## INTRODUCTION

Redfish, Sebastes fasciatus Storer, have supported a substantial domestic fishery in the Gulf of Maine and the Georges Bank (Great South Channel) regions off the northeast coast of the United States (Northwest Atlantic Fisheries Organization [NAFO] Subarea 5) since the late 1930s when the development of freezing techniques enabled a widespread distribution of the frozen product throughout the country. Landings by domestic vessels rose rapidly, peaking at 56,000 tin 1942 in Subarea 5, then declined throughout the 1940s and 1950s (Table l, Figure 1). As landings declined in local waters, U.S. fishing effort began to expand to the Scotian Shelf and the Gulf of St. Lawrence (NAFO Subarea 4), and finally to the Grand Bank ofNewfoundland (NAFO Subarea 3). This expansion continued throughout the 1940s and early 1950s, culminating with a peak U.S catch of $130,000 \mathrm{t}$ in 1952 (Figure 1). By the mid-1950s, redfish stocks throughout the Northwest Atlantic were heavily exploited by U.S and Canadian fleets (Atkinson 1987), and total landings began to decline in all Subareas.

With the declaration of exclusive economic zones by the United States and Canada in 1977, U.S. vessels were prohibited from fishing in all but a small portion of Subarea 4 off Southwest Nova Scotia. Landings from the Gulf of Maine subsequently increased temporarily during the late 1970s, but have been declining throughout the 1980s. Recent landings from this stock are at their lowest level since the directed fishery commenced in 1934.

The status of this stock has been assessed since the 1970s with a variety of techniques including production models (Schaefer 1954, 1957; Pella and Tomlinson 1969; Fox 1975), yield per recruit (Beverton and Holt 1957) and virtual population analysis (VPA). By the late 1970s it was recognized within the International Commission for the Northwest Atlantic Fisheries (ICNAF) that then current catch levels were not sustainable. Prellminary production model results which suggested a long-term potential yield of $20,000 \mathrm{t}$ from this stock (Mayo 1975) were modified to between 9,000 and 13,000 t (Mayo 1976) to account for nonequilibrium conditions (Walter 1976) and allow for recovery of the stock. With the inclusion of standardized fishing effort in the analysis, estimates of maximum yield at $f_{\text {msy }}$ and two-thirds $\mathrm{f}_{\text {msy }}$ (Doubleday 1976), which would allow for potential recovery of the stock were estimated at $5,200 \mathrm{t}$ and $3,500 \mathrm{t}$, respectively (Mayo et al. 1979).

Based on these analyses, ICNAF agreed on

9,000 $t$ as the TAC for redfish in Subarea 5 for calendar year 1977. This TAC was never enforced due to extension of U.S. jurisdiction in early 1977. Since 1977, management of the stock has been the responsibility of the New England Fishery Management Council. Between 1977 and 1986, when redfish were first included in the Northeast Multi-species Fishery Management Plan (FMP), the U.S. redfish fishery remained essentially unregulated. Even since 1986, management measures incorporated in the FMP have not imposed restrictions on redfish catches or fishing mortality.

Virtual population analysis, which was first performed on this stock using catch at age data from 1969-1980, indicated that age 9+ fishing mortality rates, in the range of 0.18 to 0.28 throughout most of the 1970 s, were accompanied by a $62 \%$ decline in exploitable (age 5+) biomass between 1969 and 1980 (Mayo et al. 1983). A subsequent analysis, which included additional catch at age data through 1983, indicated that although $F$ had begun to decline from a maximum value of 0.26 in 1979 to 0.17 in 1983, exploitable biomass had been reduced by $75 \%$ from the 1969 level by 1984 (NEFC 1986). The VPA was discontinued after 1986, but further declines in redfish landings since then suggest that $F$ is now likely to be rather low (possibly in the range of M ), rendering the convergence of VPAs somewhat unlikely.

The potential for this stock to return to levels observed in the 1960s is limited, in part, by the combination of delayed maturation relative to the age at entry to the fishery. Even at relatively low levels of $F$, ranging from 0.03 to 0.05 , Mayo (1987) noted that restoration of the 1969 age structure is not likely to occur except under extremely favorable recruitment conditions over the next 30 to 40 years.

## COMMERCIAL FISHERY

Redfish have been harvested primarily by domestic vessels, although some distant-water fleets took considerable quantities for a brief period during the early 1970s (Table 1). Redfish are harvested almost exclusively by otter trawlers fishing out of Maine and Massachusetts ports. Landings in 1991 ( 525 t ) were at an historic low level, although 1992 landings are estimated to have increased to about 900 t (Table 1).

