure C3).

Landings and spawning stock biomass levels in 1993 were predicted to decline to new record low levels under all options and recruitment scenarios (below 600 mt and 1000 mt , respectively). In 1994, landings remained at or below 600 mt in all cases, and continued to decline under medium and low recruitment scenarios, to about 200 mt when F was reduced to $\mathrm{F}_{20 \%}$. By 1995, three consecutive years of high recruitment could increase spawning stock biomass to 10,000 to $14,500 \mathrm{mt}$, with highest spawning stock biomass from most restrictive F option. If recruitment is assumed to be totally independent of spawning stock biomass, the probability of 3 consecutive years of high recruitment would be $(0.33)^{3}=0.04$. If recruitment is dependent on spawning stock biomass, the probability of three consecutive "high" recruitment levels would be substantially less. Medium recruitment would produce spawning stock biomasses ranging from 3,000 to $5,000 \mathrm{mt}$, while low recruitment would maintain spawning stock biomass at or below $2,500 \mathrm{mt}$, although with slight increases under more restrictive fishing mortality options. Under three consecutive years of medium recruitment. landings could range from $540 \mathrm{mt}\left(\mathrm{F}_{200 \%}\right)$ to 1,000 $\mathrm{mt}\left(\mathrm{F}_{2.3}\right)$, with associated spawning stock biomasses of $4,800 \mathrm{mt}$ to $3,000 \mathrm{mt}$.

The SARC noted that the projection methodology incorporated the uncertainty of the estimates of stock size, and partially accounted for the uncertainty in future recruitment. Alternative formulations of recruitment stochasticity, including incorporation of a stock-recruitment function, should be examined.

## SUMMARY

1. Stock abundance is at record-low levels, based on results of research vessel surveys, and virtual population analyses.
2. Stock abundance has declined continuously since the recruitment of the 1987 year class. This year class is absent or insignificant in age-structured indices of abundance and landings in 1992.
3. The three most recent year classes, 19891991, appear to be among the poorest observed over the 1973-1992 period examined here. From initial indications of the NESFC spring survey, the 1992 year class is likely to be below average.
4. The age structure of the stock has become truncated in recent years to contain few or no fish older than age 5.
5. Fishing mortality rates are well in excess of biological reference levels, with exploitation rates of approximately $85 \%$.
6. Traditional analytic techniques including virtual population analysis, and separable models are compromised for this stock by truncated age structure in the stock, and likely changing fishery targeting patterns with year class strength or regulation. Precision of assessment results is declining with stock status.

## RESEARCH RECOMMENDATIONS

- Evaluate potential changes in growth, sex ratios and maturity related to increased fishing pressure, decreasing stock size, and possibly, water temperature.
- Evaluate potential bias in length frequency distributions and age-length keys arising from cluster sampling by sex.
- Develop sea sampling coverage to allow direct estimation of discards for all seasons of the fishery.
- Investigate alternative models for population assessment.

## D. BLUEFISH

## TERMS OF REFERENCE

The following terms of reference were established for bluefish by the Steering Committee:
a. Agree on standard aging methodology and/or length-based aging methods for bluefish.
b. Compile catch at age for commercial and recreational bluefish fisheries from Maine to Florida.
c. Compile research catch per tow indices for bluefish from available state and federal surveys from Maine to Florida.
d. Assess the status of bluefish through 1992 and characterize the variability of stock abundance and fishing mortality rates. Review past biological reference points and update as necessary.
e. Provide 1994 projected estimates of catch and 1995 SSB options at various levels of F .

The Stock Assessment Workshop (SAW) Pelagic/Coastal Subcommittee met on October 2526, 1993 and on November 16, 1993 at the Connecticut Division of Marine Fisheries in Old Lyme, Conn. to initiate a reassessment of the status of Atlantic coast bluefish in response to direction from the SAW Steering Committee. At the October meeting, the Subcommittee considered terms of reference A-C, and developed a consistent series of catch at age data and fishery independent survey indices. Results of the initial meeting and associated data are included in this report. Based on the acceptance of the catch at age matrix, the data were distributed to Subcommittee in early November for analysis with retrospective techniques including ADAPT tuning of VPA (Parrack 1986, Gavaris 1988, Conser and Powers 1990) and CAGEAN (Deriso, et al. 1985; catch-age analysis). At the November meeting, several trial runs using both methods were considered, using different underlying assumptions and combinations of tuning indices, but the Subcommittee was unable to reach a consensus on estimates of stock size and fishing mortality rates. Therefore, terms of reference D and E were not met.

## INTRODUCTION

- Bluefish(Pomatomus saltaitix) are found along the U.S. Atlantic coast from Maine to Florida, migrating northward from the South Atlantic Bight in the spring and returning southward in the late fall. They are the target of a major recreational fishery along the Atlantic coast, with catches averaging $44,200 \mathrm{mt}$ per year during 1979 to 1992. For the same period, the commercial landings of bluefish, mainly by otter trawls, averaged $6,300 \mathrm{mt}$ per year. The management unit for the Fishery Management Plan (FMP) for the Bluefish Fishery, developed jointly by the Mid-Atlantic Fishery Management Council (MAFMC) and the Atlantic States Marine Fisheries Commission (ASMFC), has been defined as the entire bluefish population along the Atlantic Coast of the United States (MAFMC 1990).

Atlantic coast bluefish exhibit fast growth during the first two years of life, attaining fork lengths of over 40 cm by age 2 (Hamer 1959, Lassiter 1962, Richards 1976, Wilk 1977). They may reach ages of at least 12 years and sizes in excess of 100 cm fork length and 14 kg in weight. About fifty percent of bluefish reach sexual maturity by the second year of life, and they are fully mature by age 2 (Wilk 1977). Spawning occurs during two major periods: March and April in the South Atlantic Bight near the inner edge of the Gulf Stream, with a peak about 1 April; and June through September in the Mid-Atlantic Bight, with a peak about 1 August (Wilk 1977, Kendall and Walford 1979, Nyman and Conover 1988). Some spawning also occurs in the South Atlantic Bight during the fall and into early winter (September through January; McBride, et al. 1993).

Lund and Maltezos (1970) used analysis of mark and recapture data to conclude that several bluefish populations are present along the Atlantic coast. Wilk (1977) suggested that two populations of bluefish, corresponding to the major spawning groups, exist along the Atlantic coast. Chiarella and Conover (1990) presented evidence that fish from the major spawning groups mix extensively during their lifespan, as summer spawning fish were observed to originate from both spring- and summer-spawned cohorts, and concluded that year classes of bluefish therefore consist of varying proportions of seasonal cohorts. Graves, et al. (1992) used analysis of
mitochondrial DNA to investigate the genetic basis of stock structure of bluefish along the Atlantic coast, and were unable to detect significant genetic differences among spring- and sum-mer-spawned bluefish. Graves, et al. (1992) concluded that bluefish along the mid-Atlantic coast comprise a single genetic stock.

In anticipation of a fisheries management plan to regulate commercial and recreational catches of Atlantic coast bluefish, the ASMFC and the MAFMC, in cooperation with the Na tional Marine Fisheries Service (NMFS), began work on stock assessment in 1986. Length frequency data collected by the Northeast Fisheries Science Center (NEFSC) (bottom trawls, 19741986) and NMFS Marine Recreational Fishery Statistics Survey (MRFSS) (1979-1985) was available for analytical assessment (i.e., virtual population analysis). However, no consistent time series of geographically comprehensive age-length keys were available for estimating age frequency from length frequency data. Therefore, an agelength key (hereafter referred to as the ASMFC pooled key) was developed by pooling data collected by the fisheries agencies of several Atlantic coast states from 1982 to 1986 (Crecco, et al. 1987, Terceiro 1987).

There were concerns about the potential for biased results using the ASMFC pooled key, due to influence of interannual variation in growth, recruitment, or mortality rate, given the broad temporal and geographic scale over which the age-length data were collected (Westrheim and Ricker 1978). As a result, no consensus was reached on the utility of the ASMFC pooled key, catch at age data, or subsequent analyses presented in Crecco, et al. (1987) and Terceiro (1987).

Following implementation of the bluefish FMP in 1990, stock assessment work for bluefish was renewed by ASMFC. A yield-per-recruit analysis was developed to provide new biological reference points. Parameters of the von Bertalanffy growth function ( $L_{t}=L_{\text {inf }}\left[1-e^{-K(t-t)]}\right)$ ), derived from weighted mean calculated lengths at annulus formation presented in NOAA (1989), were used as an expedient alternative to the ASMFC pooled key to age MRFSS sample bluefish length frequency data by cohort slicing (i.e., solving for $t$ in the von Bertalanffy growth equation, given $L_{\text {inf }}, L_{t}$, K , and $\mathrm{t}_{0}$ ). Length at age, weight at age, and partial recruitment vectors for the yield-per-recruit analysis were developed from this version of the MRFSS length-age data.

Reviews of this yield-per-recruit analysis at the Eleventh NEFSC Stock Assessment Workshop (NEFSC 1990) noted that variation in mean lengths at age and subsequently derived growth parameters, likely inherent when data from sev-

Figure Dl. Trends in recreational catch (includes catch type B2, fish released alive) and commercial landings for bluefish, Maine to Florida, 1979-1992.
eral disparate sources are considered, could lead to biased results from cohort slicing. The Eleventh NEFSC Stock Assessment Workshop (NEFSC 1990) recommended testing alternative methods, such as mixture of distributions methods, and data sources in lieu of a time-series of agelength keys for the estimation of bluefish ages from length frequency data. Terceiro and Ross (1993) compared the utility of two simple methods for estimating bluefish ages from lengthfrequency data (cohort slicing using growth parameters, and application of a pooled age-length key) with two more rigorous statistical methods (the iterated age-length key method of Kimura and Chikuni (1987), and the MULTIFAN method of Fournier, et al. (1990)). Terceiro and Ross (1993) found that MULTIFAN was the best alternative to a time series of fishery-specific agelength keys for the estimation of Atlantic coast bluefish ages from length data.

## FISHERY DATA

## Commercial Landings

Total U.S. commercial landings of bluefish from Maine to Florida peaked in 1981 at nearly $7,500 \mathrm{mt}$ ( 16 million pounds, Table D1, Figure

Table D1. Estimated bluefish catch: commercial landings, recreational landings, recreational catch, and foreign landings, Maine to Florida, east coast (metric tons). Recreational landings include catch type A (fish landed and available for sampling), type B1 (fish landed but not available for sampling), and $25 \%$ of type B2 (fish released alive, assuming a $25 \%$ discard mortality rate). Recreational catch includes catch types A and B1, plus all catch type B2. Total landings include commercial landings, recreational landings, and foreign landings. Total catch includes commercial landings, recreational catch, and foreign landings.

Table D3. Summary of NEFSC sampling of the NER (ME-VA) commercial fishery for bluefish, 1982-1992. Age samples are currently archived. NEFSC weighout landings are those characterized directly by length frequency sample data. Total NER landings include weighout plus general canvas data. Length frequency distributions based on NEFSC weighout landings are raised to NER total landings.

ational fishery has been evaluated, sampling intensity is expressed in terms of metric tons of total NER landings per 100 fish lengths measured. The sampling is proportionally stratified by market category and fishing gear, with the sampling distribution generally reflecting the distribution of weighout landings by market category and gear. Sampling intensity has been in general low, deteriorated since 1988, and was very poor during 1990-1992.

Length composition of the NER commercial landings for 1982-1992 was estimated annually for pooled market categories and statistical areas, using standard NEFSC procedures (length frequency samples converted to mean weights by length-weight relationships; mean weights in turn divided into landings to calculate numbers at length; Table D4). Length compositions were estimated by gear type when samples were adequate (1983-1988). The NER commercial landings at length matrix does not include the landings from states not participating in the NEFSC weighout system (e.g., North Carolina to Florida).

No age data from NER fisheries are available for conversion of the NER landings at length. although the age structures (scales) are archived. For this assessment, the Subcommittee compared the mean weights in the NER fishery with those from the North Carolina (N.C.) winter fish-
eries (gillnet and otter trawl) as a means of judging the applicability of North Carolina Division of Marine Fisheries (NC DMF) commercial winter fishery age-length keys for aging NER commercial fishery lengths. The Subcommittee judged that mean weights in the fisheries were similar, and so NC DMF commercial winter fishery annual age-length keys were used to convert NER commercial fishery length data to age. For 1990-1992, the NER commercial fishery length sampling was judged to be inadequate to provide a reliable sample of the landings (Table D3). To overcome this deficiency, the N.C. commercial winter fishery proportions at age were applied to the NER commercial fishery landings to estimate landings at age (Tables D4-D5).

## North Carolina Commercial Fishery

The N.C. commercial fishery accounts for about one-third ( 30 to $35 \%$ ) of the commercial landings along the Atlantic coast. A separate landings at age matrix for this component of the commercial fishery was developed from NC DMF length-age frequency sampling data. The NC DMF program sampled the commercial fishery landings at a rate of about 100 mt of landings per 25 ages during 1982-1992 (Table D6). Lengths

Table D4. Northeast region (Maine to Virginia) commercial fishery landings at age for bluefish (thousands of fish). The $1982-1989$ lengths were converted to age using NC DMF annual age-length keys from the North Carolina winter fishery. The 1990-1992 landings were assumed to have the same age composition as the North Carolina winter fishery landings.

and ages are sampled from the summer pound net, summer long haul seine, winter gill net, and winter trawl fisheries, and separate matrices were developed for each, before summing to provide an estimate of total N.C. commercial fishery landings at age and mean weights at age (Tables D7-D8).

