## NOAA TECHNICAL REPORTS

## National Marine Fisheries Service, Special Scientific Report--Fisheries Series

The major responsibilities of the National Marine Fisheries Service (NMFS) are to monitor and assess the abundance and geographic distribution of fishery resources, to understand and predict fluctuations in the quantity and distribution of these resources, and to establish levels for optimum use of the resources. NMFS is also charged with the development and implementation of policies for managing national fishing grounds, development and enforcement of domestic fisheries regulations, surveillance of foreign fishing off United States coastal waters, and the development and enforcement of international fishery agreements and policies. NMFS also assists the fishing industry through marketing service and economic analysis programs, and mortgage insurance and vessel construction subsidies. It collects, analyzes, and publishes statistics on various phases of the industry.
The Special Scientific Report-Fisheries series was established in 1949. The series carries reports on scientific investigations that document long-term continuing programs of NMFS, or intensive scientific reports on studies of restricted scope. The reports may deal with applied fishery problems. The series is also used as a medium for the publication of bibliographies of a specialized scientific nature.

NOAA Technical Reports NMFS SSRF are available free in limited numbers to governmental agencies, both Federal and State. They are also available in exchange for other scientific and technical publications in the marine sciences. Individual copies may be obtained (unless otherwise noted) from NOAA Publications Section, Rockville, Md. 20852. Recent SSRF's are:

# LENGTH WEIGHT RELATIONS OF HADDOCK FROM COMMERCIAL LANDINGS IN NEW ENGLAND, 1931-55 

By<br>Bradford E. Brown and Richard C. Hennemuth, National Marine Fisheries Service Biological Laboratory, Woods Hole, Massachusetts 02543

#### Abstract

Length-weight relations (including the conversion of dressed to live weight) are needed to study the population dynamics of haddock on Georges and Browns Banks. Analyses of covariance were used to compare these relations among market categories, years, fishing areas, and months. There was considerable variation among samples taken on different trips and among subsamples taken on a single trip. Separate regression lines are recommended for market categories (large and scrod) and for Georges and Browns Banks. No yearly or seasonal trends were evident. Estimating equations are presented.

## INTRODUCTION

Samples of length and weight measurements of haddock in commercial landings of United States otter trawlers were collected in several of the years from 1931 to 1955 . A large part of these data was examined by Clark and Dietsch (1959), who reported that seasonal trends were evident in the length-weight relationships, and presented sets of weight at length tables for each month by special sampling areas (Figure 1) which have been used to convert length to weight in routine estimates of haddock statistics. It was desirable, however, to conduct a more critical and comprehensive analysis of all available length-weight data for haddock, particularly since studies of the dynamics of the haddock fishery depend on the use of these data to estimate from lengthfrequency samples and weight of landings the number landed. In the present study, variation among size categories, years, areas, and months
was estimated, and statistical tests were applied to determine the degree of homogeneity and the most appropriate length-weight equations to be used in the study of population dynamics of haddock.

The estimation of factors for converting dressed weights, gutted or gilled and gutted, to live weight is also included.

## COLLECTION OF DATA AND METHODS OF ANALYSIS

All measurements were taken from fish landed at the Port of Boston. Fork lengths were recorded to the nearest centimeter and weights to the nearest 0.1 pound. Haddock were landed either gutted, or gutted and gilled. From April to November the fish were required to be gutted and gilled, and they were frequently so treated in the winter months also. Only the data from the gutted and gilled

Figure 1.-Sampling areas.
category were sufficient for analysis. Commercial catches were sorted into scrod (those fish under approximately 2.5 pounds) and large size categories at sea by the fishermen. Fish of each size category were unloaded from the vessels in carts of about 500 -pound capacity. A sample was composed of varying numbers of fish taken from one or more of these carts from a single vessel's trip.

There were 82 samples collected over the years for a total of 7,774 measurements. The distribution of these samples among the various factors is presented in Table 1. The geographical areas are outlined in Figure 1.

Samples were not taken in strictly random fashion. In order to treat these data statistically, we must assume the samples taken from each boat's catch to be representative of the total catch and the boats sampled were representative of all boats fishing.

To study the relation of dressed to round weights, lengths and weights of individual fish were recorded at sea while fresh and at the dock after the fish had been dressed and stored aboard commercial vessels for periods up to 10 days. In one case both sets of measurements were made at dock side. There were nine samples of fish with measurements of gutted and round weights, and two samples with gutted and gilled, and round weights (Table 4).