Commercial catch per unit effort (CPUE) indices for directed redfish trips were standardized by vessel tonnage class as described by Mayo et

Figure 1. United States landings of redfish (metric tons) from the Northwest Atlantic, 1934-1991: Subarea 3 - Grand Bank, Subarea 4 - Scotian Shelf and Gulf of St. Lawrence, Subarea 5-Gulf of Malne and Georges Bank
al. (1979). The resulting calculated fishing effort values were derived by dividing total annual landings by the directed CPUE index. Directed CPUE has declined steadily from more than 10 t per day flshed during the late 1960 s to less than 2 t per day flshed since 1984 (Table 1, Figure 2a). The 70 to $80 \%$ decline is consistent with the 60 to $70 \%$ declines in exploitable biomass estimated by previous VPAs (Mayo et al. 1983; NEFC 1986). Total flshing effort, after peakding during the late 1970s (colncident with the highest estimates of fishing mortallty [NEFC 1986]), appeared to stablize during the mid-1980s before declining precipitously through 1989.

Historically, 80 to $90 \%$ of the total redfish catch and 20 to $40 \%$ of the total number of trips on which redflish were taken were accounted for in the directed CPUE calculation ( $50 \%$ redflsh trips) (Table 2). These percentages declined
sharply between 1979 and 1982, and are now at levels that preclude any definitive interpretation of the CPUE and effort trends (Figure 2b). Despite these limitations, it is clear that commercial CPUE remalns extremely low relative to earlier periods.

Commerclal length sampling for redfish has generally been sufficlent with one sample being taken for every 100 to 200 t landed (Table 3). The apparent sampling intensity has improved in recent years as landings have declined at a faster rate than the reduction in sampling. However, sampling must be maintained at relatively high levels in order to reflect the age structure of the population. Age samples have been routinely collected since the 1960 s but production ageing has ceased since 1985.

In 1978 the landings still reflected a fairly broad size (and age) structure in the population

of both males and females with the 1971 year class accounting for the mode between 20 and 30 cm (Figure 3). With the lack of subsequent recruitment, modes shifted toward larger sizes until fish from the 1978 year class appeared in 1983 and 1984. As landings continued to decrease throughout the 1980s, modal lengths shifted further until in 1991 few fish between 20 and 30 cm could be seen recruiting to the fishery. Shifts in modal lengths can also be seen in annual changes in mean length (Figure 4). Increases in mean length occur during periods of poorrecruitment (such as 1965-1976) while sharp decreases generally signify the appearance of a strong year class entering the fishery. The declines that began in 1976 and 1983 indicate recruitment of the 1971 and 1978 year classes entering the fishery at age 5 . The overall increasing trend indicates a gradual aging of the available population as recruitment frequency has declined over the past 30 years.

The catch at age matrix based on all available commercial length and age data from 1969
through 1985 is given in Table 4. The sharp discontinuity in the age structure of the population created by poor recruitment since the 1960s can be inferred from the age composition of the catch. The most striking feature is the singular presence of the 1971 year class progressing through the fishery since 1974 with almost negligible recruitment evident for five to six years before or after.

## RELATIVE ABUNDANCE AND RECRUITMENT

Bottom trawl surveys have been conducted bythe Northeast Fisheries Science Center (NEFSC) in the Gulf of Maine - Georges Bank region since the autumn of 1963 and the spring of 1968 (Azarovitz 1981). Abundance (stratified mean number per tow) and biomass (stratified mean weight per tow) indices have been calculated for inshore (strata 26, 27, 39, and 40) and offshore (strata 24, 28-30, 36-38) strata sets in order to

detect recruitment trends from Western Gulf of Maine coastal nursery areas as described by Mayo et al. (1990). An overall index has also been computed based on a combined (strata 24, 2630, 36-40) strata set. Recruitment indices have been derived from the inshore data by computing the summed stratified mean number per tow within prescribed length ranges corresponding to ages 1-3 as determined by inspection of historical length frequency data.

Relative abundance of redfish has declined sharply in both survey series, from peak levels of around 100 fish per tow in the late 1960s and early 1970s to generally fewer than 10 fish per tow during the mid-1980s (Tables 5 and 6). The decline in biomass has been of the same order (Figures 5a and 5b). Both series suggest a slight increase in abundance and biomass in 1992, but the overall levels continue to remain well below historic observations. As with commercial mean lengths, sharp declines in mean length of redfish in the surveys indicate the emergence of a relatively strong year class (Figures 6a and 6b). This is most evident in the autumn series of inshore data (Figure 6b), which has provided the most consistent recruitment patterns over time. The sharp declines that occur Immediately after 1971, 1978, and 1984 reflect the initial appearance and
subsequent increased influence of these year classes in the bottom trawl survey indices.

The 1964 year class appeared very strong at ages 1 and 2, and the 1961 through 1965 year classes were strong at age 2 (Table 7). The 1971 year class also appeared to be very strong at age 0 , but was not as evident at ages 1 and 2 as were year classes from the early 1960s. Viewed in this perspective, the 1978 year class and those that have appeared since the mid-1980s are relatively weak compared to those which recruited in the earlier years.
Length composition data from spring and autumn surveys (Figure 7) illustrate the changes in relative abundance and size structure of the population that resulted from the decline in recruitment over time. The redfish population was composed of a relatively broad range of sizes in the 1960s resulting from consistent recruitment of year classes from the 1950s and early 1960s. By the 1970s, however, abundance of large fish had declined substantially and only the 1971 year class remained a dominant feature in the demographics of the population. The consistency of the survey indices had begun to erode by the beginning of the 1980s and, throughout the decade, only sporadic indications of the 1978 and subsequent year classes were evident. In 1992,

Figure 3. Length composition of U.S. commercial landings of Gulf of Malne-Georges Bank rednsh. 1978-1991.