## Commercial Discards

Data on bluefish catch have been collected by the NEFSC sea sampling program in the Gulf of Maine groundfish gillnet fishery and the Southern New England/Mid-Atlantic otter trawl fishery for 1989-1992. The Subcommittee found these data indicated that in both fisheries, discards have comprised less than $10 \%$ of the total catch per trip. Length frequency sampling has been inconsistent, and the data are not adequate to develop an estimate of either total discard or discard at length for the 1989-1992 period.

## Commercial Fishery-based Indices of Abundance

A General Linear Model (GLM; SAS 1989) standardized index of abundance for bluefish was developed based on NER commercial otter trawl fishery weighout data for 1982-1992. An initial model including year, state, calendar quarter, 3 -digit statistical area, and tonnage class explained $31 \%$ of the variation in log-transformed otter trawl landings per trip (mt per days fished), but interaction terms between state/area and quarter/area were statistically significant and nearly as important as the main effects, and some empty cells were present. Aggregating areas to 2digit divisions reduced the magnitude of the interaction terms, but they still were nearly as important as the main effects, and empty cells remained. A final main effects model incorporating year, state, calendar quarter, and tonnage class had no empty cells, minor potential interaction terms, and explained $25 \%$ of the variation in log-transformed otter trawl landings per trip. This index indicated a pattern of decreasing stock size from 1985 to 1988, with a stable level since 1989 (Table D9, Figure D2). Proportions at age from the NER fishery (in weight) were applied to this index to develop an age-disaggregated index for VPA tuning (after division by mean weights to provide an index in numbers (Table D10).

GLM standardized indices of abundance have also been developed from total catch per trip data (landings plus discard, metric tons per days fished) for trips sampled in the otter trawl and sink gillnet groundfish fisheries. Significant main effects (other than year) were calendar quarter and individual vessel in both models. The year effect was not significant in the gillnet fishery model, suggesting no effect of stock biomass on CPUE, although this model was significant and explained a large proportion ( $41 \%$ ) of the variation in log-transformed catch per trip. The otter trawl model also did not have a significant (at the $1 \%$ level) year effect, although $\mathrm{R}^{2}=$ 0.51 . The Subcommittee judged that neither index of abundance based on sea sampling data gave a reliable estimate of bluefish stock abundance.

## Recreational Catch and Effort

Summary fishery statistics collected by the MRFSS are presented in Tables D11-D16. The 1992 recreational fishery total catch (catch type

Table D7. North Carolina commercial fishery landings at age for bluefish. This matrix is a sum of component matrices from the North Carolina landings from pound nets, long haul seines, gill nets, and trawls. Landings from South Carolina, Georgia, and Florida are included in the gillnet landings.

A: fish landed and available for sampling, plus type Bl: fish landed but not available for sampling, plus type B2: fish released alive) was about $17,000 \mathrm{mt}$ ( 37.5 million lb), well below the 19791991 average of $46,300 \mathrm{mt}$ ( 102 million lb; Tables D1 and D11, Figure D1). The share of total catch taken by the recreational sector was $77 \%$ in 1992. The proportion of fish released alive has increased since 1979, peaking at $37.3 \%$ of total catch in 1992 (Table DIl).

The number of directed bluefish trips (those catching bluefish, or with bluefish indicated as a target species but with zero catch) was estimated by applying the proportion of sampled trips targeting bluefish by two-month sampling wave/ state/fishing mode/fishing area (distance from shore) strata to the estimated number of fishing trips for all species in those strata (Table D14, Figure D3). Nominal catch per trip in number and weight (Tables D15-D16) was calculated from the total catch estimates. These indices of abundance indicate a steady decline in bluefish stock size and biomass since 1979. On a regional and fishing mode basis, these nominal indices of abundance have declined at higher rates in the North Atlantic region (Maine-Conn.) than in the

Figure D2. Indices of stock abundance for bluefish, based on recreational and commercial fishery General Linear Model (GLM) standardized catch (numbers) per unit effort.

Table D10. General Linear Model (GLM) standardized index of abundance at age (in numbers) for bluefish from the NER commercial otter trawl fishery

Mid-Atlantic (N.Y.-Vir.) and South Atlantic (N.C.Fla.) regions. This may imply that the availability of bluefish to anglers in New England waters has declined relative to the more southern waters (Figures D4-D5).

The length frequency sampling intensity for the recreational fishery for bluefish was calculated on a metric tons of total catch per 100 lengths measured basis. Sampling intensity has not met the generally accepted target of 200 mt per 100 lengths measured, and in most years has been very poor relative to this target level (Burns, et al. 1983)(Table D17). The length composition of the recreational catch during 1979-1992 was estimated by two-month sampling period (wave), state, fishing mode (shore and boat), and fishing area (inland and territorial sea, EEZ) strata by merging MRFSS intercept length frequency samples with estimated type A, B1, and B2 catches. Catch types B1 and B2 were assumed to have the same length frequency distribution as catch type A, and catch type B2 was assumed to have a hooking (discard) mortality rate of $25 \%$, based on analogy with species such as striped bass (Diodati 1991), black sea bass (Bugley and Shepherd 1991), and Pacific halibut (IPHC 1988). The length frequencies of the recreational catches in 1980 (highest level of recreational catch since implementation of the MRFSS in 1979), 1987 (average level of recreational catch in MRFSS time series), and 1992 (most recent year, lowest
level of recreational catch in MRFSS time series) are presented in Figure D6.

No age structures are sampled by the MRFSS from fish captured in the recreational fishery. The Subcommittee considered two options for converting recreational lengths to ages: 1) using MULTIFAN (Fournier, et al. 1990), a mixture of distributions method for resolving ages from length frequencies using maximum likelihood methods, and incorporating consideration of growth patterns, or 2 ) application of NC DMF commercial fishery annual age length keys. An initial comparison for three years (1983, 1987, and 1992) suggested the results would be comparable for ages 0 to 3 , with some divergence at older ages. The MULTIFAN method tended to convert larger lengths to ages based on the mean pattern of growth (which is influenced strongly by the growth pattern evident for the younger ages) and to form a large "plus group." The NC DMF keys tended to provide a smoother decline in numbers at age, improved coherence of strong and weak cohorts at age 5 and older, and a broader distribution at older ages.

The Subcommittee performed a comparison of Connecticut Department of Marine Fisheries (CT DMF) trawl survey age-length keys for 19841987 with the NC DMF commercial keys using the method of Hayes (1993) to determine if application of those keys would cause a serious bias in conversion of lengths to age if applied to

Table D11. Estimated total number (thousands) of bluefish caught by recreational fishermen, MRFSS 1979-1992. Shore fishing mode includes catch taken from beaches, banks, and man-made structures; boat fishing mode includes catch taken from party/charter and private/rental boats. For annual totals, numbers of fish released alive (catch type B2) is also totaled and expressed as a percentage of the total catch. Total landed includes catch type A (fish landed and available for sampling), type B1 (fish landed but not available for sampling), and $25 \%$ of type B2 (fish released alive, assuming a $25 \%$ discard mortality rate).

Figure D3. Trends in recreational catch and effort for bluefish, Maine to Florida, 1989-1992. Catch includes fish released alive (catch type B2), effort is trips catching or targeting bluefish.
recreational fishery length frequencies. The method computes the probability of obtaining the observed difference between proportions at age for a given length interval in the age-length key by random chance. The method suggested no serious bias would be caused if the annual NC DMF age-length keys were used to age the recreational length data.

For further comparison, the recreational lengths were converted to age using both methods to develop parallel recreational catch at age and mean weights at age matrices, and thus parallel total (commercial and recreational) catch at age and mean weights at ages matrices, for the 1982-1992 time series. After considering the results of application of the Hayes method (1993) and upon inspection of the catch at age matrices developed with the alternative length to age conversion methods, the Subcommittee judged the use of the NC DMF keys to be the preferred approach, and adopted the catch at age matrices compiled with the keys as the best estimate of recreational catch at age (Tables D18-D19).

Figure D4. Trends in nominal recreational catch per trip (CPUE) for bluefish for anglers fishing from boats in the North Atlantic (MaineConnecticut). Mid-Atlantic (New YorkVirginia) and South Atlantic Regions (North Carolina-Florida). Top panel shows nominal CPUE, bottom panel shows linear regression line over the time series.

## Recreational Fishery-based CPUE Indices

In addition to the nominal indices derived from estimated catch and effort statistics (described above), the intercept sample data from the MRFSS 1979-1992 were used directly to develop an index of abundance. The Subcommittee suggested a revision of previous analyses to include not only those trips catching bluefish, but also those with zero catch which targeted

Figure D5. Trends in nominal recreational catch per trip (CPUE) for bluefish for anglers fishing from shore in the North Atlantic (MaineConnecticut), Mid-Atlantic (New YorkVirginia) and South Atlantic Regions (North Carolina-Florida). Top panel shows nominal CPUE, bottom panel shows linear regression line over the time series.
bluefish as the primary or secondary species sought. A GLM analysis was used to model the variation in MRFSS intercept log-transformed catch per trip for all intercepts coastwide, and produce a standardized index of stock numbers based on year category regression coefficients. A main effects (year, state, two-month sampling wave, and fishing mode) model accounted for about $9 \%$ of the variation in intercept catch per trip. This standardized index suggests a general decline in bluefish abundance since 1979 (Table D20, Figure D2). Age-disaggregated indices for VPA tuning were calculated by applying propor-

Table D20. General Linear Model (GLM) of recreational fishery (MRFSS 1979-1992) intercept catch (types $\mathrm{A}+\mathrm{B} 1+\mathrm{B} 2$ ) per trip data to develop standardized index of abundance. Includes trips with bluefish catch and trips with zero bluefish catch but which targeted bluefish. Variation in log-transformed catch per trip (LOGCA) is modeled with year (YR), state (ST), two-month sampling period (WAVE) and fishing mode (MODE) as main effects, with no interactions. The corrected, retransformed YR parameter estimates are indices of stock numbers (total number of fish caught per trip).

Corrected, retransformed YR parameter estimates

|  | Estimate | Lower 95\% CI | Upper 95\% CI |
| :--- | :---: | :---: | :---: |

tions at age from the recreational fishery (using NC DMF keys) to the annual aggregate indices (Table D21).

## Total Catch Composition at Age

NER commercial landings, N.C. commercial landings, and recreational fishery catch (landings plus release mortalities) at age matrices were summed to provide an estimate of total catch at age of bluefish, 1982-1992. Mean weights at age in the total catch were calculated as a weighted mean (by number) of the mean weights at age in the component fisheries (Tables D22D23).

## RESEARCH SURVEY ABUNDANCE AND BIOMASS INDICES

## NEFSC Fall Inshore

Long-term trends in bluefish abundance were derived from a stratified random bottom trawl survey conducted by NEFSC between Cape Hatteras and Nova Scotia. Catches of bluefish in spring surveys and in offshore strata are low and sporadic. Bluefish are caught consistently in relatively large numbers during the fall survey, in inshore strata (Tables D24-D26). Generally, over $90 \%$ of the bluefish caught in the fall inshore

Table D21. General Linear Model (GLM) standardized index of abundance at age from the recreational fishery (MRFSS 1982-1992). Lengths converted to age using NC DMF commercial fishery annual age-length keys.

|  | Age |  |  |  |  |  |  |  |  |  |  |  |  |

survey are less than 40 cm fork length, and therefore mainly age 0 and age 1 fish. For 19821992, lengths were converted to ages using the corresponding annual NC DMF commercial fishery age-length keys. The NEFSC survey suggests that strong year classes of bluefish recruited to the stock in 1977, 1981, 1984, 1986, 1988, and 1989. The series indicates that poor recruitment occurred in 1974, 1978, 1983, 1987, 1990, and 1993 (Tables D24 and D26, Figure D7).

## Rhode Island DFW

A standardized bottom trawl survey has been conducted during the fall months in Narragansett Bay and state waters of Rhode Island Sound by the Rhode Island Division of Fish and Wildlife (RI DFW) since 1979. An index of age 0 bluefish abundance developed from this survey (mean number per tow less than 30 cm ) indicated strong year classes in 1984, 1987, and 1991, with very weak year classes in 1979 and 1992. The RI DFW has also conducted a beach seine survey consisting of 15 stations sampled during June-October since 1986. An age-0 index developed from those data indicated strong year classes in 1987, 1990, and 1991, with the poorest year classes in 1992 and 1993 (Table D27, Figure D7).

## Connecticut DEP

A fall (September-October) bottom trawl survey conducted by the Connecticut Department of Environmental Protection (CT DEP) catches bluefish over the full range of lengths in the stock. These data suggest that strong year classes recruited to the stock in 1984-1986, and 1989, with poor year classes in 1987, 1988 and 1993 (Table D28, Figure D7).