For the length-weight regressions, an equation of the form $W=c L^{b}$ was assumed, where:
$W=$ weight in pounds, to the nearest tenth,
$L=$ fork length in centimeters, and $c$ and $b$ are constants to be estimated.
Regressions were fitted by the least squares method to the equation $Y=a+b X$, where:

$$
\begin{aligned}
Y & =\log _{e} W \\
X & =\log _{e} L \\
a & =\log _{e} c
\end{aligned}
$$

It is realized that the least squares fit to this equation is not the same as the least squares fit to the untransformed equation; however, it is convenient to deal with the linear form The regression statistics for each sample are given in Appendix A1. Notations for regressions and covariance analyses throughout this report follow Snedecor (1956). The term significant refers to a probability level less than 0.05 .

Inadequate distribution of samples prevented the use of a factorial analysis to determine the existence and significance of interactions among the factors. Therefore, where data permitted, a separate analysis of covariance among the levels of a given factor (e.g., among years) was run within each of the other factor combinations, and the series of analyses thus obtained were pooled to yield a single result.

An approximate $F$ test was used to take subsample variation into account when tests were made using samples from a single trip. The mean squares for the differences in regression coefficients and adjusted means were divided by the corresponding mean squares for differences among subsamples taken from Appendix Table A2 (see Appendix Table A3).

Since many of the sample cells (Table 1) contain only one or two samples, comparisons among them would not provide for adequate estimates of error variance. It seemed best to pool all the available estimates of sample-tosample variation to provide a single denominator for all tests. In these cases the denominators in the $F$ tests were the estimates of variations among samples taken from Appendix Table A3 (see Appendix Table A5).

In this paper, the term Approximate $F$ Test refers to either of the aforementioned ratios. Because of the variable sample numbers, the probability levels are not exact, and thus the use of term approximate.

Table 1.-Number of trips sampled for haddock length-weight study.

*large market category/scrod market category

When utilizing covariance analyses it is always possible that the difference is not due to the factor examined, for example area, but to some other factor. One possible confounding factor could be the different size of fish within the market category being examined contributing to differences in length-weight equations. The mean $\ln$ length of the samples are given in Appendix Table A1 and visual examination of these values does indicate large differences in the size of the different samples.

## ESTIMATION OF SAMPLING VARIATION

## Subsamples

The samples used in these pooled analyses were known to consist of fish from several carts for each trip. However, the data for each cart (subsample) were not recorded separately.

In April, 1942, landings of five trips from eastern Georges Bank were sampled in an attempt to measure variation within trips, i.e., among subsamples. These samples were taken over a 10-day period from landings of boats fishing in the same section of eastern Georges Bank in depths of 45 to 55 fathoms. Each
subsample was composed of 25 fish taken from a single cart, and from four to eight subsamples were taken from each trip. All of these fish were in the large size category.

The analysis of covariance among subsamples is presented in Appendix Table A2. There was a significant difference among the adjusted means of the subsamples. The mean square among samples (trips) was not significant.

The differences found between subsamples could have been the result of varying lengths of time or the position that the fish were kept in the hold. Also, each part may have contained fish caught in different sections of the general area that the boat fished in.

The mean square for among subsamples is twice as large as that among samples. The assumptions of the model would be violated if, in fact, the difference was significant. The inverted $F$-ratio $(0.01222 / 0.0065=1.88)$, with 58 and 8 degrees of freedom does not, in fact, exceed the tabular $F$ at the 5 percent probability level.

We may conclude that sample to sample variation is negligible. This is not surprising because the short time period and restricted
area of collection would lead to time-area variations of catches within all the sampled trips to be the major source of error.

We shall utilize these estimates of subsample variations to test the significance of sample-to-sample variation in subsequent analyses.

## Samples (between trips)

Analyses of covariance among samples were computed for each cell (each combination of given year, area, month, and size category) containing more than one sample (cf. Table 1). The pooled analysis of covariance showed significant adjusted mean differences among samples, or trips, for both large and scrod size categories (Appendix Table A3). The among sample mean squares of large and scrod haddock for this pooled analysis ( 0.0364 and 0.0369 ) were greater than that among the five samples used in the analysis of subsample variation ( 0.0065 , cf., Table A2). This may have occurred because the five special samples came from a more restricted time and area within the sampling area than the general samples. The among sample mean square is also about five times larger than the within sample or common mean squares which are used for testing in a one-stage analysis.