Figure 4. Trends in mean length of female and male redish landed in the Gulf of Malne-Georges Bank U.S. fishery, 1942-1991. (1942-1964 data from: Brown and Hennemuth 1965).
however, substantial numbers of redflsh between 20 and 26 cm appeared as likely 5-to 6-year-old flsh from 1986 or 1987 year classes.

## GROWTH AND MATURATION

Redfish are relatively long-lived, slow growing fish with an extremely low natural mortality rate compared to most highly exploited specles. Growth studies have indicated maximum ages ranging from 50 to 60 years at lengths of 45 to 50 cm (Mayo et al 1990) (Figure 8). Perlmutter and Clark (1949) provided early evidence that Immature redilish in the Gulf of Maine exhlbited extremely slow growth and that maturation was delayed until about age 9 . Kelly and Wolf (1959) further demonstrated the extremely slow growth of adult redfish up to age 20. More recently, Mayo et al. (1981) provided further validation of the
slow growth rates for redflsh up to age 7 based on length mode progression and edge formation analysis. Consequently, an instantancous natural mortallty rate of 0.05 has been employed in virtual population and yield and SSB per recruit analyses, consistent with the longevity of this species. Moreover, growth and maturation appear to be linked. The most recent estimates of redfish maturation suggest a median age of about 5.5 years (Mayo et al. 1990; O'Brien et al. In Press) (Figure 9).

## YIELD AND SSB PER RECRUIT

Yield and spawning stock blomass (SSB) per recruit were calculated according to the methods described by Thompson and Bell (1934) and Gabriel et al. (1989). Partial recrultment was taken from the most recently published VPA

(NEFC 1986) which reflects the recruitment of the 1971 year class. Natural mortality was assumed to be 0.05 . Mean weights at age for the yield per recruit calculations were taken as the 1969-1984 mean of the commercial mean weights at age (Table 4). Growth and maturation data for SSB/R analysis were taken from the female data presented by Mayo et al. (1990) and O'Brien et al. (In Press).

Estimates of $\mathrm{F}_{0.1}(0.06)$ and $\mathrm{F}_{\max }(0.13)$ (Table 8, Figure 10) are similar to those reported by Mayo (1980) using the Beverton-Holt approach with the same value of $M(0.05)$ for 89 mm mesh (males) and 102 mm mesh (females). The F at $20 \%$ of Maximum Spawning Potential was estimated as 0.12 , slightly below the estimate of $\mathrm{F}_{\max }$. However, considering the life history characteristics of redfish, the $20 \%$ MSP level is likely to be unrealistically low and the corresponding Freference point unrealistically high to allow the stock to replace itself on a sustained basis.

## CONCLUSIONS

Landings have remained at historic low levels ( $<1,000 \mathrm{t}$ ) since 1989 after declining from an average 14,000 t during 1977-1979. Commercial CPUE in recent years has declined by more than $80 \%$ from levels observed during the 1960s, and exploitable (age $5+$ ) biomass estimates from VPA have declined by $75 \%$ between 1969 and 1984. Fully recruited (age 9+) instantaneous fishing mortality ( F ) ranged from 0.18 to 0.26 between 1969 and 1983, but has likely declined in recent years as landings have declined sharply from mid-1980s levels.

Relative abundance and blomass indices from NEFSC bottom trawl surveys have declined by over $90 \%$ between the mid- to late 1960s and late 1980s. As a consequence of extremely poor recruitment since the mid-1960s, the age structure of the population has narrowed considerably to only one or two significant year classes.

Summary of Yield per Recruit Analysis for:
REDFISH UPDATED AVE WTS, MAT VECTOR (MAYO ET AL. 1990), 1971 YC FPAT
Slope of the yleld/recruit curve at $\mathrm{F}=0.00:->7.4657$
$F$ level at slope $=1 / 10$ of the above slope ( $F_{0.1}$ ): -->.060
Yield/recruit corresponding to $\mathrm{F}_{0.1}:->.1639$
$F$ level to produce maximum yield/recruit $\left(\mathrm{F}_{\text {max }}\right)$ : $-->132$
Yield/recruit corresponding to $\mathrm{F}_{\max }:-->.1819$
$F$ level at $20 \%$ of maximum spawning potential $\left(\mathrm{F}_{20 \%}\right): \rightarrow->116$
$\mathrm{SSB} /$ recruit corresponding to $\mathrm{F}_{20}$ : $-\rightarrow->1.7605$

Table 8. Continued.