## Delaware DFW

The Delaware Division of Fish and Wildlife (DE DFW) has conducted a standardized bottom trawl survey ( 30 ft headrope trawl with 0.5 in . stretch mesh) since 1980. A recruitment index (age 0 , fish less than 30 cm ) has been developed from these data for the 1980 to 1992 year classes. The index incorporates data collected from June through October (arithmetic mean number per
tow), with age 0 bluefish separated from older fish by visual inspection of the length frequency. This index suggests that strongest year classes recruited to the stock in 1988 and 1989, with poorest recruitment in 1981 and 1991 (Table D29, Figure D7).

## Virginia Institute of Marine Science

The Virginia Institute of Marine Science (VIMS) has conducted a juvenile fish survey using trawl gear in Virginia rivers since 1955. A index of recruitment developed from these data suggests that since 1979, strongest year classes recruited to the bluefish stock in 1981, 1984, 1989, and 1990, and poorest year classes in 1979-1980, 1985-1987, and 1991. Results are incomplete for 1993. VIMS also conducts a haul seine survey targeting juvenile striped bass in Chesapeake Bay. An index of age 0 abundance for bluefish from this survey indicates strong year classes recruiting in 1983, 1985, 1987, 1991, and 1993, with poor year classes in 1986 and 1992 (Table D30, Figure D7).

## North Carolina DMF

The NC DMF has conducted a juvenile fish trawl survey, which samples fixed stations from the Cape Fear River to the mouth of Albermarle and Currituck Sounds at depths $<2 \mathrm{~m}$, during May and June since 1979. One minute tows are made using a trawl with a 3.2 m headrope and $3.2 \mathrm{~mm}(0.13 \mathrm{in}$.$) mesh codend. Indices of$ abundance developed from this survey using data for shrimp, croaker, and spot have shown good correlation with landings for those species. For age-0 bluefish, the NC DMF juvenile fish trawl survey suggests that strong year classes recruited to the stock in 1981, 1987, and 1989, with the poorest year classes recruiting in 1984, 1986, and 1992.

A recently established survey has sampled the Neuse and Pamlico Rivers and Pamlico Sound at depths $>2 \mathrm{~m}$ since 1987. This survey uses a demersal trawl rigged with a 9.1 m headrope and $1.9 \mathrm{~cm}(0.75 \mathrm{in}$.$) mesh codend. An index of age-$ 0 bluefish abundance developed from these survey data suggests that the best year classes of bluefish recruited in 1990 and 1991 (Table D31, Figure D7).

Table D23. Total commercial landings and recreational catch mean weights at age (kilograms) for bluefish. Lengths converted to age using NC DMF commercial fishery annual age-length keys.

|  |  | Age |  |  |  |  |  |  |  |  |  |  |  |

## Summary of Recruitment Trends in Research Surveys

Indices of abundance for bluefish from research surveys were used to qualitatively detect recent trends in recruitment. Most surveys agreed that the best recent year classes recruited in 1984 and 1989, with relatively poor year classes in 1992 and 1993 (Figure D7).

## ASSESSMENT RESULTS

The Subcommittee was unable to reach a consensus on the status of the bluefish stock, but the SARC recognized that the data and analyses that were presented by the Subcommittee represented an interim step in the development of an age-structured assessment. However, the SARC also felt that it was necessary to review the data and analyses presented by the Subcommittee that addressed terms of reference A-C, and to make a statement concerning the status of the stock.

The SARC noted that total catches have declined from a peak of $76,500 \mathrm{mt}$ in 1980 to only $22,000 \mathrm{mt}$ in 1992. Most of the decline has been due to a general decrease in recreational catch. Commercial catches have remained stable (Figure D1). Recreational fishing effort has declined from the peak level in 1980, but has been stable during 1987-1992 (Figure D3). Recent indices of age-0 bluefish abundance from NEFSC, Rhode Island, Connecticut, Delaware, Virginia, and North Carolina research surveys indicated recruitment was strong in 1984 and 1989, and relatively poor in 1992 and 1993 (Figure D7). Indices of stock abundance available from fisheries data suggest a general decline from record high bluefish stock biomass levels since 1979 (Figure D2). Indices of abundance have declined at higher rates in more northern waters, implying that availability of bluefish in New England waters (Maine-Conn.) has declined relative to the Mid-Atlantic (N.Y.Vir.) and South Atlantic (N.C.-Fla.) regions (Figures D4-D5). Current levels of stock biomass are probably similar to levels that occurred prior to the increase of the stock in the 1970s. The SARC concluded the bluefish stock was at a medium level of historic abundance (1960-1993) and is probably fully exploited.

The declining trend in recreational catch combined with relatively low recruitment since 1989

Figure D7. Indices of recruitment (age 0) for bluefish from research trawl surveys.
will likely result in lower recreational catches in 1994. Commercial catches have been stable in recent years. The reasons for the differential trends in the fisheries are not well understood, but probably reflect changes in availability and targeting of local concentrations of bluefish. The SARC concluded that a reduction of the fishing mortality rate on bluefish could be used to reduce the rate of decline of stock abundance.

## SARC COMMENTS

The SARC debated at length the appropriateness of various assumptions and analytical techniques used in the bluefish assessment. Various definitions of directed recreational fishing effort for deriving CPUE measures were discussed. These included defining directed effort as only those trips catching bluefish, versus considering both trips catching fish as well as those that target bluefish but have zero catch. Development of an analytical assessment for bluefish is critically dependent on abundance-at-age indices from the recreational survey.

The natural mortality rate for bluefish has previously been assumed to be 0.35 , based on the scarcity of fish older than age 8 in available length-age data, and an assumed maximum age of 12 years. Current length-age data (i.e., the NC DMF age-length keys) indicate that significant numbers of fish at least 12 years old are present in the catch and it seems likely that bluefish reach ages older than 12 years. The SARC suggested that values of $M$ for bluefish in the range of 0.2 to 0.25 might be more appropriate.

The Subcommittee has not yet tabled an analytical assessment, since there is considerable debate as to the most appropriate assessment technique and assumptions such as natural mortality rate. The SARC expressed concern that the Subcommittee may not reach a consensus on these issues and that if a single analytical assessment cannot be agreed upon by the Subcommittee, that the SARC assume the role of arbiter. It was agreed that the SARC could, in theory, provide valuable external review when a Subcommittee could not reach a consensus. The Subcommittee members present concluded that

it was possible to reach consensus and table an analytical assessment for bluefish incorporating the useful comments by the SARC concerning data and assumptions. The SARC review is based on indices of abundance from commercial and recreational fisheries and research vessel surveys. In particular, the evaluation of the level of exploitation is tenuous and will be improved by more definitive results from analytical assessments. With SARC concurrence, the Subcommittee will continue the development of analytical assessments with a goal of tabling an agreedupon assessment in January 1994.

The SARC Pelagic/Coastal Subcommittee met on 5 January 1994 to review new assessment analyses of bluefish (completed after the SAW-17 SARC meeting in early December 1993) and to reach a consensus on best estimates of stock size and fishing mortality rates. The Subcommittee reviewed results from three different assessment models (ADAPT VPA. Delury, and CAGEAN), evaluated fishery and research survey selectivity patterns, examined alternative yield per recruit analyses, and discussed the adequacy and appropriateness of various indices of stock abundance and fishing effort. Although a number of issues were resolved during the meeting, the Subcommittee was unable to agree upon a definitive assessment, and hence unable to provide consensus of best estimates of stock abundance and fishing mortality.

The Subcommittee believes that both the DeLury and CAGEAN models offer promise in developing a definitive, quantitative assessment of bluefish. However, further Subcommittee analyses examining the assumptions and input sensitivity of these models are required before accepting any of the results. The Subcommittee envisages that these analyses can be completed by mid-February 1994.

## RESEARCH RECOMMENDATIONS

- The intensity of biological sampling of the NER commercial and coastwide recreational fisheries (expressed as mt/ 100 lengths) has historically been low, and has worsened since 1989 for the NER commercial fishery. The SARC recommends increased biological sam-
pling of the NER commercial and recreational fisheries, and the collection of age samples from the recreational fishery.
- There are some inconsistent patterns in mean weights at age across years (e.g., during 19901992, ages 0-2). Some of these patterns may be due to changing contributions of different gears, which exploit certain age groups of fish at different times of the year, or due to inadequate sampling. The SARC suggests using sums-of-product checks, examination of sample mean length/weight at age data, or other appropriate analytical methods to investigate potential errors. Presentation of catch at age, mean length at age, and mean weight at age matrices for each of the four NC commercial fisheries (summer pound net, summer haul seine, winter gill net, and winter trawl) may help clarify why these inconsistencies are present. Mean length at age matrices for the NER commercial and recreational fisheries should also be presented in the assessment.
- A great deal of discussion was undertaken regarding the appropriate measure of effort for the recreational fishery. The SARC decided that the Subcommittee could enhance the present method of calculating recreational effort by examining alternate definitions of recreational fishing effort. The Subcommittee should readdress effective effort in the future to better reflect the question of targeting. The Subcommittee should present measures of CPUE under different assumptions of effective effort to allow evaluation of the sensitivity of results.
- The question of the units of effort expended in the recreational CPUE was also raised, i.e. whether catch per trip is a realistic measure when trips may be of variable duration. The SARC recommends that the Subcommittee assess these topics and explore the potential effect of these parameters.
- Concerns were raised by the committee over the adequacy of data to provide meaningful catch at age models. The SARC suggested that perhaps other models could provide a better analysis given the variability and reliability of the underlying data. The SARC recommends that the Subcommittee examine the current age-structured approach to see if it is appropriate given the low level of biological sampling of the NER commercial
and coastwide recreational fisheries. It may be beneficial to explore other methods such as length-based and modified DeLury models in determining the best alternative.
- Many difficulties evident in this assessment reflect the unavailability of a version of the ADAPT VPA that can be used by a wider spectrum of assessment scientists. The SARC supports development of a user-friendly version of the ADAPT VPA software and a tutorial on using the method.

## E. ATLANTIC BUTTERFISH

## TERMS OF REFERENCE

The following terms of reference were ad dressed:
a. Compute revised research vessel survey indices and evaluate the stock with respect to survey-based management reference points
b. Develop CPUE series based on GLM models incorporating area, vessel, and percent directed fishing
c. Assess the role of discards in the fishery
d. Review MSY

## INTRODUCTION

Atlantic butterfish (Peprilus triacanthus) range from Newfoundland to Florida and are found in commercially-exploitable concentrations between Cape Hatteras and Southern New England. For management purposes, the butterfish population in waters north of Cape Hatteras is assumed to constitute a unit stock. This stock migrates inshore and northward during the summer and offshore and southward during the winter in response to seasonal changes in water temperature on the shelf.

## DESCRIPTION OF THE FISHERY

Atlantic butterfish have been landed by domestic fishermen since the 1800 s, and from 1920 to 1962 the annual domestic harvest has averaged $3,500 \mathrm{mt}$ per year. Foreign landings began in the mid-1960s and averaged $8,000 \mathrm{mt}$ during 1965-1976 (Table E1). Total annual landings peaked in 1973 at 19,500 mt but since 1977 have ranged between $2,000 \mathrm{mt}$ and $12,400 \mathrm{mt}$. From 1977 to 1987 (when foreign fishing was being phased out), annual landings of butterfish averaged $6,100 \mathrm{mt}$. Since 1988 , annual landings (solely U.S.) have averaged $2,500 \mathrm{mt}$ per year.

In 1992, butterfish landings totaled $2,700 \mathrm{mt}$ in 1992, 25\% higher than in 1991, but still among the lowest domestic harvests since 1978. Nearly half ( $45 \%$ ) of the 1992 landings was taken

${ }^{1}$ Predicted
from Southern New England waters (Statistical Area 53, Figure 2, page 6), and landings from Southern New England and the New York Bight (Area 61) accounted for over 75\% of the 1992 total (Table E2). Temporally, $48 \%$ of the 1992 harvest was taken in January and February. Landings patterns in 1992 were similar to those in recent years.

Based on provisional January-October 1993 landings data, total butterfish landings in 1993 are projected to be $2,700 \mathrm{mt}$.

Butterfish are managed by the Mid-Atlantic Fishery Management Council under provisions of the Atlantic Mackerel, Squid, and Butterfish Fishery Management Plan. In 1992, the maximum optimum yield and the allowable biological catch for butterfish were each set at $16,000 \mathrm{mt}$, and the domestic allowable harvest was set at $10,000 \mathrm{mt}$ (MAFMC 1991). Identical specifications pertain in 1993 and 1994 (MAFMC 1992).

## DATA SOURCES

Commercial U.S. landings data from 1989 through 1992 were taken from the NEMFIS data base and general canvass sources. Landings data for 1965 to 1988 were provided in the Report of the 10th SAW (NEFSC 1990). Effort data used in the analysis of domestic LPUE from 1982-1992 were extracted from the NEMFIS data base. Domestic observer data used to quantify discarding of butterfish were taken from the NEFSC Domestic Sea Sampling Program data base.

A multiplicative GLM model (Gavaris 1980) was used to standardize fishing effort (in terms of days absent) during 1982-1992 in the U.S. otter trawl fishery for butterfish (Brodziak 1993). A main effects model was used with year, area, and tonnage class as factors ( $\mathrm{R}^{2}=0.34$ ) (Table E3). Month was initially included as a factor but contributed little to the Type III sum of squares, and was thus subsequently excluded to avoid overparameterization of the model (Searle 1987).