## COMPARISON AMONG FACTOR LEVELS

## Size Categories

To determine whether separate lengthweight equations should be used for scrod and large haddock, covariance analyses were computed for 16 trips from which both size categories were sampled. The pooled analysis is presented in Appendix Table A4; significant differences were found for adjusted means. Only subsample variation need be accounted for in this analysis as comparison was between large and scrod samples from the same boat.

The adjusted means were calculated and compared for each of these pairs of regression equations. In all cases the adjusted mean was greater for large than for scrod haddock (Table 2). The observed differences are to be expected if the fish were sorted primarily on the basis of heavy appearance, i.e., within the range of cull-sizes the short, plump fish would be considered large whereas the longer, slender

Table 2.-Natural logarithms of adjusted mean weights (pounds) for samples of large and scrod haddock.

| Pair <br> Number | Adjusted means <br> for large haddock | Adjusted means <br> for scrod haddock |
| :---: | :---: | :---: |

| 15 | 0.6554 | 0.6228 |
| 16 | 1.1104 | 1.0369 |

individuals would be classed as scrod.

## Years

An analysis of covariance among years was computed within each month, area, and size category classification containing samples from two or more years. For example, comparisons between 1931 and 1932 were made for the western Georges Bank area in each of the months January, June, and July. A single regression equation was used for each year, combining several samples where required. The several analyses were then pooled and no significant differences were found when the differences among samples were taken into consideration in the Approximate $F$ Test (Appendix Table A5). As the years tested contained time differentials from 1 to 22 years, both short- and long-term changes appear nonsignificant.

## Areas

Comparisons were made between samples from eastern and western Georges Bank within year, month, and size category strata in the same manner as described above. No significant differences were found when the Approximate $F$ Test using sample-to-sample differences was applied (Appendix Table A6).

The same procedure was followed to test

Table 3.-Duncan multiple range test between months for large haddock from Georges Bank (underlined values are homogeneous groups).

| Months | Jan. | July | Mar. | Feb. | Sept. | June | Apr. | Dec. |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Adjusted <br> means | 1.4893 | 1.4154 | 1.2744 | 1.2149 | 1.2053 | 1.1572 | 1.1336 | 1.0874 |
| Individual |  |  |  |  |  |  |  |  |
| comparisons <br> of adjusted <br> means |  |  |  |  |  |  |  |  |

differences between samples from Browns Bank and the western banks of Nova Scotia. No significant differences were found between these areas (Appendix Table A7). However, comparisons were only possible between two samples for each size category.

A further series of covariance analyses were made between samples from Georges Bank and those for the Nova Scotian area within year and month and size category strata. The pooled analysis for large haddock showed a significant difference in adjusted means in the Approximate $F$ Test (Appendix Table A8).

## Months

To investigate the variation between months, all samples of large haddock from Georges Bank were utilized for each month, as yearly and area differences had been shown to be nonsignificant. Only for this size category and area were there enough data for a meaningful comparison. These monthly regressions were tested by covariance analyses and significant differences were found among adjusted means (Appendix Table A9). The adjusted monthly means of the $\log _{e}$ weights were then computed and compared using the multiple range test of Duncan (1955) with Kramer's (1956, 1957) adjustment for unequal sized samples and Finney's (1946) approximation for the variance term. There were no seasonal trends evident (Table 3). The lack of a seasonal trend is contrary to the conclusion of Clark and Dietsch (1959).

## CONVERSION OF DRESSED AND ROUND WEIGHT FOR HADDOCK

In the United States, haddock are almost
invariably landed in a dressed condition. For certain reports and research studies, it is necessary to use round (whole) weights. This section presents results of an analysis of available data to determine an estimator for converting dressed weights to round weights.

## Lengths at Sea Versus Lengths Ashore

The average length of the 199 fish was 524 mm with a standard error of 8.0 when measured fresh at sea and was 521 mm with a standard error of 7.9 when measured after landing. The ratio of length measured at sea to that on shore was 1.005 . The mean of the difference between the paired measurements was found to be within the realm of normal error of measurement and, thus, fresh measurements only were used in analysis.