As in previous assessments (NEFSC 1990). indices of relative abundance of butterfish were derived from NEFSC spring and autumn bottom trawl surveys conducted from Cape Hatteras to Georges Bank [offshore strata 1-14, 16, 19-20, 23, 25, and 61-76; inshore strata 1-46] (Grosslein 1969; Azarovitz 1981).

## ASSESSMENT RESULTS

## Abundance and Mortality

Standardized fishing effort (in terms of days absent) increased in 1992 while standardized LPUE slightly declined (Table E3, Figure E1). The LPUE and standardized abundance indices were highest during 1982-1984. The lowest values in both series have occurred in recent years (i.e.,

Figure El. Comparison of butterfish recruit abundance per survey tow and standardized LPUE from 1982-1992.
from 1988 onward). Effort has fluctuated without trend since 1984.

NEFSC research survey indices indicate that butterfish stock abundance was low during the late 1960s-early 1970s but high during 19791985 and 1988-1990 (Tables E4 and E5; Figure E2). The most recent indices (spring 1992-1993; autumn 1991-1992) indicate a decline in abundance and biomass from 1990; the autumn 1992 weight-per-tow index and the age $1+$ number-per-tow index were among the lowest values in the survey time series (Table E5). The spring 1993 weight-per-tow index was also among the lowest ever observed (Table E4).

In contrast to the total stock indices, survey pre-recruit (age 0) indices have remained high in recent years (Table E5). Prerecruit indices in autumn 1988-1990 were among the highest on record, and the 1991 and 1992 prerecruit values were average and $40 \%$ above-average, respec-

Figure E2. Abundance and weight per tow of butterfish from the NEFSC Fall bottom trawl survey.
tively. Thus, despite declines in the adult (age 1+) stock, butterfish recruitment has continued to be good.

Estimates of total instantaneous mortality (Z) for butterfish (Table E6) were calculated from NEFSC autumn survey number per tow at age indices (Table E5) by:

$$
\begin{equation*}
Z=\ln \left(\frac{N_{\text {age-1 }}(t-1)}{N_{\text {age }}(t)}\right) \tag{1}
\end{equation*}
$$

Total mortality rates for all age groups appear to have increased in recent years. Values of $Z$ during 1989-1992 for age 0 fish are the highest on record, and the 1989-1991 values for age 1 butterfish are among the highest. Age 2 fish have displayed very high $Z$ 's from 1986 onward.

## Discard Rates

Domestic observer data collected by the NEFSC Sea Sampling Program were used to quantify discarding of butterfish caught with bottom otter trawl gear during 1989 to 1992. Monthly observations on butterfish discards from
a total of 159 tows were pooled across trips and years (Table E7). Monthly discard ratios (percentage of total catch discarded) range from 69\% to $100 \%$ (Table E8). However, the quantities of butterfish kept in all months is very low, suggesting that the available sea sampling data are not representative of the directed fishery for butterfish (where much larger quantities kept would be expected). Further evaluation of the precision and design of the sea sampling program in adequately characterizing butterfish discards (by fishery) is needed, before attempting to estimate the absolute magnitude of discards. A previous report on butterfish (Waring 1986) noted that "very high discard rates ( 30 to $100 \%$ ) were observed by NMFS port agents during mid-19831985".

## Biological Reference Points

Overfishing for butterfish is defined to occur when the three-year moving average of prerecruits from the NEFSC autumn bottom trawl survey is below the first quartile of this series. For the purpose of applying the definition in 1992, 1993, and 1994, the lowest quartile consists of the seven lowest age 0 indices (Table E5); the threeyear moving average of the prerecruit series must be less than the largest index in this quartile for overfishing to occur. Given the 1992 autumn age 0 index of 230.3 (Table E5), the three-year moving prerecruit average in 1992 was 242.3 . If the 1993 and 1994 prerecruit indices are both 0 , the corresponding three-year moving averages would be 132.9 and 76.8 , respectively. The largest prerecruit index in the lower quartile of values during 1992, 1993, and 1994 would correspond to $78.59,73.20$, and 47.73 . Thus, according to the overfishing definition, butterfish were not overfished in 1992, and will not be overfished in 1993 and 1994.

No new information was available that could be used as a basis for changing the current MSY.

Murawksi and Waring (1979) estimated that $\mathrm{F}_{0.1}$ for Atlantic butterfish was $0.47,0.69,0.96$, and 1.38 for mesh sizes of $30,60,80$, and 100 mm , respectively, provided that instantaneous natural mortality was $0.8 \mathrm{yr}^{-1}$. Corresponding estimates of $\mathrm{F}_{\text {max }}$ were $0.71,1.33$, and greater than 2.50 for mesh sizes of 30,60 , and 80 or 100 mm , respectively. A high natural mortality rate, such as 0.8 , has a large influence on the magnitudes of reference points such as $F_{0.1}$ and $F_{\max }$. This reduces the proportional impact of fisheryrelated mortality (i.e., landings and discards) on

the magnitudes of the reference points. Waring and Anderson (1983) estimated $\mathrm{F}_{0.1}$ for butterfish at 1.60 . This value is based on data that was collected over a decade ago; thus, an updated estimate of $\mathrm{F}_{0.1}$ based on current exploitation patterns is needed.

## DISCUSSION

Since 1987, butterfish landings have averaged $2,500 \mathrm{mt}$ per year - only $25 \%$ of the Domestic

Allowable Harvest of $10,000 \mathrm{mt}$ - and well below historical yields (Table E1). Japanese demand for butterfish exports has decreased in recent years (MAFMC 1992), and this has probably had a negative impact on butterfish landings. Since 1987, commercial LPUE has remained low while standardized fishing effort has remained relatively stable (Table E3). Butterfish abundance, based on both NEFSC age $1+$ survey indices and commercial LPUE indices, was lower in 19911992 than during the $1982-1987$ period (Figure E2).

Research survey indices (Table E5) suggest that butterfish survival to age 2 has declined since 1990. Estimates of total mortality derived from these indices suggest that age 0 butterfish mortality rates have increased since 1989, and that age 2 mortality has been high since 1987 (Table E6). Despite the recent decline in the
adult stock (Table E5), the abundance of prerecruits has remained above average since 1987.

While survey data indicate that abundance of butterfish prerecruits has remained high, estimates of survival among older ages has decreased. This may reflect one or more of the following: an increase in the rate of natural mortality in recent years, an increase in discard mortality, a reduction in availability of older individuals relative to younger individuals. Given this uncertainty, estimates of $Z$ as well as $F$ from the survey data are unreliable.

Overall, it appears that the butterfish stock is at a low to medium biomass level. While exploitation rates could not be determined, butterfish are underexploited relative to management targets. An increase in landings seems unlikely unless market demand improves.

Table E6. Estimates of age-specific instantaneous total mortality rates ( $Z$ ) for Atlantic butterfish (Peprilus triacanthus) derived from the NEFSC autumn bottom trawl surveys, 1968 - 1992

## RESEARCH RECOMMENDATIONS

- Given that butterfish is a short-lived species, new approaches to the assessment and management of the stock may be required. A more adaptive, real-time assessment/management system will be needed to attain full exploitation of the stock while, at the same time, ensuring that adequate levels of spawning stock are achieved. Examples of the types of assessment and management procedures that have proved successful for short-lived species are provided in the 1993 report of the ICES Working Group on Methods of Fish Stock Assessment (ICES 1993).
- Data need to be collected to make reliable estimates of discards, particularly discards associated with the directed fishery. The design and/or implementation of the Sea Sampling program needs to be improved so that data are collected from all components of the fishing fleet. Data currently available from the NEFSC sea sampling program are not adequate because most of data appear to come from trips in which butterfish was not the target species.
- The exploitation pattern and levels of discarding need to be estimated to allow revised computation of exploitation rates and biological reference points such as $\mathrm{F}_{0.1}$ and $\mathrm{F}_{\max }$.

## F. LONG-FINNED SOUID

## TERMS OF REFERENCE

Terms of reference for Loligo pealeiwere finalized by the SAW Steering Committee in September 1993 [see Report of the 16th Northeast Regional Stock Assessment Workshop (16th SAW), The Plenary, NEFSC Ref. Doc. 93-19: p. 52-54]. The assessments of Loligo was designated by the Steering Group as ' 1 st priority' - indicating that all terms of reference should be met. The following terms of reference, provided by the SAW Steering Committee, were addressed:
a. Provide updated calculation of yield and spawning stock biomass per recruit and other standard biological reference points.
b. Provide updated minimum biomass and recruitment estimates based on areal expansion of research vessel survey data.
c. Continue development of DeLury population estimators based on research vessel survey and commercial CPUE and length composition data.
d. Recalculate CPUE series based on general linear models, by vessel size class, area, and season. Investigate the predictability of fishery success from research vessel surveys.
e. Review MSY.

## INTRODUCTION

Long-finned squid (Loligo pealei) ${ }^{1}$ are distributed in shelf and slope waters extending from Newfoundland, Canada (Dawe et al. 1990) to the Gulf of Venezuela (Summers 1983). Previous assessments assumed a lifespan of at most three years (USDOC 1988) based upon analyses of length frequency data (Verrill 1882; Mesnil 1977; Lange and Sissenwine 1980). However, inferences about the age and growth of squids based on length frequency analyses must be regarded with caution unless they are accompanied by supplementary age data (Caddy 1991) because (i) squid growth rates exhibit high variability and can vary with season, food availability, temperature, and population density; (ii) squid populations can be composed of several broods or
microcohorts that have different growth and survival rates; (iii) if separate microcohorts enter the sampled population at successive times, modal analysis of length frequency data sampled from a mixture of microcohorts will not represent the true growth rate. Research on the age and growth of several species of squid based on counts of daily statolith growth increments (e.g., Lipinski 1978; Spratt 1979; Dawe et al. 1985; Lipinski 1986; Yang et al. 1986; Jackson 1990; Rodhouse and Hatfield 1990; Jerebet al. 1991; Jackson and Choat 1992; Jackson et al. 1993) indicates that statolith aging is useful technique. Statolith aging of Loligo pealei indicates that this species has a lifespan of less than 1 year (Macy 1992; Macy MS, Figure F1) and that spawning occurs during the winter (Figure F2). As a result, the previous hypothesis that Loligo have a cross-over life cycle (Mesnil 1977) with spawning peaks in the spring and fall and protracted spawning during the summer has been replaced with the working hypothesis thatLoligo are an annual, semelparous species that has the capacity to spawn throughout the year.

At present, collaborative research between the NEFSC and the University of Rhode Island is being conducted to examine seasonal and spatial patterns of growth and to further validate the one day-one ring hypothesis of statolith increment formation in Loligo pealei. Loligo are assumed to constitute a unit stock throughout their range of commercial exploitation in the Northwest Atlantic, and the stock unit consists of all Loligo within U.S. jurisdiction outside the Gulf of Mexico and the Caribbean Sea (MAFMC 1990).

## DESCRIPTION OF THE FISHERY

The domestic fishery for Loligo off the Northeastern United States began in the late 1800s with squid being primarily used as bait. From 1928 to 1967, annual squid landings from Maine to North Carolina (including Illex illecebrosus landings) averaged roughly $2,000 \mathrm{mt}$. A directed foreign fishery for Loligo developed in 1967 and exploited Loligo throughout the 1970s and early 1980s (Table F1). Total annual landings averaged $20,400 \mathrm{mt}$ from 1967-1986 with a peak of $37,600 \mathrm{mt}$ in 1973. In 1987, foreign fishing effort ceased, and annual domestic landings have aver-

Figure F2. Hatching dates of Loligo pealei from Macy (MS).
aged 17,800 mt during 1987-1992.
In 1992, Loligo landings (5,708 fishing trips) totaled $18,172 \mathrm{mt}$ with an exvessel value of $\$ 23,342,000$ and an average price of $\$ 1.28$ per kg ( $\$ 0.58$ per lb). Nearly half of the 1992 harvest ( $8,112 \mathrm{mt}$; $45 \%$ ) was taken from one statistical area (SA 616); six statistical areas (SA 616, 537, $613,622,612$, and 526) accounted for $87 \%$ of the total landings (Table F2). Temporally, $81 \%$ of the 1992 landings occurred in winter and autumn (Jan-Apr; Oct-Dec).

Nearly all landings (99\%) were made with bottom otter trawl gear (Table F3). The smallvessel ( 5 to 50 GRT) fishery - prosecuted in inshore areas between May-July - accounted for $1 \%$ ( 150 mt ) of the 1992 otter trawl landings, while the large-vessel ( 51 to 900 GRT) fishery occurring primarily in offshore waters during November-April - accounted for $99 \%(15,590 \mathrm{mt})$ (Table F4; Figure F3). Historically (1982-1992), the inshore fishery has accounted for as much as $35 \%$ of the U.S. catch (e.g., in 1983); since 1985, however, the inshore fishery has accounted for a very much smaller proportion ( $1-8 \%$ ) of the annual landings (Table F4).

Based on provisional January-October 1993 landings data, total Loligo landings in 1993 are projected to be about $22,900 \mathrm{mt}, 26 \%$ higher than in 1992 (Table F1).

Loligo are managed by the Mid-Atlantic Fishery Management Council under provisions of the Atlantic Mackerel, Squid, and Butterfish Fishery Management Plan. In 1992, the maximum optimum yield was $44,000 \mathrm{mt}$, the allowable biological catch was $37,000 \mathrm{mt}$ and the domestic allowable harvest was $34,000 \mathrm{mt}$ (MAFMC 1991).

For 1993 and 1994, the allowable biological catch and domestic allowable harvests have been increased to 44,000 mt (MAFMC 1992).

## DATA SOURCES

Commercial landings data for 1992 were derived from the NEMFIS data base and general canvas sources. Landings data for 1989 to 1991 were reported at the 12 th and 14 th SAWs (NEFSC 1991, 1992), while landings data for 1963-1988 were given in the Report of the 10th SAW (NEFSC 1990). Effort data used in the analysis of domestic LPUE from 1982 to 1992 were derived from the NEMFIS data base.

Numbers of Loligo landed by the commercial fishery during 1982-1992 (Table F5) were estimated using NEFSC commercial size frequency sampling data.

Multiplicative GLM main effects models (Gavaris 1980) was used to standardize fishing effort (days fished) and landings per unit of effort (LPUE) in both the small-vessel and largevessel fisheries for Loligo during 1982 to 1992 (Brodziak MS 1993). In the small-vessel analysis, year and area were used as factors to standardize fishing effort ( $\mathrm{R}^{2}=.45$ ) (Table F6; Figure F4). In the large-vessel analysis, fishing effort was standardized using year, tonnage class, quarter, and area as factors ( $\mathrm{R}^{2}=.24$ ) (Table F7; Figure F5). In both analyses, standardized LPUE (ratio of fleet landings to standardized effort) and a standardized abundance index (ratio of annual LPUE to LPUE in 1982) were calculated.

Research survey indices of relative abundance of Loligo offshore (depth $>27 \mathrm{~m}$ ) were derived from NEFSC spring (1967-1993) and autumn (1967-1992) bottom trawl surveys con-
ducted from Cape Hatteras to Georges Bank [offshore strata 1-23, 25, and 61-761 (Grosslein 1969; Azarovitz 1981). In previous Loligo assessments, NEFSC survey catches were adjusted to a standard tow duration of 30 minutes. However, results from a regression analysis of Loligo catch (kilograms) per tow on tow duration indicated that tow duration has no significant effect on Loligo catches (Table F8). As a result, both spring and autumn NEFSC bottom trawl survey time series were recomputed without the tow standardization option (Tables F9 and F10).

Indices of relative abundance of Loligo inshore were computed from Commonwealth of Massachusetts spring inshore bottom trawl surveys conducted during 1982 to 1993 (Table F11).

## ASSESSMENT RESULTS

## Relative Abundance

Standardized fishing effort and LPUE for the small-vessel fishery declined sharply in 1992 (Table F6), while effort and LPUE slightly increased in the large-vessel fishery (Table F7). In the small-vessel fleet, LPUE and standardized fishing effort have declined markedly since 1988. Small-vessel LPUE in 1992 was a record-low, while small-vessel effort in 1992 was the secondlowest in the 1l-year time series (Table F6; Figure F4). In the large-vessel fleet, LPUE and standardized fishing effort have markedly increased since the early 1980s; in 1992, largevessel LPUE and fishing effort were the secondhighest on record (Table F7; Figure F5).

Spring and autumn NEFSC survey indices of Loligo abundance in 1992 were somewhat dis-

Figure F3. Annual landings in the small-vessel inshore and large-vessel fisheries for Loligo pealei.
parate (Tables F9 and F10). The 1992 spring number-per-tow index was slightly above average, but $50 \%$ less than the high 1991 index. Similarly, the spring 1992 weight-per-tow index was equal to the average, but $40 \%$ lower than the 1991 value. Based on these results, Loligo abundance during the 1992 spring/summer inshore fishery was expected to be average - and well below that in 1991.

In contrast, the NEFSC autumn 1992 num-ber-per-tow index was the largest in the survey time series (about 2.5 times higher than the longterm average) due to a record-high level of prerecruits (Table F10). However, the autumn 1992 weight-per-tow index was $35 \%$ below the mean and less than half of the 1991 index. The record-high prerecruit index (Table F10) suggested that a large cohort would be recruiting to the offshore fishery during Winter of 1993. This cohort was also expected to generate elevated catch-per-tow indices in the 1993 NEFSC spring survey, if landings during the winter fishery were not substantial.

However, Loligo catch-per-tow indices in the spring 1993 survey were sharply lower than in 1992 and well below the long-term means (Table F9). These results suggested that Loligo abundance during the 1993 spring/summer inshore fishery would be no higher - and perhaps much lower - than in 1992.

The 1992 and 1993 Massachusetts inshore spring survey catch-per-tow indices were the lowest ever recorded (Table F11). Although the 1993 indices were higher than in 1992, these still suggested that inshore abundance of Loligo in

southern New England during 1993 would be well below average.

## Absolute Abundance

Minimum estimates of absolute biomass and numbers (total and pre-recruits) of Loligo on the Northeast U.S. continental shelf from Cape Hatteras to the Gulf of Maine were calculated by areal expansion of NEFSC autumn bottom trawl indices obtained during 1982 to 1992 (Table F12). These estimates (Table F13) were based upon areal expansion of Loligo catches in offshore survey strata 1-30, 33-40, and 61-76 (Cape Hatteras to Gulf of Maine) and inshore survey strata 1-55 (Cape Hatteras to Cape Cod). These estimates require three assumptions: (i) catchability of Loligo is constant in space and time; (ii) catchability is equal for all sizes of Loligo; (iii) all Loligo within the area swept by the survey gear are captured. Thus, these estimates are likely to be biased low because these assumptions are unlikely to hold.

Loligo have a tendency to disperse vertically upward in the water column at night (Summers 1968, 1969). This behavior reduces availability to bottom trawl gear and will cause the areaswept estimates of population size derived from the NEFSC research vessel surveys to be underestimates - since survey tows are made round-the-clock during both day and night. Analysis of autumn 1967-1991 survey catches of Loligo taken in tows during day, dawn-dusk, and at night suggest that diurnally-adjusted, area-swept es-

timates may be $50-85 \%$ higher than the nonadjusted estimates provided in Table F13. However, more work is needed to thoroughly evaluate day-night differences, including possible sizerelated differences in diumal catchability between prerecruit and recruit animals. More work is needed to evalute the effects of this behavior upon relative abundance indices.

Provisional estimates of annual surplus production of Loligo during 1982-1992 indicate similar trends in biomass as those from the areaswept method. Estimates of virgin biomass and MSY from the surplus production model were relatively sensitive to the assumed values of catchability ( $q$ ) and stock resilience (A). Further work in examining the assumptions and application of the model for Loligo is warranted.

## OVERFISHING DEFINITION

Overfishing for Loligo is defined to occur when the three-year moving average of prerecruits from the NEFSC autumn bottom trawl survey is below the first quartile of this series. For the purpose of applying the overfishing definition in 1992, 1993, and 1994, the lowest quartile of values consists of the seven lowest prerecruit indices (Table F10); the three-year moving average of the prerecruit series must be less than the largest index in this quartile for overfishing to occur (Table F14). Given the record-high 1992 autumn prerecruit index (755.8), the three-year moving prerecruit average in 1992 was 412.4. If the 1993 and 1994 prerecruit indices are both 0 , the corresponding three-year moving averages

Table F10. Stratified mean catch per tow in numbers and weight (kiolgrams) of Loligo pealei in NEFSC autumn bottom trawl surveys, Cape Hatteras to Georges Bank (Strata 1-23, 25, and 61-76), 1967-1992. Mean number per tow indices are presented for all sizes of Loligo, for prerecruits ( $\leq 8 \mathrm{~cm}$ ), and for recruits ( $>8 \mathrm{~cm}$ ).

would be 316.8 and 251.9 , respectively. The largest prerecruit index in the lower quartile of values during 1992, 1993, and 1994 would correspond to $160.1,141.7$, and 123.4. Thus, according to the overfishing definition, Loligo were not overfished in 1992, and will not be overfished in 1993 and 1994. The provisional 1993 prerecruit index of 124.3 indicates that the minimum threeyear moving average in 1995 would be 41.4, provided that 1994 and 1995 pre-recruit indices were 0 . If this were the case, the largest index in the lowest quartile would be 123.4. Therefore it is
possible that Loligo could be overfished in 1995 given the low provisional index in 1993.

## YIELD AND SPAWNING STOCK BIOMASS PER RECRUIT

A yield per recruit analysis was performed for Loligo using recently developed information on the age and growth of Loligo using daily statolith growth increments (Macy 1992; Macy MS). These findings indicate that Loligo is an annual species

Table Fll. Stratified mean catch per tow in numbers and weight ( kg ) of Loligo pealei in Commonwealth of Massachusetts spring inshore bottom trawl surveys, south of Provincetown, Massachusetts, 1982 1993. The mean weight (grams) per squid caught is also given.

that grows rapidly - and is not as long-lived as previously thought (Verrill 1882; Mesnil 1977; Lange and Sissenwine 1980).

Input data for a Thompson-Bell yield per recruit analysis (Ricker 1975), using a monthly time step, were derived from a sample of 87 Loligo collected during spring and winter of 1991. Animals ranged in size from 2 cm to 44 cm in dorsal-
mantle length, and from 3.6 to 9.7 months in age (Macy, pers. comm.). Instantaneous natural mortality for Loligo was estimated to be $\mathrm{M}=4.1$ (Hoenig 1983), and knife-edged recruitment was assumed to occur at an age of 3 months ( 9 cm dorsal-mantle length).

For the spawning stock biomass per recruit analysis (Gabriel et al. 1989), sexual maturity was assumed to be knife-edged and to occur at an age of 7 months (approximately 20 cm dorsalmantle length), based on the observations of Mesnil (1977, Figure 2, 20-month cycle) on Georges Bank and the observations of Macy (1980) within Rhode Island waters during April to June. Recruits were assumed to be fully susceptible to natural and fishing mortality prior to spawning.

Results of the monthly yield and spawning stock biomass per recruit calculations (Table F.15; Figure F6) indicate that in units of month ${ }^{1}, \mathrm{~F}_{0.1}=0.16$ and $\mathrm{F}_{\text {max }}=0.26$ (in units of year ${ }^{-1}$, $F_{0.1}=1.92$ and $F_{\max }=3.12$ ). These estimates of monthly fishing mortality reference points are $47 \%$ and $76 \%$, respectively, of monthly natural mortality $\left(\mathrm{M}_{\mathrm{m}}=0.34\right)$, and suggest that fishing mortality should be kept below natural mortality for this stock.

Estimates of the total potential yield from a Fall-spawned Loligo cohort were calculated based upon the average cohort size during 1982 to 1992. Although a definitive estimate (in absolute numbers) of the size of an average cohort is not available, a provisional diurnally-adjusted value of 2.20 billion recruits was calculated using

Table F12. Stratified mean catch per tow in numbers and weight ( kg ) of Loligo pealei in NEFSC autumn bottom trawl surveys, Cape Hatteras to the Gulf of Maine (offshore strata 1-30, 33-40 and 61-76; inshore strata 1-55), 1982-1992. Mean number per tow indices are presented for all sizes of Loligo, for prerecruits ( $\leq 8 \mathrm{~cm}$ ), and for recruits ( $>8 \mathrm{~cm}$ ).

|  |  |  |  |

NEFSC autumn survey data. At $\mathrm{F}_{\mathrm{max}}$, the potential yield (MSY) from such a cohort would be $35,900 \mathrm{mt}$ (Table F16). Based on the $95 \%$ confidence interval associated with the mean cohort size of 2.2 billion squid ( 1.38 billion, lower $95 \%$ limit; 3.02 billion, upper $95 \%$ limit), the potential yield from an average cohort ranges from 22,500 to $49,200 \mathrm{mt}$ (Table F16).

Sensitivity analyses evaluating the impact on MSY of misestimation of M (from the assumed value of $\mathrm{M}_{\mathrm{m}}=0.34$ ) indicate that a $20 \%$ increase in $\mathrm{M}_{\mathrm{m}}$ would lower MSY by $30 \%$, while a $20 \%$ reduction in $M_{m}$ would increase MSY by $56 \%$ (Table F16).

## STOCK AND RECRUITMENT

Cross-correlations were computed between NEFSC spring and autumn survey indices (prerecruit and recruit number-per-tow indices) to examine possible lagged associations (Table F17). The pre-recruit and recruit series were used as approximate measures of juvenile and adult abundance. Significant positive crosscorrelations were found between: (1) the spring and autumn recruit indices with no lag; (2) the spring recruit indices lagged by one year and the autumn prerecruit indices; (3) the spring recruit and spring prerecruit indices with no lag; and (4)

the spring pre-recruit indices lagged by one year and the autumn prerecruit indices. Overall, the cross-correlation analyses suggest that the spring and autumn indices contain useful information about linkages between spawning stock and juvenile abundance in Loligo. The biological basis for these relationships, however, needs to be explored.

## PREDICTION OF FISHERY SUCCESS

Potential associations between research survey indices and fishery success were examined by correlation analysis of NEFSC spring and autumn pre-recruit and recruit indices and Massachusetts spring survey indices with small-

vessel and large-vessel LPUE values during 1982 to 1992. No significant correlations were found between any of the research survey indices and small-vessel LPUE. In contrast, large-vessel LPUE was significantly positively correlated with spring prerecruit and recruit indices.