## Difference Between Round and Dressed Weight

The ratio of round weight $\left(Y^{\prime}\right)$ to dressed weight ( $Y$ ) for given length ( $X$ ) may be written:

$$
\begin{align*}
& \frac{Y^{\prime}}{Y}=\frac{C^{\prime}}{C} X\left(b^{\prime}-b\right), \text { or }  \tag{1}\\
& \log _{e} \frac{Y^{\prime}}{Y}=\log _{e} \frac{C^{\prime}}{C}+\left(b^{\prime}-b\right) \log _{e} X \tag{2}
\end{align*}
$$

Linear regressions of (2) for each sample are presented in Table 4.

If the ratio of round to dressed weight does not differ with length, the slope of the regression ( $b^{\prime}-b$ ) would equal zero, and the antilogarithm of $\log _{e} \frac{C^{\prime}}{C}$ would be an estimate of

Table 4.-Sample regressions of ratio of round to dressed weight on length.

| Sample | Year | Month | No. | $\log _{e} \frac{C^{\prime}}{C}$ | $\left(b^{\prime} \cdot b\right)$ | $S\left(b^{\prime}-b\right)$ | Mean ratio at mean length |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Gutted |  |  |  |  |  |  |  |
| 1 | 1942 | Apr. | 46 | -1.140 | 0.301* | 0.122 | 1.16:1 |
| 2 | 1953 | May | 29 | -0.419 | 0.151* | 0.061 | 1.16:1 |
| 3 | 1953 | June | 22 | 0.151 | 0.010 | 0.072 | 1.21:1 |
| 4 | 1953 | June | 20 | 0.147 | 0.006 | 0.080 | 1.19:1 |
| 5 | 1953 | Dec. | 34 | 0.098 | 0.009 | 0.092 | 1.14:1 |
| 6 | 1954 | Jan. | 25 | 0.052 | 0.017 | 0.203 | 1.13:1 |
| 7 | 1954 | Jan. | 22 | -1.075 | 0.291 | 0.176 | 1.12:1 |
| 8 | 1954 | Feb. | 23 | -0.066 | 0.059 | 0.180 | 1.18:1 |
| 9 | 1954 | June | 39 | -0.314 | 0.122 | 0.070 | 1.14:1 |
| Total |  |  |  | 0.129 | 0.004 | 0.020 | 1.16:1 |
| Gutted and gilled |  |  |  |  |  |  |  |
| 1 | 1942 | Apr. | 21 | -0.621 | 0.192* | 0.060 | 1.17:1 |
| 2 | 1954 | Apr. | 46 | -1.171 | 0.333 | 0.208 | 1.22:1 |
| Total |  |  |  | -0.595 | 0.187* | 0.061 | 1.20:1 |

*Significantly greater than zero ( $P \leqslant .05$ )
the desired conversion factor. Three of the 11 samples were found to have slope values ( $b^{\prime}-b$ ) significantly greater than zero, and all samples had positive slopes. The slightly positive slopes, when extrapolated to zero length, gave negative or very low intercept values, which means a ratio of round to dressed less than or near unity, even though the total regression coefficient was not significantly greater than zero. Therefore, because landed fish range only from 40 to 80 cm , it is appropriate to use the mean ratios of round to gutted weight at the mean length of the samples (Table 4). No seasonal trends were evident. Thus, the overall ratio of 1.16:1 appears to be the best available estimate for converting gutted to round weights. The overall ratio estimated for converting gutted and gilled weight to round weight was 1.20:1.

In order to use the length-weight equations to estimate round weights, the following adjustments should be made:

$$
\begin{aligned}
\log _{e} Y^{\prime}= & \log _{e} C+0.1442+b \log _{e} X \\
& \text { for gutted, and }
\end{aligned}
$$

$$
\begin{aligned}
\log _{e} Y^{\prime}= & \log _{e} C+0.1857+b \log _{e} X \\
& \text { for gutted and gilled }
\end{aligned}
$$

$\log _{e} C$ is the intercept and $b$ the coefficient of the regression of dressed weight on length.

## CONCLUSIONS

Several conclusions were evident from these analyses:

1. Subsample differences were significant.
2. Large differences existed among samples (trips) within strata.
3. The sorting of fish into scrod and large categories produced significantly offset regression lines.
4. Year-to-year changes were not significant.
5. Samples within Georges Bank and Nova
Scotian regions were homogeneous.
6. Differences were found between the Georges Bank and the Nova Scotian region.
7. Seasonal trends were not present.
8. The best available equations for converting dressed to live weights utilize the mean ratios of round to gutted lengths at the mean length of the samples.