A number of potential predictors of fishery success were explored using linear regression, and some were provisionally found to be statistically significant. These analyses should continue and give proper consideration for lag effects between the timing of the surveys and the seasonality of the fisheries.

## DISCUSSION

In 1992, several indices of relative abundance (small-vessel LPUE, and NEFSC and Commonwealth of Massachusetts spring survey indices) indicated that Loligo abundance was below average (Tables F6, F9, and F11). The LPUE in the small-vessel, inshore fishery in 1992 was a record-low (Table F6), and effort markedly dropped ~ presumably in response to poor landings success. In contrast, LPUE in the large-vessel fishery remained high in 1992, and large-vessel effort increased to near-record levels (Table F7).

The autumn 1992 pre-recruit index was the largest on record (Table F10) and suggests that a large cohort would be available to the offshore fishery in Winter 1993. Provisional Loligo landings during the first four months of 1993 were $13,300 \mathrm{mt}, 67 \%$ above the corresponding period in 1992, and projected total landings in 1993 are expected to be $25,400 \mathrm{mt}$, a record-high domestic catch. The high landings during the first quarter of 1993, combined with the record-high autumn 1992 pre-recruit index, are indicative of the rapid growth and recruitment of Loligo to the offshore fishery. However, the 1993 NEFSC spring survey indices did not reflect a high abundance of Loligo; in fact, the spring 1993 indices were among the lowest in the past decade. While the low spring indices might be due to the impact of the large Winter 1993 fishery, other factors affecting the relationship between autumn and spring survey abundance indices must be explored further (particularly since the correlation between autumn prerecruit indices and the subsequent spring recruit indices was not found to be significant).

New yield per recruit calculations based on an annual life cycle for Loligo indicate that, for an estimated Fall cohort of average size ( 2.2 billion animals), a maximum yield of $36,000 \mathrm{mt}$ in yield
could be realized. However, there are many uncertainties with the input parameters used in the yield per recruit and spawning stock biomass analyses - and these need to be resolved as quickly as possible as the current MSY level of $44,000 \mathrm{mt}$ (based on a 2-year life span) now appears to be too high. The YPR and SSB/R analyses do not account for discard mortality, density-dependent mortality due to cannibalism, seasonal fluctuations in growth, or potential fluctuations in natural mortality due to variability in predation pressure or environmental factors. As such, the $36,000 \mathrm{mt}$ should not be viewed as an annual harvest target - but more of an initial, rough upper bound on the sustainable yield from a cohort. In years of lowLoligo biomass, however, this level of landings would likely result in severe reductions in SSB.

During 1973-1976 when fishing for Loligo was unrestricted, total annual landings averaged about $33,000 \mathrm{mt}$ (with a peak catch of $38,000 \mathrm{mt}$ in 1973). During this period, both spring and autumn NEFSC survey indices were among the highest on record. However, since 1976, annual landings have been much lower - suggesting that yields above $30,000 \mathrm{mt}$ may only be attainable during years of very high abundance.

Given that Loligo is now considered to be an annual semelparous species, the potential for recruitment overfishing may be substantial since only a single cohort exist at any one time and animals recruit to the fishery and the spawning stock within the same year. Failure to ensure an adequate annual level of spawning escapement can jeopardize both the stock and the fishery.

There are clear advantages to operating a real time management procedure for stocks of species that have a short (annual) life cycle. Such systems have been successfully implemented in a number of fisheries around the world (see ICES 1993). However, it is important that managers be aware that both the scientific and administrative requirements for real time management may be substantially different from those used for resources which are managed under more traditional systems.

The components of a real time management system are;

1) An assessment of data from previous years to determine the management target for the coming year. This target should be in terms of fishing mortality rate and fishing effort. If prerecruit surveys are available then the target fishing mortality rate and the projected biomass can be used to make an initial estimate of the coming seasons catch.
2) A monitoring program that obtains fishery information, e.g. catches and effort, on a fine time and spatial scale.
3) An interim assessment(s) procedure using the fishery information to date and additional survey data as it becomes available. The interim assessments are used to monitor the progress of the resource through the season and to adjust the regulations to account for new information on the incoming stock. For example, if an interim assessment indicated that recruitment had been particularly poor in a given year, the fishery may be closed early to protect spawners. Alternatively, if a very large year class was available, additional catch or a longer season might lift unnecessary constraints on the industry.
4) An agreed procedure for expanding or reducing the amount of catch or effort allowed in a given season. The rules for expanding or contracting the fishery should be agreed beforehand, so that arguments over particular actions are minimized at the time when that action is needed. The procedure should only be changed between seasons, not during the season.

These elements will require a substantial amount of development by managers and scientists. A Plan Development Team could serve as a useful vehicle for the development of such a real time system for squid and other short-lived stocks.

## SOURCES OF UNCERTAINTY

Estimation of absolute biomass from areaswept and diurnally-adjusted area-swept methods are likely to be sensitive to the assumption that catchability of prerecruit and recruits is $100 \%$ during daylight hours, and to any differences in vertical migration patterns between prerecruits and recruits.

The provisional recalculation of MSY based on maximum yield per recruit and average recruitment does not account for discard mortality, density-dependent mortality due to cannibalism, seasonal fluctuations in growth, or potential fluctuations in natural mortality due to variability in predation pressure or environmental factors.

Discarding of Loligo may be an important source of fishing-induced mortality. However, data currently available from the NEFSC sea
sampling program are inadequate to evaluate this. No sea sampling trips have been conducted on freezer-trawler vessels fishing for Loligo.

Many of the analyses which are predicated on a life span for Loligo of one year must be considered provisional as age and growth studies are still in progress.

## RESEARCH RECOMMENDATIONS

- Collaborative research between the NEFSC and the University of Rhode Island that is being conducted to examine seasonal and spatial patterns of growth and to further validate the one day-one ring hypothesis of statolith increment formation in Loligo pealei should be continued and completed as soon as possible. This information is critical to the assessment and to planned revisions to the FMP.
- If Loligo is an annual species, new approaches to the assessment and management of the stock will be required. A more adaptive, realtime assessment/management system will be needed to attain full exploitation of the stock while, at the same time, ensuring that adequate levels of spawning stock are achieved (Rosenberg et al. 1990). Examples of the types of assessment and management procedures that have proved successful for shortlived species are provided in the 1993 report of the ICES Working Group on Methods of Fish Stock Assessment (ICES 1993).
- Once the 1993 landings data become available, the relationship between the recordhigh autumn 1992 survey prerecruit index and large-vessel LPUE should be examined.
- Collection of Loligo maturity data during NEFSC bottom trawl surveys should be initiated in order to determine seasonal maturation rates, and to quantify the spatial/temporal patterns in spawning activity.
- Surplus production models to estimate Loligo population size and fishing mortality should incorporate the new information about Loligo age and growth.
- Thus, altemative definitions of overfishing for Loligo, possibly based on a minimum biomass threshold or a minimum proportional escapement level, should be investi-
gated. Future assessment research should investigate stock-recruitment relationships for Loligo. The calculation of risk-averse levels of spawning escapement should also be possible when more quantitative information on the age and growth, maturation, and timing of spawning for Loligo becomes available.
- Evaluate possible shifts in availability ofLoligo between offshore and inshore areas, and potential influences of temperature on distribution patterns.
- Examine the influence of cannibalism on estimates of natural mortality, potential yield and spawner-recruit relations.
- Standardize survey indices for size-specific variation in catchability.
- Significant improvements in the Loligo assessment require the present studies on age and growth to be completed. The SARC does not anticipate that such information will be available before spring 1995.

## G. SHORT-FINNED SQUID

## TERMS OF REFERENCE

a. Compute revised research vessel survey indices from spring and autumn surveys. Estimate minimum stock sizes from area-swept calculations. Evaluate the stock with respect to survey-based management reference points.
b. Estimate catch in numbers by cohort.
c. Examine times-series CPUE data based on GLM formulations.
d. Provide updated projections of yield and stock size based on current fishery patterns. Evaluate the stock relative to management reference points.
e. Review MSY.

## INTRODUCTION

The short-finned squid (Illex illecebrosus) ${ }^{1}$ population is assumed to constitute a unit stock throughout its range of commercial exploitation from Cape Hatteras to Newfoundland. Illex are capable of long-distance migrations (Dawe et al. 1981), and major Illex spawning grounds have been identified south of Cape Hatteras (Rowell and Trites 1985), although spawning may occur in other areas as well.

Previous assessments assumed a two-year cross-over lifecycle based upon analyses of length frequency data (Verrill 1882; Mesnil 1977; Lange and Sissenwine 1980). However, inferences about the age and growth of squids based on length frequency analyses must be regarded with caution unless they are accompanied by supplementary age data (Caddy 1991) because (i) squid growth rates exhibit high variability and can vary with season, food availability, temperature, and population density; (ii) squid populations can be composed of several broods or microcohorts that have different growth and survival rates; (iii) if separate microcohorts enter the sampled population at successive times, modal analysis of length frequency data sampled from a mixture of microcohorts will not represent the true growth rate. Research on the age and growth of several species of squid based on counts of daily statolith growth increments (e.g., Lipinski 1978; Spratt

1979; Dawe et al. 1985; Lipinski 1986; Yang et al. 1986; Jackson 1990; Rodhouse and Hatfield 1990; Jereb et al. 1991; Jackson and Choat 1992; Jackson et al. 1993) indicates that statolith aging is useful technique. Recent research on the age and growth of Illex based on counts of daily statolith growth increments indicate a lifespan of less than 300 days (Dawe et al. 1985; Dawe and Beck 1992; see Figure G1), therefore this assessment adopts the working hypothesis that Illex illecebrosus is an annual, semelparous species.

## DESCRIPTION OF THE FISHERY

Domestic landings of Illexbegan in the 1800 s as a bait fishery. From 1928 to 1967, annual squid landings from Maine to North Carolina (including Loligo pealei) averaged about 2000 mt. A directed foreign fishery for Illex developed in 1972 off the northeast coast of the United States and continued through 1982. During this 11 year period, total annual Illex landings (Cape Hatteras to the Gulf of Maine) averaged $19,250 \mathrm{mt}$, with the foreign fishery accounting for $95 \%$ of the total (Table G1; Figure G2). Since 1983, annual landings have ranged between 2000 and $17,800 \mathrm{mt}$, and have averaged 9400 mt . Foreign landings in 1983-1986 represent landings in the U.S. joint venture fishery, which ended in 1987.

Within the total stock area of Illex (NAFO Subareas 2-6), landings peaked in 1979 at $180,000 \mathrm{mt}$ but have since been very much lower, ranging between 2800 and $22,200 \mathrm{mt}$ during 1983-1991 (Figure G2).

In 1992, U.S. Illex landings ( 416 trips) totaled a record-high $17,827 \mathrm{mt}$ with an exvessel value of $\$ 9.7$ million and an average price of $\$ 0.54$ per kg ( $\$ 0.25$ per lb). Nearly two-thirds of the 1992 harvest ( $11,207 \mathrm{mt}$; $63 \%$ ) was taken from one statistical area (SA 622); three statistical areas (SA 622, 626, and 632) accounted for $96 \%$ of the total landings (Table G2). Temporally, $94 \%$ of the 1992 landings were taken during June through October.

Virtually all the 1992 landings ( $99.9 \%$ ) were taken with bottom otter trawl gear ( 356 trips). Other gear (shrimp trawls, paired trawls, and sea scallop dredges) accounted for less than $0.1 \%$ of the landings (60 trips).

[^12]

Figure GI. Linear regressions of Mlex illecebrosus dorsai mantle length on age, by sex, with results of analysis of covariance for effect of sex, for ail short-finned squid aged in Dawe and Beck (1992)

Based on provisional January-September 1993 landings data, total Illex landings for the U.S from Cape Hatteras to the Gulf of Maine in 1993 are projected to be $14,800 \mathrm{mt}$, about $17 \%$ lower than in 1992.

Illex are managed by the Mid-Atlantic Fishery Management Council under provisions of the Atlantic Mackerel, Squid, and Butterfish Fishery Management Plan. In 1992, the maximum optimum yield, the allowable biological catch, and the domestic allowable harvest were each specified as $30,000 \mathrm{mt}$ (MAFMC 1991). Identical specifications pertain in 1993 and 1994 (MAFMC 1992).

## DATA SOURCES

Commercial U.S. landings data from 1989 through 1992 were derived from the NEMFIS data base and general canvas sources. Landings

Figure G2. Ilex illecebrosus landings (metric tons), 1963-1992. ICNAF squid landings not reported by species prior to 1973. NAFO landings for 1989-91 are provisional.
data for 1963-1988 were provided in the Report of the 10th SAW (NEFSC 1990). Effort data used in the analysis of domestic LPUE from 1982 to 1992 were extracted from the NEMFIS database. Landings data from NAFO Subareas 2, 3, and 4 during 1973-1988 were obtained from ICNAF and NAFO Statistical Bulletins.

Numbers of Illex landed by the commercial fishery during 1982-1992 (Table G3) were estimated using NEFSC commercial size frequency sampling data.

A multiplicative GLM model (Gavaris 1980) was used to standardize fishing effort during

Table Gl. Short-finned squid (Mex illecebrosus) landings (metric tons) from Cape Hatteras to the Gulf of Maine during 1963 to 1993, and Mlex landings from NAFO Subareas 2, 3, and 4, inclusive, during 1973 to $1991^{1.2}$

${ }^{3}$ Predicted

1982-1992 in the U.S. otter trawl fishery for Illex (Brodziak MS 1993). The GLM had the same form as that used in the last Illex assessment (NEFSC 1992); i.e., a main effects model was employed with year, tonnage class, and area used as factors to standardize fishing effort ( $\mathrm{R}^{2}=0.75$ ) (Table G4). In addition to calculating standardized effort,
standardized LPUE (ratio of landings to standardized effort) and a standardized abundance index (ratio of annual LPUE to LPUE in 1982) were also computed.

Research survey indices of relative Illex abundance were derived from NEFSC spring (19681993) and autumn (1967-1992) bottom trawl

surveys conducted in the Mid-Atlantic through Georges Bank regions [offshore strata 1-23, 25, and 67-76] (Tables G5 and G6).

## ASSESSMENT RESULTS

## Relative Abundance

Standardized fishing effort for Illex increased sharply in 1992 to a record-high level (Table G4). Although large interannual changes in Illex effort are not uncommon, effort has trended upward since 1988 (Figure G3). The LPUE and standardized abundance indices were highest during 1987 1989. The LPUE values in 1991 and 1992 were about 30\% lower than the peak values, but near the time series average.

NEFSC research survey indices indicate a cyclical pattern in Illex abundance over the past 25 years (Tables G5 and G6). Periods of low indices (1967-1974 and 1982-1986) have been followed by periods of very high abundance indices (1975-1981 and 1988-1990). The most recent indices (spring 1992-1993; autumn 19911992), however, are neither high nor low, but about near the long-term average. Such periods of intermediate Illex abundance have not previously been observed in the surveys (Figure G4).

The spring indices do not exhibit the high/ low abundance pattern of the fall indices. The lack of concordance between the spring and fall

indices is likely due to the low availability of the stock to the spring survey.

## Absolute Abundance

Minimum stock size estimates (numbers and biomass) of Illex in the Cape Hatteras-Gulf of Maine region were derived by areal expansion of NEFSC autumn bottom trawl survey indices, 1967-1992 (Table G7). For 1967-1992, indices based on all offshore survey strata in the Cape Hatteras-Gulf of Maine region were used (offshore strata $1-30,33-40$ and 61-76). During 1982-1992, inshore survey strata (1-55) were also included in calculating the indices; comparable inshore data for 1967-1981 were not available. However, inshore strata contribute less than $0.2 \%$ to the estimated population size of Illex in any year.
Since the area-swept estimates are based on the survey indices, temporal patterns of abundance are the same. However, in years in which autumn survey abundance indices are low (19671974; 1982-1986), the minimum biomass estimates are in almost all cases less than the landings. This suggests that further work is

Table G5. Stratified mean catch per tow in numbers and weight ( kg ) of Mex illecebrosus in NEFSC spring bottom trawl surveys, Cape Hatteras to Georges Bank (Strata 123, 25, and 61-76), 1968-1993. Mean number per tow indices are presented for all sizes of Illex, for prerecruits ( $\leq 10 \mathrm{~cm}$ ). and for recruits ( $>10 \mathrm{~cm}$ ).

[^13]needed to evaluate the catchability and availability of Illex to the survey gear, and whether the areas surveyed for Illex are appropriate. Furthermore, since Illex is an annual species with a rapid growth rate, standing stock estimates should be adjusted to account for body-weight growth.

## OVERFISHING DEFINITION

Overfishing for Illex is defined to occur when the three-year moving average of prerecruits from the NEFSC autumn bottom trawl survey is below the first quartile of this series. For the purpose of applying the overfishing definition in 1992, 1993, and 1994, the lowest quartile of values consists

Table G6. Stratified mean catch per tow in numbers and weight (kg) of Illex illecebrosus in NEFSC autumn bottom trawl surveys, Cape Hatteras to Georges Bank (Strata 123. 25, and 61-76), 1967-1992. Mean number per tow indices are presented for all sizes of Illex. for prerecruits ( $\leq 10 \mathrm{~cm}$ ), and for recruits ( $>10 \mathrm{~cm}$ ).

| Year | All Sizes (CVI) | Pre <br> recruit | Recruit | Kg/Tow |
| :--- | :---: | :---: | :---: | :---: |
| 1967 | $2.1(21 \%)$ | 0.1 | 2.0 | 0.3 |
| 1968 | $2.3(24 \%)$ | 0.2 | 2.1 | 0.4 |

|  |  |  |  |  |
|  |  |  |  |  |

of the seven lowest prerecruit indices (Table G6); the three-year moving average of the prerecruit series must be less than the largest index in this quartile for overfishing to occur. Given the high 1992 autumn prerecruit index (3.3; third-highest in the survey time series), the three-year moving prerecruit average in 1992 was 1.6. If the 1993 and 1994 prerecruit indices are both 0, the corresponding three-year moving averages would be 1.2 and 1.1, respectively (Table G8). The largest prerecruit index in the lower quartile of values during 1992, 1993, and 1994 would correspond to $0.3,0.3$, and 0.2 . Thus, according to the overfishing definition, fllex were not overfished in 1992, and will not be overfished in 1993 and 1994.

Figure G3. Annual standardized fishing effort and LPUE for Ilex illecebrosus fishery, 1982-1992.

## YIELD AND SPAWNING STOCK BIOMASS

No new information is available on yield per recruit or spawning stock biomass per recruit for Ilex. However, previous calculations (e.g., Lange and Sissenwine 1980) were based on a two-year, crossover life cycle. Illex is now considered to be an annual species and thus re-evaluation of life history dynamics, biological reference points, and MSY is clearly warranted. Because of the transboundary distribution of Illex, these analyses need to be done in collaboration with Canadian scientists.

## DISCUSSION

Both commercial LPUE and research survey indices indicate that Illex abundance was low in
the mid-1980s, high during 1987-1989, and is presently at an intermediate level. The low abundance of Illex during the mid-1980s may have been the result of intensive fishing pressure between 1977 and 1980 when annual landings from the stock (NAFO Areas 2-6) averaged over $120,000 \mathrm{mt}$ (Table G1). Subsequently (until 1987), landings in NAFO Subareas $2-4$ and research survey indices of abundance markedly declined.

Domestic landings of Illex were a record-high in 1992 ( $17,800 \mathrm{mt}$ ) and are projected to be $14,800 \mathrm{mt}$ in 1993, the second-highest U.S. landings level. However, fishing effort markedly increased in 1992 (nearly double that in 1991) while commercial LPUE declined. Since recent survey indices indicate a medium level of stock abundance, annual domestic landings above the 1990-1992 average ( $13,700 \mathrm{mt}$ ) are probably not sustainable during the next several years.

Illex recruitment to fishery areas within the

Figure G4. Stratified mean number and weight per tow of Ilex illecebrosus fom the NEFSC bottom trawl survey, 1967-1992.
U.S. EEZ appears to be episodic, alternating between high and low states. This may reflect the influence of environmental factors or, alternatively, overcompensation. Given this variability, landings projections are difficult to make and are imprecise.

## SOURCES OF UNDERTAINTY

A substantial proportion of the Illex stock is probably distributed outside NEFSC survey areas in most years. To the extent this proportion varies, changes in abundance are difficult to separate shifts in availability to the survey. Since area-swept estimates are based on expansion to the survey area rather than the entire stock area, the estimates are expected to underestimate biomass.

Availability of Illex to the commercial fishery and to the research survey may vary substantially in response to environmental conditions and predation pressure. Because the U.S. EEZ lies near the edge of Illex distribution in the Northwest Atlantic, the response of the stock to localized fishing patterns may be difficult to discern from variability in recruitment and migration patterns to inshore areas.

## RESEARCH RECOMMENDATIONS

1 Present studies on the life history dynamics of Illex need to be examined so that new assessment analyses - incorporating annual life history parameters - can be conducted. Biological reference points and MSY will need to be recalculated based on this new information.

Table G7. Area-swept estimates of minimum biomass (metric tons) and minimum population size (millions of animals) of Ilex squid between Cape Hatteras and the Gulf of Maine, derived from NEFSC fall bottom trawl surveys, 1967-1992.

- Given that Mlex is an annual species, new approaches to the assessment and management of the stock will be required. A more adaptive, real-time assessment/management system will be needed to attain full exploitation of the stock while, at the same time, ensuring that adequate levels of spawning stock are achieved (Rosenberg et al. 1990). Examples of the types of assessment and management procedures that have proved successful for short-lived species are provided in the 1993 report of the ICES Working Group on Methods of Fish Stock Assessment (ICES 1993).
- Collection of Illex maturity data during NEFSC bottom trawl surveys should be initiated in order to determine seasonal maturation rates, and to quantify the spatial/temporal patterns in spawning activity.
- Relationships between Illex distribution/reproduction and environmental factors (i.e., sea surface temperature) should be investigated. The use of remote sensing data may be helpful in this work.
- Alternative definitions of overfishing for Mlex, possibly based on a minimum biomass threshold or a minimum proportional escapement level, should be investigated. Future assessment research should investigate stock-recruitment relationships for Illex. The calculation of risk-averse levels of spawning escapement should also be possible when more quantitative information on the age and growth, maturation, and timing of spawning for Illex becomes available.
- Illex is a transboundary stock between the U.S. and Canada. A joint assessment approach, involving US and Canadian scientists, is strongly recommended.

Table G8. Three-year moving average of the Illex illecebrosus pre-recruit number per tow index from the NEFSC fall bottom trawl survey, 1969-1992

| Year | Average $^{1}$ Prerecruit <br> Number per Tow |
| :---: | :---: |
| 1969 | 0.1 |

## ASSESSMENT METHODS SUBCOMMITTEE TERMS OF REFERENCE

Candidate terms of reference for the Assessment Methods Subcommittee were tabled at SARC 16 in June 1993 ( 16 th SAW SARC Report pages 113-114). Due to lack of time, however, these terms of reference were not discussed during the SARC 16 meeting. The SARC reviewed the terms of reference during this meeting, established priorities, and discussed several general issues regarding assessment methods software development and support.

The role of the Assessment Methods Subcommittee within the overall SARC process was reviewed, i.e.:
(1) to address the practical methodological and statistical problems encountered by the species oriented subcommittees in the course of carrying out their respective assessments;
(2) to suggest alternative procedures or methods to address these problems;
(3) to evaluate new assessment methods (e.g. methods developed elsewhere) and make recommendations regarding their usage in SAW/SARC assessments; and
(4) to develop new assessment methods, as needed, to address recurring problems or to improve the quality and precision of SAW/SARC assessments.

The terms of reference for the Assessment Methods Subcommittee should be closely tied to the ongoing work within the species oriented subcommittees. Members of the Methods Subcommittee also serve as members of one of the species oriented subcommittees, and will participate fully in the ongoing assessment work. Outside experts should be invited to participate in the Methods Subcommittee meetings.

The candidate terms of reference evolved from three sources:
(1) Suggestions tabled during the SARC 16 Meeting (June 1993).
(2) Items that by implication must be examined to address the above issues.
(3) Suggestions that arose during SARC 15 and earlier meetings.

The SARC noted that there are several constraints governing the number and scope of the terms of reference that can be undertaken at a single meeting of the Methods Subcommittee, i.e.
(a) Subcommittee Meeting duration limited to 5 days or so.
(b) Intensive computing work needed to address most issues.

Much of it will need to be done during the Subcommittee meeting.
(c) Assimilation of results, report writing, etc. during meeting.
(d) Background and interests of Subcommittee members.

The candidate terms of reference are summarized below and include, in parentheses, the specific concerns of the SARC at this time.
(1) Potential biases in SARC assessment results (including, among other things, investigation of implications of uncertainty in the catch at age matrix)
(2) Methods for medium-term stochastic projections ***
(3) Multiple indices of abundance within the DeLury model ***
(4) CPUE-based indices of abundance for VPA tuning ${ }^{* * *}$ (including, among other things, methods of construction of fishery dependent indices of abundance)
(5) Calibration of recruitment indices
(6) Effects of outliers in survey data (including, among other things, methods of construction of resource survey indices of abundance)
(7) Sensitivity of ADAPT results to multiple indices ***
(8) Extending the time series of stock-recruitment data
(9) ADAPT tutorial ***

The items labeled with asterisks were identified as priority items by the SAW Steering Committee at its August 1993 meeting. Additionally, Item (9) was added to the original list of candidate terms of reference by the Steering Committee.

Item (9), the ADAPT tutorial, was discussed at length by the SARC. Given its central role in all of the age-structured assessments carried out in the Region, the SARC agreed that an ADAPT tutorial should be held, perhaps as early as February 1994. However, given that few of the current Methods Subcommittee members have expertise with the ADAPT framework, the SARC does not feel that an ADAPT tutorial would be a productive term of reference for the Subcommittee as a whole. The SARC recommends that the Center take on this responsibility instead, thereby allowing the Methods Subcommittee to take on other pressing items from the candidate terms of reference list.