Estimating equations and standard errors for scrod and large haddock from Georges Bank and from the Nova Scotian area are set forth in Table 5. A length-weight conversion table based on these equations is given in Appendix Table A10. It will be noted that all four equations estimate very similar weights for the same length. The loss of precision in using the total regression equations rather than using the separate equations derived from a sample from each trip is estimated in Table 6. The highest of these ratios of respective mean squares indicates a 43 percent loss. However, it would be impractical to try to obtain a regression equation for each trip landed, and for past data, this, of course, is impossible. There is no apparent statistical justification for
using finer breakdowns into year or area strata, and samples for each month are not available. Such differences that may actually be present between these categories were obscured by the large variation among samples.

The differences found in the length-weight regressions between Georges Bank and the areas off Nova Scotia considered in this paper agree with other evidence on the separation of these stocks of haddock. Grosslein (1962) reported that tag returns indicated a small degree of movement between these two regions. Hennemuth et al. (1964) found growth rates of haddock collected from southern and central Nova Scotia to be similar to each other but differing from those on Georges Bank.

In view of the large sampling error, the use of length-weight regressions to compute the numbers of fish in the catch is inefficient. Since for this purpose what is needed is the average weight per fish in the length-frequency samples, a better procedure would be to obtain the total weight of all fish measured and divide by the number of fish to calculate the average weight per fish in each sample.

Table 5.-Regression statistics for haddock length-weight estimating equations ( $\log _{e}$ units).

| Description | Equation | Standard <br> error of <br> $Y$ |
| :--- | :---: | :---: |
| Large haddock from Georges Bank | $1^{\prime} Y=-10.0580+2.8053 X$ | $\pm 0.0014$ |
| Scrod haddock from Georges Bank | $2 Y=-9.2184+2.5864 X$ | $\pm 0.0027$ |
| Large haddock from Nova Scotia area | $3^{\prime} Y=-10.6191+2.9389 X$ | $\pm 0.0027$ |
| Scrod haddock from Nova Scotia area | $4 Y=-9.4570+2.6362 X$ | $\pm 0.0043$ |

[^0]Table 6.-Loss of precision in using total regression equations.

| Category | Within sample <br> mean square | Mean square <br> for the total <br> regression | Ratio <br> total <br> samples | Number <br> of <br> Samples |
| :--- | :---: | :---: | :---: | :---: |
| Georges Bank <br> large haddock | 0.0072 | 0.0103 | 1.43 | 43 |
| Georges Bank <br> scrod haddock | 0.0070 | 0.0090 | 1.28 | 20 |
| Nova Scotia <br> large haddock | 0.0080 | 0.0089 | 1.11 | 14 |
| Nova Scotia <br> scrod haddock | 0.0065 | 0.0065 | 1.00 | 5 |

\(2 \quad \Sigma \mathrm{xy}=\Sigma \mathrm{XY}-(\Sigma \mathrm{X})(\Sigma \mathrm{Y}) / \mathrm{N} 1\)
\(3 \quad \Sigma y^{2}=\Sigma Y^{2}-(\Sigma Y)^{2} / N\)
\(4 \quad S S=\Sigma y^{2}-(\Sigma x y)^{2} / \Sigma x^{2}\)
5 MS = SS/
    (N-2)
```

*Letters correspond to areas in Figure 1.

Table A2.-Pooled analysis of covariance for subsample and sample variation for five selected trips.

| Source of variation | DF | SS | MS | F |
| :---: | :---: | :---: | :---: | :---: |
| Total | 848 | 6.908 | 0.0081 |  |
| Among samples | 8 | 0.052 | 0.0065 | 1 NS |
| Among subsamples | 58 | 0.707 | 0.0122 |  |
| Regression coefficients | 29 | 0.236 | 0.0081 | 1.02 |
| Adjusted means | 29 | 0.471 | 0.0162 | 2.0 |
| Within subsamples | 782 | 6.149 | 0.0079 |  |
| Common subsample variation ${ }^{(2)}$ | 811 | 6.385 | 0.0079 |  |

(1) * = significant at $5 \%$ level
** = significant at 1\% level
NS $=$ non-significant
(2) For testing adjusted means among subsamples

Table A3.-Pooled analysis of covariance among samples within each factor combination, i.e. each cell of Table 1.

Table A4.-Pooled analysis of covariance between size categories.

Table A5.-Pooled analysis of covariance between years for identical months and areas.

Table A6.-Pooled analysis of covariance between eastern and western Georges Bank for identical months and years.

| Source of variation | DF | SS | MS |