Ideally, an ADAPT tutorial should cover:
(a) Background and history
(b) Data requirements for its use
(c) Description of the methodology and assumptions
(d) Use of model diagnostics in designing the appropriate ADAPT formulation
(e) Interpretation of the output
(f) Hands-on usage of user-friendly ADAPT software

An ADAPT tutorial, covering items (a) through (e), above, should be held two days in the near future. Dr. Steve Murawski was requested to look into the interest of potential participants and to set a date for the tutorial. However, userfriendly ADAPT software is not available within the Center, and given the complexity of the ADAPT framework, will take considerable time and resources to develop. The SARC recommends that the Center develop user-friendly ADAPT software, as well as appropriate software
for all other assessment methods regularly used for within the Region, and that Item (f), above, be covered in a follow-up tutorial after the userfriendly software has been written. Further, the Methods Subcommittee should contribute to this effort by formulating detailed design specifications for ADAPT and other methods software. These specifications should emphasize userfriendliness and maintainability using state-of-the-art, modular programming techniques.

With regard to the other candidate terms of reference, above, the SARC agreed that Items (1) and (2) should be given the highest priority. Bias considerations (including retrospective analysis) should be included routinely in all assessments presented to the SARC (Item 1). Often this is not done because of technical and software problems that could be addressed productively by the Methods Subcommittee. Similarly, assessments should routinely include stochastic projections (i.e. projections that take uncertainty into account), and advice on how best do such projections could be rendered by the Subcommittee.

The SARC agreed that candidate terms of reference (3) and (5), are priority items, but with less importance than terms of reference (1) and (2). The other candidate terms of reference were considered useful for the Subcommittee to consider, but with a lower priority than those mentioned above. In summary, there are three priority groupings for the Methods Subcommittee:

1st Priority: Candidate terms of reference (1), (2), and ADAPT software design.
2nd Priority: Candidate terms of reference (3) and (5)

3rd Priority: Candidate terms of reference (4), (6), (7) and (8)

The SARC felt that the Subcommittee should meet and address the first priority candidate terms of reference -- (1) Potential biases in SARC assessment results and (2) Methods for mediumterm stochastic projections -- as well as ADAPT software design, before May, 1994.

The SARC also briefly discussed whether the Methods Subcommittee should be asked to quantify the potential impact on assessment results of the modifications in port sampling protocol that are currently being considered within the Region. The SARC agreed that although the effects may be important, it is premature to ask the Subcommittee to evaluate them quantitatively until the new protocols are in place and data are available for analysis.

## OTHER BUSINESS

## FUTURE SAWS

The Chairman reported that the SAW Steering Committee met on 21 September 1993. At that meeting, dates were set for the two sessions of the 18th Northeast Regional Stock Assessment Workshop (SAW-18) and five species were suggested for assessment during SAW-18. A number of species to review at SAW-19 were also discussed.

- SAW-18 Stock Assessment Review Committee (SARC) Meeting
20-24 June 1994
NEFSC, Woods Hole, MA
- SAW-18 Plenary Meeting

In Conjunction with the NEFMC Meeting
9 August 1994
King's Grant Inn, Danvers, MA

- Suggested agenda for SAW-18 SARC

Review analyses for mackerel, witch flounder, summer flounder, dogfish, and lobster

- SAW-19

Although dates have not yet been set for the SAW-19 sessions, species discussed for possible review at SAW-19 SARC include cod, scallops, white hake, scup, and black sea bass; and possibly shad, and river herring.

In discussion of this information at the SARC meeting, it was indicated that there would not be much new material to present on lobster at the time of SAW-18 and members suggested that the lobster be replaced by scallop. Because there was not enough time at the SAW-17 SARC meeting to review Georges Bank cod and Georges Bank yellowtail flounder (second priority), cod (two stocks) and yellowtail flounder (two stocks), as well as haddock and white hake (suggested to be more important to review at this time than cod), be considered for the SAW-19. As it is becoming obvious that the SARC can comfortably manage to review only five species/stocks at a week long meeting, an optimum group of species was identified to include cod (two stocks), yellowtail flounder (two stocks), and haddock.

It was suggested to hold the SAW-17 Plenary meetings during two days, beginning in the afternoon of the first day.

The question of meeting dates for SARC meetings in general was debated. Although SARC meetings are slipping too far into the spring and fall seasons, considering the responsibilities of people concerned, June and November were currently determined to be the best months for the SARC to meet after all. This may not be changed in the near future. The best week in November remains to be the week after Thanksgiving. One suggestion was to hold meetings from Tuesday to the following Wednesday, taking only Sunday off. The possibility of holding three SARC meetings a year was also voiced.

The Steering Committee is scheduled to meet again on 15 February 1994 to reevaluate the species to review vis $a$ vis the most current management needs, confirm the agenda for SAW18, and set the dates for SAW-19. The Chairman will present the SARC's comments and suggestions at that meeting.

It was noted, with great apprehension, that the SARC may have to revisit all the fisheries every year in the future, as status reports will be required to effectively monitor species under new regulations such as those concerning groundfish.

## CONDUCT OF THE SARC

The conduct of the SARC was discussed to some extent at the end of the meeting. Generally it was suggested that SARC meetings must be more efficient and interesting in order for people to want to participate. Specific comments by individuals are summarized below. Please note that these are individual comments and do not reflect a consensus of the SARC members. The SARC Chair, in fact, strongly disagrees with some of these comments.

- Re-examine the objectives of the SARC, i.e, peer review of assessments, development of the technical report, and development of advice.
- Separate peer review from report writing tasks. After all, SARC's primary responsibility is to identify the information that should go into its reports (Consensus Summary of Assessments and the Advisory Report on Stock

Status). Reports can be edited and reviewed by SARC members after the meeting.

- Develop a standard protocol for conducting meetings, as the only reference to conducting SARC meetings, available to date, is the 15 th SAW Plenary report.
- The responsibilities of the SARC, the Rapporteurs, and SARC Leaders should be more thoroughly described in the Chairman's memo prior to each SARC meeting.
- The Chairman's introductory notes should have been sent to SARC members and the Rapporteurs prior to the meeting.
- The SARC Leader for each species/stock should keep notes and review exactly what changes need to be made in a report at the end of each presentation.
- Have one person do all the figures to assure consistency in format, or provide more guidance regarding preparation of figures.
- Subdivide the SARC for the purpose of quality control and formatting documentation, then, assemble for the last two days to agree on documents.
- Better frame or formulate the terms of reference. For example, there was no reference to the silver hake juvenile fishery this time.
- Get Steering Committee approval of the terms of reference sooner, as Subcommittees would benefit from more lead time.
- Subcommittee drafts should more closely resemble the sections of the SARC report.
- Subcommittees should take more lead time to get information together to better meet SARC reporting needs. (This time Subcommittees held their meetings too close (in terms of time) to the SARC meeting.)
- Subcommittee presentations should consist of summaries of data and identified problems.
- Take into consideration that new analyses and methods need more careful review, thus, requiring more SARC time than established ones.
- Reduce the number of species the SARC should review at a meeting.
- The SARC meeting program should include seminars, e.g., assessment techniques such as an ADAPT workshop, or invited speakers like Bill Macy whose research on squid was relevant to the Loligo assessment.

Finally, it was noted that as the current SAW structure is quite new, it may be too soon to say how effective it is and should go through another cycle before it is evaluated.

## REVIEW PROCESSES IN OTHER REGIONS

Chris Annand described the assessment review process in Canada where a more restricted group of assessment scientists participate. Meetings are not open and fishermen and academics do not participate, although fishermen are consulted prior to meetings. The most current material, basically tables, is presented for review. One person writes the advisory report. which the committee reviews one week after the meeting. All graphs are prepared by one person, assuring consistency in format.

Terry Smith discussed the review system in the North Pacific where analyses on 30 to 40 species are presented to a group of assessment scientists. Summaries are prepared and presented on an individual basis, the chair has the option to limit discussion and a draft is completed at the end of the meeting. Under this system species get three levels of review: 1) from a Planning Team, including biologists and social scientists from the states, academia, and the fisheries centers; 2) from persons responsible for certain species, includes state people; and, 3) from a Team Consensus. The quality of assessments in that region, however, is not as consistent as in the Northeast.

The 17th Northeast Regional Stock Assessment Workshop is documented in seven separate reports, listed below. The Northeast Fisheries Science Center Reference Documents are a series of informal reports produced by the Center for timely transmission of results obtained through work at NEFSC labs. The documents are reviewed internally before publication, but are not considered formal literature. The National Marine Fisheries Service does not endorse any proprietary material, process, or product mentioned in these reports. To obtain additional copies of this report or other Center Reference Documents contact, Information Services Unit, Northeast Fisheries Science Center, Woods Hole, MA 02543 (508-548-5123, ext. 260 or 378).

## Reports of the 17th Stock Assessment Workshop (17th SAW)

CRD 94-01 Estimation of Discards in the Silver Hake Fisheries and its Implications on the LongTerm Yield of the Stocks by T. Helser and R. Mayo

CRD 94-02 Assessment of Yellowtail Flounder Pleuronectes ferrugineus, 1993
by P. Rago, W. Gabriel, and M. Lambert
CRD 94-03 Stock Assessment of Atlantic Butterfish, Peprilus triacanthus, in the Northwest Atlantic During 1992
by J. Brodziak
CRD 94-04 Stock Assessment of Long-Finned Squid, Loligo pealei, in the Northwest Atlantic During 1992
by J. Brodziak
CRD 94-05 Stock Assessment of Short-Finned Squid, Ilex illecebrosus, in the Northwest Atlantic During 1992
J. Brodziak and L. Hendrickson

CRD 94-06 Report of the 17th Northeast Regional Stock Assessment Workshop, Stock Assessment Review Committee Consensus Summary of Assessments

CRD 94-07 Report of the 17th Northeast Regional Stock Assessment Workshop, The Plenary

[^0]:    ${ }^{1}$ Adjusted from \#41 trawl catches to equivalent \#36 trawl catches using a .334:1 ratio.

[^1]:    Instantaneous natural mortality (m) assumed to be 0.40 .
    ${ }^{2}$ Estimates derived from: Auturnn. $\ln \left(\Sigma\right.$ age $2^{+}$for year $\mathrm{i}-1$ to $j-1 / \Sigma$ age $3^{+}$for year $i$ to $j$. Spring, $\ln$ ( $\Sigma$ age $3^{+}$for year i to $\mathrm{j} / \Sigma$ age $4^{+}$for year $\mathrm{i}+1$ to $\mathrm{j}+1$.
    ${ }^{3}$ Provisional estimate; does not include spring 1993 survey abundance estimates.

[^2]:    ${ }^{1}$ Includes Bulgaria, Cuba, German Democratic Republic, Italy, Japan, Mexico, Poland, Romania. Spain
    ${ }^{2}$ Recreational catch estimates taken from Almeida (1987)

[^3]:    ${ }^{1}$ Values in parenthesis for annual sampling intensity indicate that no samples were taken for given landings.

[^4]:    ${ }^{1}$ Adjusted from offshore \#36 trawl catches to equivalent inshore-offshore \#36 trawl catches using a .960:1 ratio.
    ${ }^{2}$ Adjusted from offshore \#41 trawl catches to equivalent inshore-offshore \#36 trawl catches using a . 320:1 ratio.
    ${ }^{3}$ Adjusted from offshore \#41 trawl catches to equivalent inshore-offshore \#36 trawl catches using a .334:1 ratio.
    ${ }^{4}$ Adjusted from offshore \#36 trawl catches to equivalent inshore-offshore \#36 trawl catches using a .890:1 ratio.
    ${ }^{5}$ Strata 1-19 only.
    ${ }^{5}$ Estimates from autumn bottom trawl survey not available.

[^5]:    ${ }^{1}$ Adjusted from offshore \#41 trawl catches to equivalent inshore-offshore \#36 trawl catches using a . $320: 1$ ratio.
    ${ }^{2}$ Adjusted from offshore \#41 trawl catches to equivalent inshore-offshore \#36 trawl catches using a . 334:1 ratio.
    ${ }^{3}$ Adjusted from offshore \#36 trawl catches to equivalent inshore-offshore \#36 trawl catches using a $890: 1$ ratio.

[^6]:    ${ }^{1}$ Taken from Helser (1993) 1989-1992 period.
    ${ }^{2}$ From applying length-weight equation ( $W=0.00000593 L^{3.09}$ ) to mean length at age from von Bertalanffy growth equations (Pentilla et al. 1989).

[^7]:    ${ }^{1}$ Marine Angling Survey estimates, adjusted as per Boreman (1983) - these surveys used a different methodology than the MRFSS, and are not directly comparable to recreational catch estimates since 1979.

[^8]:    * Aged using annual NC DMF age-length keys from NC commercial fisheries, 1993 NC DMF keys used to age 1992 NEFSC lengths.

[^9]:    - Catches of 0 are due to rounding

[^10]:    1. Ratio of weight discarded to total weight kept and discarded.
[^11]:    ${ }^{1}$ For brevity, Loligo pealet is referred to as Loligo whenever possible

[^12]:    ${ }^{1}$ For brevity, Illex illecebrosus is subsequently referred to as Illex wherever possible.

[^13]:    ${ }^{1}$ Coefficient of variation for the all sizes index.

[^14]:    ${ }^{1}$ Average of prerecruit index in years T, T-1, and T-2, where T is the current year.
    ${ }^{2}$ Provisional
